PREFACE

While books and journals of high quality have proliferated in discrete and computational geometry during recent years, there has been to date no single reference work fully accessible to the nonspecialist as well as to the specialist, covering all the major aspects of both fields. The *Handbook of Discrete and Computational Geometry* is intended to do exactly that: to make the most important results and methods in these areas of geometry readily accessible to those who use them in their everyday work, both in the academic world—as researchers in mathematics and computer science—and in the professional world—as practitioners in fields as diverse as operations research, molecular biology, and robotics.

A significant part of the growth that discrete mathematics as a whole has experienced in recent years has consisted of a substantial development in discrete geometry. This has been fueled partly by the advent of powerful computers and by the recent explosion of activity in the relatively young field of computational geometry. This synthesis between discrete and computational geometry, in which the methods and insights of each field have stimulated new understanding of the other, lies at the heart of this Handbook.

The phrase “discrete geometry,” which at one time stood mainly for the areas of packing, covering, and tiling, has gradually grown to include in addition such areas as combinatorial geometry, convex polytopes, and arrangements of points, lines, planes, circles, and other geometric objects in the plane and in higher dimensions. Similarly, “computational geometry,” which referred not long ago to simply the design and analysis of geometric algorithms, has in recent years broadened its scope, and now means the study of geometric problems from a computational point of view, including also computational convexity, computational topology, and questions involving the combinatorial complexity of arrangements and polyhedra. It is clear from this that there is now a significant overlap between these two fields, and in fact this overlap has become one of practice as well, as mathematicians and computer scientists have found themselves working on the same geometric problems and have forged successful collaborations as a result.

At the same time, a growing list of areas in which the results of this work are applicable has been developing. It includes areas as widely divergent as engineering, crystallography, computer-aided design, manufacturing, operations research, geographic information systems, robotics, error-correcting codes, tomography, geometric modeling, computer graphics, combinatorial optimization, computer vision, pattern recognition, and solid modeling.

With this in mind, it has become clear that a handbook encompassing the most important results of discrete and computational geometry would benefit not only the workers in these two fields, or in related areas such as combinatorics, graph theory, geometric probability, and real algebraic geometry, but also the *users* of this body of results, both industrial and academic. This Handbook is designed to fill that role. We believe it will prove an indispensable working tool both for researchers in geometry and geometric computing and for professionals who use geometric tools in their work.

The Handbook covers a broad range of topics in both discrete and computational geometry, as well as in a number of applied areas. These include geometric data structures, polytopes and polyhedra, convex hull and triangulation algorithms, packing and covering, Voronoi diagrams, combinatorial geometric questions, com-

putational convexity, shortest paths and networks, computational real algebraic geometry, geometric arrangements and their complexity, geometric reconstruction problems, randomization and de-randomization techniques, ray shooting, parallel computation in geometry, oriented matroids, computational topology, mathematical programming, motion planning, sphere packing, computer graphics, robotics, crystallography, and many others. A final chapter is devoted to a list of available software. Results are presented in the form of theorems, algorithms, and tables, with every technical term carefully defined in a glossary that precedes the section in which the term is first used. There are numerous examples and figures to illustrate the ideas discussed, as well as a large number of unsolved problems.

The main body of the volume is divided into six parts. The first two, on combinatorial and discrete geometry and on polytopes and polyhedra, deal with fundamental geometric objects such as planar arrangements, lattices, and convex polytopes. The next section, on algorithms and geometric complexity, discusses these basic geometric objects from a computational point of view. The fourth and fifth sections, on data structures and computational techniques, discuss various computational methods that cut across the spectrum of geometric objects, such as randomization and de-randomization, and parallel algorithms in geometry, as well as efficient data structures for searching and for point location. The sixth section, which is the longest in the volume, contains chapters on fourteen applications areas of both discrete and computational geometry, including low-dimensional linear programming, combinatorial optimization, motion planning, robotics, computer graphics, pattern recognition, graph drawing, splines, manufacturing, solid modeling, rigidity of frameworks, scene analysis, error-correcting codes, and crystallography. It concludes with a fifteenth chapter, an up-to-the-minute compilation of available software relating to the various areas covered in the volume. A comprehensive index follows, which includes proper names as well as all of the terms defined in the main body of the Handbook.

A word about references. Because it would have been prohibitive to provide complete references to all of the many thousands of results included in the Handbook, we have to a large extent restricted ourselves to references for either the most important results, or for those too recent to have been included in earlier survey books or articles; for the rest we have provided annotated references to easily accessible surveys of the individual subjects covered in the Handbook, which themselves contain extensive bibliographies. In this way, the reader who wishes to pursue an older result to its source will be able to do so.

On behalf of the sixty-one contributors and ourselves, we would like to express our appreciation to all those whose comments were of great value to the authors of the various chapters: Pankaj K. Agarwal, Noga Alon, Boris Aronov, Saugata Basu, Margaret Bayer, Louis Billera, Martin Blümlinger, Jürgen Bokowski, B.F. Caviness, Bernard Chazelle, Danny Chen, Xiangping Chen, Yi-Jen Chiang, Edmund M. Clarke, Kenneth Clarkson, Robert Connelly, Henry Crapo, Isabel Cruz, Mark de Berg, Jesús De Loera, Giuseppe Di Battista, Michael Drmota, Peter Eades, Jürgen Eckhoff, Noam D. Elkies, Eva Maria Feichtner, Ioannis Fudos, Branko Grünbaum, Dan Halperin, Eszter Hargittai, Ulli Hund, Jürg Hüsler, Peter Johansson, Norman Johnson, Amy Josefczyk, Gil Kalai, Gyula Károlyi, Kevin Klenk, Włodzimierz Kuperberg, Endre Makai, Jr., Jiří Matoušek, Peter McMullen, Hans Melissen, Bengt Nilsson, Michel Pocchiola, Richard Pollack, Jörg Rambau, Jürgen Richter-Gebert, Allen D. Rogers, Marie-Françoise Roy, Egon Schulte, Dana Scott, Jürgen Sellen, Micha Sharir, Peter Shor, Maxim Michailovich Skriganov, Neil J.A. Sloane, Richard

P. Stanley, Géza Tóth, Ioannis Tollis, Laureen Treacy, Alexander Vardy, Gert Vegter, Pamela Vermeer, Siniša Vrećica, Kevin Weiler, Asia Ivić Weiss, Neil White, Chee-Keng Yap, and Günter M. Ziegler.

In addition, we would like to convey our thanks to the editors of CRC Press for having the vision to commission this Handbook as part of their *Discrete Mathematics and Its Applications* series; to the CRC staff, for their help with the various stages of the project; and in particular to Nora Konopka, with whom we found it a pleasure to work from the inception of the volume.

Finally, we want to express our sincere gratitude to our families: Josy, Rachel, and Naomi Goodman, and Marylynn Salmon and Nell and Russell O'Rourke, for their patience and forbearance while we were in the throes of this project.

Jacob E. Goodman
Joseph O'Rourke

PREFACE TO THE SECOND EDITION

This second edition of the *Handbook of Discrete and Computational Geometry* represents a substantial revision of the first edition, published seven years earlier. The new edition has added over 500 pages, a growth by more than 50%. Each chapter has been thoroughly revised and updated, and we have added thirteen new chapters. The additional room permitted the expansion of the curtailed bibliographies of the first edition, which often required citing other surveys to locate original sources. The new bibliographies make the chapters, insofar as is possible, self-contained. Most chapters have been revised by their original authors, but in a few cases new authors have joined the effort. All together, taking into account the chapters new to this edition, the number of authors has grown from sixty-three to eighty-two.

In the first edition there was one index; now there are two: in addition to the Index of Defined Terms there is also an Index of Cited Authors, which includes everyone referred to by name in either the text or the bibliography of each chapter. The first edition chapter on computational geometry software has been split into two chapters: one on the libraries LEDA and CGAL, the other on additional software. There are five new chapters in the applications section: on algorithms for modeling motion, on surface simplification and 3D-geometry compression, on statistical applications, on Geographic Information Systems and computational cartography, and on biological applications of computational topology. There are new chapters on collision detection and on nearest neighbors in high-dimensional spaces. We have added material on mesh generation, as well as a new chapter on curve and surface reconstruction, and new chapters on embeddings of finite metric spaces, on polygonal linkages, and on geometric graph theory.

All of these new chapters, together with the many new results contained within the Handbook as a whole, attest to the rapid growth in the field since preparation for the first edition began a decade ago. And as before, we have engaged the world's leading experts in each area as our authors.

In addition to the many people who helped with the preparation of the various chapters comprising the first edition, many of whom once again gave invaluable assistance with the present edition, we would also like to thank the following on behalf

of both the authors and ourselves: Nina Amenta, David Avis, Michael Baake, David Bremner, Hervé Brönnimann, Christian Buchta, Sergio Cabello, Yi-Jen Chiang, Mirela Damian, Douglas Dunham, Stefan Felsner, Lukas Finschi, Bernd Gärtner, Ewgenij Gawrilow, Daniel Hug, Ekkehard Köhler, Jeffrey C. Lagarias, Vladimir I. Levenshtein, Casey Mann, Matthias Müller-Hannemann, Rom Pinchasi, Marc E. Pfetsch, Charles Radin, Jorge L. Ramírez Alfonsín, Matthias Reitzner, Thilo Schröder, Jack Snoeyink, Hellmuth Stachel, Pavel Valtr, and Nikolaus Witte.

We would also like to express our appreciation to Bob Stern, CRC's Executive Editor, who gave us essentially a free hand in choosing how best to fill the additional 500 pages that were allotted to us for this new edition, as well as to Christine Andreasen for her sharp eye and unfailing good humor.

Jacob E. Goodman
Joseph O'Rourke

TABLE OF CONTENTS

<i>Prefaces</i>	vii
<i>Contributors</i>	xiii
COMBINATORIAL AND DISCRETE GEOMETRY	1
1 Finite point configurations (<i>J. Pach</i>)	3
2 Packing and covering (<i>G. Fejes Tóth</i>)	25
3 Tilings (<i>D. Schattschneider and M. Senechal</i>)	53
4 Helly-type theorems and geometric transversals (<i>R. Wenger</i>)	73
5 Pseudoline arrangements (<i>J.E. Goodman</i>)	97
6 Oriented matroids (<i>J. Richter-Gebert and G.M. Ziegler</i>)	129
7 Lattice points and lattice polytopes (<i>A. Barvinok</i>)	153
8 Low-distortion embeddings of finite metric spaces (<i>P. Indyk and J. Matoušek</i>)	177
9 Geometry and topology of polygonal linkages (<i>R. Connelly and E.D. Demaine</i>)	197
10 Geometric graph theory (<i>J. Pach</i>)	219
11 Euclidean Ramsey theory (<i>R.L. Graham</i>)	239
12 Discrete aspects of stochastic geometry (<i>R. Schneider</i>)	255
13 Geometric discrepancy theory and uniform distribution (<i>J.R. Alexander, J. Beck, and W.W.L. Chen</i>)	279
14 Topological methods (<i>R.T. Živaljević</i>)	305
15 Polyominoes (<i>S.W. Golomb and D.A. Klarner</i>)	331
POLYTOPES AND POLYHEDRA	353
16 Basic properties of convex polytopes (<i>M. Henk, J. Richter-Gebert, and G.M. Ziegler</i>)	355
17 Subdivisions and triangulations of polytopes (<i>C.W. Lee</i>)	383
18 Face numbers of polytopes and complexes (<i>L.J. Billera and A. Björner</i>)	407
19 Symmetry of polytopes and polyhedra (<i>E. Schulte</i>)	431
20 Polytope skeletons and paths (<i>G. Kalai</i>)	455
21 Polyhedral maps (<i>U. Brehm and E. Schulte</i>)	477
ALGORITHMS AND COMPLEXITY OF FUNDAMENTAL GEOMETRIC OBJECTS	493
22 Convex hull computations (<i>R. Seidel</i>)	495
23 Voronoi diagrams and Delaunay triangulations (<i>S. Fortune</i>)	513
24 Arrangements (<i>D. Halperin</i>)	529
25 Triangulations and mesh generation (<i>M. Bern</i>)	563
26 Polygons (<i>J. O'Rourke and S. Suri</i>)	583
27 Shortest paths and networks (<i>J.S.B. Mitchell</i>)	607
28 Visibility (<i>J. O'Rourke</i>)	643
29 Geometric reconstruction problems (<i>S.S. Skiena</i>)	665
30 Curve and surface reconstruction (<i>T.K. Dey</i>)	677
31 Computational convexity (<i>P. Gritzmann and V. Klee</i>)	693
32 Computational topology (<i>G. Vegter</i>)	719
33 Computational real algebraic geometry (<i>B. Mishra</i>)	743

GEOMETRIC DATA STRUCTURES AND SEARCHING	765
34 Point location (<i>J. Snoeyink</i>)	767
35 Collision and proximity queries (<i>M.C. Lin and D. Manocha</i>)	787
36 Range searching (<i>P.K. Agarwal</i>)	809
37 Ray shooting and lines in space (<i>M. Pellegrini</i>)	839
38 Geometric intersection (<i>D.M. Mount</i>)	857
39 Nearest neighbors in high-dimensional spaces (<i>P. Indyk</i>)	877
COMPUTATIONAL TECHNIQUES	893
40 Randomization and derandomization (<i>O. Cheong, K. Mulmuley, and E. Ramos</i>)	895
41 Robust geometric computation (<i>C.K. Yap</i>)	927
42 Parallel algorithms in geometry (<i>M.T. Goodrich</i>)	953
43 Parametric search (<i>J.S. Salowe</i>)	969
44 The discrepancy method in computational geometry (<i>B. Chazelle</i>)	983
APPLICATIONS OF DISCRETE AND COMPUTATIONAL GEOMETRY	997
45 Linear programming (<i>M. Dyer, N. Megiddo, and E. Welzl</i>)	999
46 Mathematical programming (<i>M.J. Todd</i>)	1015
47 Algorithmic motion planning (<i>M. Sharir</i>)	1037
48 Robotics (<i>D. Halperin, L.E. Kavraki, and J.-C. Latombe</i>)	1065
49 Computer graphics (<i>D. Dobkin and S. Teller</i>)	1095
50 Modeling motion (<i>L.J. Guibas</i>)	1117
51 Pattern recognition (<i>J. O'Rourke and G.T. Toussaint</i>)	1135
52 Graph drawing (<i>R. Tamassia and G. Liotta</i>)	1163
53 Splines and geometric modeling (<i>C.L. Bajaj</i>)	1187
54 Surface simplification and 3D geometry compression (<i>J. Rossignac</i>)	1209
55 Manufacturing processes (<i>R. Janardan and T.C. Woo</i>)	1241
56 Solid modeling (<i>C.M. Hoffmann</i>)	1257
57 Computation of robust statistics: Depth, median, and related measures (<i>P.J. Rousseeuw and A. Struyf</i>)	1279
58 Geographic information systems (<i>M. van Kreveld</i>)	1293
59 Geometric applications of the Grassmann-Cayley algebra (<i>N.L. White</i>)	1315
60 Rigidity and scene analysis (<i>W. Whiteley</i>)	1327
61 Sphere packing and coding theory (<i>G.A. Kabatiansky and J.A. Rush</i>)	1355
62 Crystals and quasicrystals (<i>M. Senechal</i>)	1377
63 Biological applications of computational topology (<i>H. Edelsbrunner</i>)	1395
GEOMETRIC SOFTWARE	1413
64 Software (<i>M. Joswig</i>)	1415
65 Two computational geometry libraries: LEDA and CGAL (<i>L. Kettner and S. Näher</i>)	1435
<i>Index of Cited Authors</i>	1465
<i>Index of Defined Terms</i>	1497

COMBINATORIAL AND DISCRETE GEOMETRY

1 FINITE POINT CONFIGURATIONS

János Pach

INTRODUCTION

The study of combinatorial properties of finite point configurations is a vast area of research in geometry, whose origins go back at least to the ancient Greeks. Since it includes virtually all problems starting with “consider a set of n points in space,” space limitations impose the necessity of making choices. As a result, we will restrict our attention to Euclidean spaces and will discuss problems that we find particularly important. The chapter is partitioned into incidence problems (Section 1.1), metric problems (Section 1.2), and coloring problems (Section 1.3).

1.1 INCIDENCE PROBLEMS

In this section we will be concerned mainly with the structure of incidences between a finite point configuration P and a set of finitely many lines (or, more generally, k -dimensional flats, spheres, etc.). Sometimes this set consists of all lines connecting the elements of P . The prototype of such a question was raised by Sylvester [Syl93] more than one hundred years ago: Is it true that for any configuration of finitely many points in the plane, not all on a line, there is a line passing through exactly two points? This question was rediscovered by Erdős [Erd43], and affirmative answers to it were given by Gallai and others [St44]. Generalizations for circles and conic sections in place of lines were established by Motzkin [Mot51] and Wilson-Wiseman [WW88], respectively.

GLOSSARY

Incidence: A point of configuration P lies on an element of a given collection of lines (k -flats, spheres, etc.).

Simple crossing: A point incident with exactly two elements of a given collection of lines or circles.

Ordinary line: A line passing through exactly two elements of a given point configuration.

Ordinary circle: A circle passing through exactly three elements of a given point configuration.

Ordinary hyperplane: A $(d-1)$ -dimensional flat passing through exactly d elements of a point configuration in Euclidean d -space.

Motzkin hyperplane: A hyperplane whose intersection with a given d -dimensional point configuration lies—with the exception of exactly one point—in a $(d-2)$ -dimensional flat.

Family of pseudolines: A family of two-way unbounded Jordan curves, any two of which have exactly one point in common, which is a proper crossing.

Family of pseudocircles: A family of closed Jordan curves, any two of which have at most two points in common, at which the two curves properly cross each other.

Regular family of curves: A family Γ of curves in the xy -plane defined in terms of D real parameters satisfying the following properties. There is an integer s such that (a) the dependence of the curves on x, y , and the parameters is algebraic of degree at most s ; (b) no two distinct curves of Γ intersect in more than s points; (c) for any D points of the plane, there are at most s curves in Γ passing through all of them.

Degrees of freedom: The smallest number D of real parameters defining a regular family of curves.

Spanning tree: A tree whose vertex set is a given set of points and whose edges are line segments.

Spanning path: A spanning tree that is a polygonal path.

Convex position: P forms the vertex set of a convex polygon or polytope.

k -set: A k -element subset of P that can be obtained by intersecting P with an open halfspace.

Halving plane: A hyperplane with $\lfloor |P|/2 \rfloor$ points of P on each side.

SYLVESTER-TYPE RESULTS

1. Gallai theorem (dual version): Any set of lines in the plane, not all of which pass through the same point, determines a simple crossing. This holds even for families of pseudolines [KR72].

2. Pinchasi theorem: Any set of at least five pairwise crossing unit circles in the plane determines a simple crossing.

Any sufficiently large set of pairwise crossing pseudocircles in the plane, not all of which pass through the same pair of points, determines an intersection point incident to at most three pseudocircles [NPP⁺02]

3. Pach-Pinchasi theorem: Given n red and n blue points in the plane, not all on a line, there always exists a bichromatic line containing at most two points of each color [PP00].

Any finite set of red and blue points contains a monochromatic spanned line, but not always a monochromatic ordinary line [Cha70].

4. Motzkin-Hansen theorem: For any finite set of points in Euclidean d -space, not all of which lie on a hyperplane, there exists a Motzkin hyperplane [Mot51, Han65]. We obtain as a corollary that n points in d -space, not all of which lie on a hyperplane, determine at least n distinct hyperplanes. (A hyperplane is *determined* by a point set P if its intersection with P is not contained in a $(d-2)$ -flat.) Putting the points on two skew lines in 3-space shows that the existence of an ordinary hyperplane cannot be guaranteed for $d > 2$.

If $n > 8$ is sufficiently large, then any set of n noncocircular points in the plane determines at least $\binom{n-1}{2}$ distinct circles, and this bound is best possible [El167]. The number of ordinary circles determined by n noncocircular points is known to be at least $11n(n-1)/247$ [BB94].

5. Csima-Sawyer theorem: Any set of n noncollinear points in the plane determines at least $6n/13$ ordinary lines ($n > 7$). This bound is sharp for $n = 13$ and false for $n = 7$ (see Figure 1.1.1). [KM58, CS93]. In 3-space, any set of n noncoplanar points determines at least $2n/5$ Motzkin hyperplanes [Han80, GS84].

FIGURE 1.1.1

Extremal examples for the (dual) Csima-Sawyer theorem:

- (a) 13 lines (including the line at infinity) determining only 6 simple points;
- (b) 7 lines determining only 3 simple points.

6. Orchard problem [Syl67]: What is the maximum number of collinear triples determined by n points in the plane, no four on a line? There are several constructions showing that this number is at least $n^2/6 - O(n)$, which is asymptotically best possible, cf. [BGS74, FP84]. (See Figure 1.1.2.)

FIGURE 1.1.2

12 points and 19 lines, each passing through exactly 3 points.

7. Dirac's problem [Dir51]: Does there exist a constant c such that any set of n points in the plane, not all on a line, has an element incident to at least $n/2 - c$ connecting lines? If true, this result is best possible, as is shown by the example of n points distributed as evenly as possible on two intersecting lines. (It was believed that, apart from some small examples listed in [Grü72], this statement is true with $c = 0$, until Felsner exhibited an infinite series of configurations, showing that $c \geq 3/2$.) It is known that

there is a positive constant c such that one can find a point incident to at least cn connecting lines. A useful equivalent formulation of this assertion is that any set of n points in the plane, no more than $n - k$ of which are on the same line, determines at least $c'kn$ distinct connecting lines, for a suitable constant $c' > 0$. Note that according to the $d = 2$ special case of the Motzkin-Hansen theorem, due to Erdős (see No. 4 above), for $k = 1$ the number of distinct connecting lines is at least n . For $k = 2$, the corresponding bound is $2n - 4$, ($n \geq 10$).

8. Ungar's theorem [Ung82]: n noncollinear points in the plane always determine at least $2\lfloor n/2 \rfloor$ lines of different slopes (see Figure 1.1.3); this proves Scott's conjecture. Furthermore, any set of n points in the plane, not all on a line, permits a spanning tree, all of whose $n - 1$ edges have different slopes [Jam87]. Pach, Pinchasi, and Sharir showed that n noncoplanar points in 3-space determine at least $2n - 3$ different directions if n is even and at least $2n - 2$ if n is odd, provided that no 3 points are on a line. Even without this latter assumption, the number of different directions is at least $2n - O(1)$.

FIGURE 1.1.3

7 points determining 6 distinct slopes.

UPPER BOUNDS ON THE NUMBER OF INCIDENCES

Given a set P of n points and a family Γ of m curves or surfaces, the number of incidences between them can be obtained by summing over all $p \in P$ the number of elements of Γ passing through p . If the elements of Γ are taken from a regular family of curves with D degrees of freedom [PS90], the maximum number of incidences between P and Γ is $O(n^{D/(2D-1)} m^{(2D-2)/(2D-1)} + n + m)$. In the most important applications, Γ is a family of straight lines or unit circles in the plane ($D = 2$), or it consists of circles of arbitrary radii ($D = 3$). The best upper bounds known for the number of incidences are summarized in Table 1.1.1. It follows from the first line of the table that for any set P of n points in the plane, the number of distinct straight lines containing at least k elements of P is $O(n^2/k^3 + n/k)$, and this bound cannot be improved (Szemerédi-Trotter). In the second half of the table, $\kappa(n, m)$ and $\beta(n, m)$ denote extremely slowly growing functions, which are certainly $o(n^\epsilon m^\epsilon)$ for every $\epsilon > 0$. A family of pseudocircles is *special* if its curves admit a 3-parameter algebraic representation. A collection of spheres in 3-space is said to be in *general position* here if no three of them pass through the same circle [CEG⁺90, NPP⁺02].

MIXED PROBLEMS

Many problems about finite point configurations involve some notions that cannot be defined in terms of incidences: convex position, midpoint of a segment, etc.

TABLE 1.1.1 Maximum number of incidences between n points of P and m elements of Γ [SzT83, CEG⁺90, NPP⁺02].

PT. SET P	FAMILY Γ	BOUND	TIGHT
Planar	lines	$O(n^{2/3}m^{2/3} + n + m)$	yes
Planar	pseudolines	$O(n^{2/3}m^{2/3} + n + m)$	yes
Planar	unit circles	$O(n^{2/3}m^{2/3} + n + m)$	?
Planar	pairwise crossing circles	$O(n^{1/2}m^{5/6} + n^{2/3}m^{2/3} + n + m)$	?
Planar	special pseudocircles	$O(n^{6/11}m^{9/11}\kappa(n, m) + n^{2/3}m^{2/3} + n + m)$	?
Planar	pairwise crossing pseudocircles	$O(n^{2/3}m^{2/3} + n + m^{4/3})$	?
3-dim'l	spheres	$O(n^{4/7}m^{9/7}\beta(n, m) + n^2)$	?
3-dim'l	spheres in gen. position	$O(n^{3/4}m^{3/4}\beta(n, m) + n + m)$	?
d -dim'l	circles	$O(n^{6/11}m^{9/11}\kappa(n, m) + n^{2/3}m^{2/3} + n + m)$	?

Below we list a few questions of this type. They are discussed in this part of the chapter, and not in Section 1.2 which deals with metric questions, because we can disregard most aspects of the Euclidean metrics in their formulation. For example, convex position can be defined by requiring that some sets should lie on one side of certain hyperplanes. This is essentially equivalent to introducing an order along each straight line.

1. Erdős-Klein-Szekeres problem: What is the maximum number of points that can be chosen in the plane so that no three are on a line and no k are in convex position ($k > 3$)? If this number is denoted by $c(k)$, it is known [TV98, ES35, ES61] that

$$2^{k-2} \leq c(k) \leq \binom{2n-5}{n-2}.$$

Let $e(k)$ denote the maximum size of a planar point set P that has no three elements on a line and no k elements that form the vertex set of an “empty” convex polygon, i.e., a convex k -gon whose interior is disjoint from P . We have $e(3) = 2$, $e(4) = 4$, $e(5) = 9$, and Horton showed that $e(k)$ is infinite for all $k \geq 7$ [Har78, Hor83]. It is an outstanding open problem to decide whether $e(6)$ is finite.

2. The number of empty k -gons: Let $H_k^d(n)$ ($n \geq k \geq d+1$) denote the minimum number of k -tuples that induce an empty convex polytope of k vertices in a set of n points in d -space, no $d+1$ of which lie on a hyperplane. Clearly, $H_2^1(n) = n-1$ and $H_k^1(n) = 0$ for $k > 2$. For $k = d+1$, we have

$$\frac{1}{d!} \leq \lim_{n \rightarrow \infty} H_k^d(n)/n^d \leq \frac{2}{(d-1)!},$$

[Val95]. For $d = 2$, the best estimates known for $H_k^2 = \lim_{n \rightarrow \infty} H_k^2(n)/n^2$ are given in [Dum00] and [BV03]:

$$1 \leq H_3^2 \leq 1.62, \quad 1/2 \leq H_4^2 \leq 1.94, \quad 0 \leq H_5^2 \leq 1.021,$$

$$0 \leq H_6^2 \leq 0.201, \quad H_7^2 = H_8^2 = \dots = 0.$$

3. The number of k -sets [ELSS73]: Let $N_k^d(n)$ denote the maximum number of k -sets in a set of n points in d -space, no $d + 1$ of which lie on the same hyperplane. In other words, $N_k^d(n)$ is the maximum number of different ways in which k points of an n -element set can be separated from the others by a hyperplane. It is known that

$$ne^{\Omega(\sqrt{\log k})} \leq N_k^2(n) \leq O\left(n(k+1)^{1/3}\right)$$

[Tót01, Dey98]. The most interesting case is $k = \frac{n}{2}$ in the plane, which is the maximum number of distinct ways to cut a set of n points in the plane in half (number of halving lines). For the number of halving planes [SST01], $N_{\lfloor n/2 \rfloor}^3(n) = O(n^{5/2})$, and

$$n^{d-1}e^{\Omega(\sqrt{\log n})} \leq N_{\lfloor n/2 \rfloor}^d(n) = o(n^d)$$

[Tót01, ŽV92].

FIGURE 1.1.4

12 points determining 15 combinatorially distinct halving lines.

The maximum number of *at-most- k* -element subsets of a set of n points in d -space, no $d + 1$ of which lie on a hyperplane, is $O\left(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil}\right)$, and this bound is asymptotically tight [CS89]. In the plane the maximum number of *at-most- k* -element subsets of a set of n points is kn for $k < \frac{n}{2}$, which is reached for convex n -gons [AG86, Pe85].

4. The number of midpoints: Let $M(n)$ denote the minimum number of different midpoints of the $\binom{n}{2}$ line segments determined by n points in convex position in the plane. One might guess that $M(n) \geq (1 - o(1))\binom{n}{2}$, but it was shown in [EFF91] that

$$\binom{n}{2} - \left\lfloor \frac{n(n+1)(1 - e^{-1/2})}{4} \right\rfloor \leq M(n) \leq \binom{n}{2} - \left\lfloor \frac{n^2 - 2n + 12}{20} \right\rfloor.$$

5. Midpoint-free subsets: As a partial answer to a question proposed in [BMP04], it was proved by V. Bálint et al. that if $m(n)$ denotes the largest number m such that every set of n points in the plane has a midpoint-free subset of size m , then

$$\left\lceil \frac{-1 + \sqrt{8n+1}}{2} \right\rceil \leq m(n).$$

However, asymptotically, $n^{1-c}/\sqrt{\log n} \leq m(n) \leq n/\log^{c'} n$, for suitable constants $c, c' > 0$ [Pac03].

OPEN PROBLEMS

Here we give six problems from the multitude of interesting questions that remain open.

1. Motzkin-Dirac conjecture: Any set of n noncollinear points in the plane determines at least $n/2$ ordinary lines ($n > 13$).
2. Generalized orchard problem (Grünbaum): What is the maximum number $c_k(n)$ of collinear k -tuples determined by n points in the plane, no $k+1$ of which are on a line ($k \geq 3$)? In particular, show that $c_4(n) = o(n^2)$. Grünbaum [Grü76] established the lower bound $c_k(n) = \Omega(n^{1+1/(k-2)})$, which was improved by Ismailescu [Is02] to $c_k(n) = \Omega(n^{\frac{\log k + 4}{\log k}})$ for $5 \leq k \leq 18$, $c_k(n) = \Omega(n^{\frac{1}{k-3.58}})$ for $k \geq 18$. For $k = 3$, we have $c_3(n) = n^2/6 - \Theta(n)$ [BGS74, FP84].
3. Maximum independent subset problem (Erdős): Determine the largest number $\alpha(n)$ such that any set of n points in the plane, no four on a line, has an $\alpha(n)$ -element subset with no collinear triples. Füredi [Fü91] has shown that $\Omega(\sqrt{n \log n}) \leq \alpha(n) \leq o(n)$.
4. Slope problem (Jamison): Does every set of n points in the plane, not all on a line, permit a spanning path, all of whose $n-1$ edges have different slopes?
5. Empty triangle problem (Bárány): Does every set of n points in the plane, no three on a line, determine at least $t(n)$ empty triangles that share a side, where $t(n)$ is a suitable function tending to infinity?
6. Balanced partition problem (Kupitz): Does there exist an integer k with the property that for every planar point set P , there is a connecting line such that the difference between the number of elements of P on its left side and right side does not exceed k ? Some examples due to Alon show that this assertion is not true with $k = 1$. Pinchasi proved that there is a connecting line, for which this difference is $O(\log \log n)$.

1.2 METRIC PROBLEMS

The systematic study of the distribution of the $\binom{n}{2}$ distances determined by n points was initiated by Erdős in 1946 [Erd46]. Given a point configuration $P =$

$\{p_1, p_2, \dots, p_n\}$, let $g(P)$ denote the number of distinct distances determined by P , and let $f(P)$ denote the number of times that the unit distance occurs between two elements of P . That is, $f(P)$ is the number of pairs $p_i p_j$ ($i < j$) such that $|p_i - p_j| = 1$. What is the minimum of $g(P)$ and what is the maximum of $f(P)$ over all n -element subsets of Euclidean d -space? These questions have raised deep number-theoretic and combinatorial problems, and have contributed richly to many recent developments in these fields.

GLOSSARY

- Unit distance graph:** A graph whose vertex set is a given point configuration P , in which two points are connected by an edge if and only if their distance is one.
- Diameter:** The maximum distance between two points of P .
- General position in the plane:** No three points of P are on a line, and no four on a circle.
- Separated set:** The distance between any two elements is at least one.
- Nearest neighbor of $p \in P$:** A point $q \in P$, whose distance from p is minimum.
- Farthest neighbor of $p \in P$:** A point $q \in P$, whose distance from p is maximum.
- Homothetic sets:** Similar sets in parallel position.

REPEATED DISTANCES

Extremal graph theory has played an important role in this area. For example, it is easy to see that the unit distance graph assigned to an n -element planar point set P cannot contain $K_{2,3}$, a complete bipartite graph with 2 and 3 vertices in its classes. Thus, by a well-known graph-theoretic result, $f(P)$, the number of edges in this graph, is at most $O(n^{3/2})$. This bound can be improved to $O(n^{4/3})$ by using more sophisticated combinatorial techniques (apply line 3 of [Table 1.1.1](#) with $m = n$); but we are still far from knowing what the best upper bound is.

TABLE 1.2.1 Estimates for the maximum number of unit distances determined by an n -element planar point set P .

POINT SET P	LOWER BOUND	UPPER BOUND	SOURCE
Arbitrary	$n^{1+c/\log \log n}$	$O(n^{4/3})$	[Erd46, SST84]
Separated	$\lfloor 3n - \sqrt{12n - 3} \rfloor$	$\lfloor 3n - \sqrt{12n - 3} \rfloor$	[Reu72, Har74]
Of diameter 1	n	n	[HP34]
In convex position	$2n - 7$	$O(n \log n)$	[EH90, Für90]
No 3 collinear	$\Omega(n \log n)$	$O(n^{4/3})$	Kárteszi
Separated, no 3 coll.	$(2 + 5/16 - o(1))n$	$(2 + 3/7)n$	[T6t97]

In Table 1.2.1, we summarize the best currently known estimates on the maximum number of times the unit distance can occur among n points in the plane, under various restrictions on their position. In the first line of the table—and throughout this chapter— c denotes (unrelated) positive constants. The second and third lines show how many times the minimum distance and the maximum distance, resp., can occur among n arbitrary points in the plane. Table 1.2.2 contains some analogous results in higher dimensions. In the first line, $\beta(n)$ is an extremely slowly growing function, closely related to the functional inverse of the Ackermann function.

FIGURE 1.2.1

A separated point set with $\lfloor 3n - (12n - 3)^{1/2} \rfloor$ unit distances ($n = 69$). All such sets have been characterized by Kupitz [Kup94].

TABLE 1.2.2 Estimates for the maximum number of unit distances determined by an n -element point set P in d -space.

POINT SET P	LOWER BOUND	UPPER BOUND	SOURCE
$d = 3$, arbitrary	$\Omega(n^{4/3} \log \log n)$	$O(n^{3/2} \beta(n))$	[Erd60, CEG ⁺ 90]
$d = 3$, separated	$6n - O(n^{2/3})$	$6n - \Omega(n^{2/3})$	Newton
$d = 3$, diameter 1	$2n - 2$	$2n - 2$	[Grü56, Hep56]
$d = 3$, on sphere (rad. $1/\sqrt{2}$)	$\Omega(n^{4/3})$	$O(n^{4/3})$	[EHP89]
$d = 3$, on sphere (rad. $r \neq 1/\sqrt{2}$)	$\Omega(n \sqrt{\log n})$	$O(n^{4/3})$	[SV04b]
$d = 4$	$\lfloor \frac{n^2}{4} \rfloor + n - 1$	$\lfloor \frac{n^2}{4} \rfloor + n$	[Bra97, vW99]
$d \geq 4$ even, arb.	$\frac{n^2}{2} \left(1 - \frac{1}{\lfloor d/2 \rfloor}\right) + n - O(d)$	$\frac{n^2}{2} \left(1 - \frac{1}{\lfloor d/2 \rfloor}\right) + n - \Omega(d)$	[Erd67]
$d > 4$ odd, arb.	$\frac{n^2}{2} \left(1 - \frac{1}{\lfloor d/2 \rfloor}\right) + \Omega(n^{4/3})$	$\frac{n^2}{2} \left(1 - \frac{1}{\lfloor d/2 \rfloor}\right) + O(n^{4/3})$	[EP90]

The second line of Table 1.2.1 can be extended by showing that the smallest distance cannot occur more than $3n - 2k + 4$ times between points of an n -element set in the plane whose convex hull has k vertices [Bra92a]. The maximum number of occurrences of the second-smallest and second-largest distance is $(24/7 + o(1))n$ and $3n/2$ (if n is even), respectively [Bra92b, Ves78].

Given any point configuration P , let $\Phi(P)$ denote the sum of the numbers of farthest neighbors for every element $p \in P$. Table 1.2.3 contains tight upper bounds on $\Phi(P)$ in the plane and in 3-space, and asymptotically tight ones for higher dimensions [ES89, Csi96, EP90]. Dumitrescu and Guha raised the following related question: given a colored point set in the plane, its *heterocolored diameter* is the largest distance between two elements of different colors. Let $\phi_k(n)$ denote

FIGURE 1.2.2
n points, among which the second-smallest distance occurs $(\frac{24}{7} + o(1))n$ times.

the maximum number of times that the heterocolored diameter can occur in a k -colored n -element point set between two points of different colors. It is known that $\phi_2(n) = n$, $\phi_3(n)$ and $\phi_4(n) = 3n/2 + O(1)$ and $\phi_k(n) \leq (2 - \frac{1}{\lfloor k/2 \rfloor})n$ for every k .

TABLE 1.2.3 Upper bounds on $\Phi(P)$, the total number of farthest neighbors of all points of an n -element set P .

POINT SET P	UPPER BOUND	SOURCE
Planar, n is even	$3n - 3$	[ES89, Avi84]
Planar, n is odd	$3n - 4$	[ES89, Avi84]
Planar, in convex position	$2n$	[ES89]
3-dimensional, $n \equiv 0 \pmod{2}$	$n^2/4 + 3n/2 + 3$	[Csi96, AEP88]
3-dimensional, $n \equiv 1 \pmod{4}$	$n^2/4 + 3n/2 + 9/4$	[Csi96, AEP88]
3-dimensional, $n \equiv 3 \pmod{4}$	$n^2/4 + 3n/2 + 13/4$	[Csi96, AEP88]
d -dimensional ($d > 3$)	$n^2(1 - 1/\lfloor d/2 \rfloor) + o(1)$	[EP90]

DISTINCT DISTANCES

It is obvious that if all distances between pairs of points of a d -dimensional set P are the same, then $|P| \leq d + 1$. If P determines at most g distinct distances, we have that $|P| \leq \binom{d+g}{d}$; see [BBS83]. This implies that if d is fixed and n tends to infinity, then the minimum number of distinct distances determined by n points in d -space is at least $\Omega(n^{1/d})$. Denoting this minimum by $g_d(n)$, for $d \geq 3$ we have the following results [SV04a]:

$$\Omega(n^{\frac{2}{d} - \frac{2}{d(d+2)}}) \leq g_d(n) \leq O(n^{2/d}).$$

For $d = 3$, Solymosi and Vu established a better bound, $g_3(n) = \Omega(n^{0.5643})$. In Table

1.2.4, we list some lower and upper bounds on the minimum number of distinct distances determined by an n -element point set P , under various assumptions on its structure.

TABLE 1.2.4 Estimates for the minimum number of distinct distances determined by an n -element point set P in the plane.

POINT SET P	LOWER BOUND	UPPER BOUND	SOURCE
Arbitrary	$\Omega(n^{0.8641})$	$O(n/\sqrt{\log n})$	[ST01, KT04]
In convex position	$\lfloor n/2 \rfloor$	$\lfloor n/2 \rfloor$	[Alt63]
No 3 collinear	$\lceil (n-1)/3 \rceil$	$\lfloor n/2 \rfloor$	Szemerédi [Erd75]
In general position	$\Omega(n)$	$O(n^{1+c/\sqrt{\log n}})$	[EFPR93]

RELATED RESULTS

1. Integer distances: There are arbitrarily large, noncollinear finite point sets in the plane such that all distances determined by them are integers, but there exists no infinite set with this property [AE45].
2. Generic subsets: Any set of n points in the plane contains $\Omega(n^{0.287})$ points such that all distances between them are distinct [LT95]. This bound could perhaps be improved to about $n^{1/3}$.
3. Borsuk's problem: It was conjectured that every (finite) d -dimensional point set P can be partitioned into $d+1$ parts of smaller diameter. It follows from the results quoted in the third lines of Tables 1.2.1 and 1.2.2 that this is true for $d=2$ and 3. Surprisingly, Kahn and Kalai [KK93] proved that there exist sets P that cannot be partitioned into fewer than $(1.2)^{\sqrt{d}}$ parts of smaller diameter. In particular, the conjecture is false for $d=321$ (see, e.g., O. Pikhurko). On the other hand, it is known that for large d , every d -dimensional set can be partitioned into $(\sqrt{3/2} + o(1))^d$ parts of smaller diameter [Sch88].
4. Nearly equal distances: Two numbers are said to be nearly equal if their difference is at most one. If n is sufficiently large, then the maximum number of times that nearly the same distance occurs among n separated points in the plane is $\lfloor n^2/4 \rfloor$. The maximum number of pairs in a separated set of n points in the plane, whose distance is nearly equal to any one of k arbitrarily chosen numbers, is $\frac{n^2}{2}(1 - \frac{1}{k+1} + o(1))$, as n tends to infinity [EMP93].
5. Repeated angles: In an n -element planar point set, the maximum number of noncollinear triples that determine the same angle is $O(n^2 \log n)$, and this bound is asymptotically tight for a dense set of angles (Pach-Sharir). The corresponding maximum in 3-space is at most $O(n^{8/3})$ [CCEG79]. In 4-space the angle $\pi/2$ can occur $\Omega(n^3)$ times, and all other angles can occur at most $O(n^{\frac{74}{25}})$ times [Pu88]. For dimension $d \geq 5$ all angles can occur $\Omega(n^3)$ times.

6. Repeated areas: Let $t_d(n)$ denote the maximum number of triples in an n -element point set in d -space that induce a unit area triangle. It is known that $\Omega(n^2 \log \log n) \leq t_2(n) \leq O(n^{7/3})$, $t_3(n) = O(n^{8/3})$, $t_4(n), t_5(n) = o(n^3)$, and $t_6(n) = \Theta(n^3)$ ([EP71, PS90]). Maximum- and minimum-area triangles occur among n points in the plane at most n and at most $\Theta(n^2)$ times [BRS01].
7. Congruent triangles: Let $T_d(n)$ denote the maximum number of triples in an n -element point set in d -space that induce a triangle congruent to a given triangle T . It is known [AS01, ÁF02] that

$$\Omega(n^{1+c/\log \log n}) \leq T_2(n) \leq O(n^{4/3}),$$

$$\Omega(n^{4/3}) \leq T_3(n) \leq O(n^{5/3+\epsilon}),$$

$$\Omega(n^2) \leq T_4(n) \leq O(n^{2+\epsilon}),$$

$$T_5(n) = \Theta(n^{7/3}), \text{ and}$$

$$T_d(n) = \Theta(n^3) \text{ for } d \geq 6.$$

8. Similar triangles: There exists a positive constant c such that for any triangle T and any $n \geq 3$, there is an n -element point set in the plane with at least cn^2 triples that induce triangles similar to T . For all quadrilaterals Q , whose points, as complex numbers, have an algebraic cross ratio, the maximum number of 4-tuples of an n -element set that induce quadrilaterals similar to Q is $\Theta(n^2)$. For all other quadrilaterals Q , this function is slightly subquadratic. The maximum number of pairwise homothetic triples in a set of n points in the plane is $O(n^{3/2})$, and this bound is asymptotically tight [EE94, LR97]. The number of similar tetrahedra among n points in three-dimensional space is at most $O(n^{2.2})$ [ATT98]. Further variants were studied in [Bra02].
9. Isosceles triangles, unit circles: In the plane, the maximum number of triples that determine an isosceles triangle, is $O(n^{2.102})$ [PT02]. The maximum number of distinct unit circles passing through at least 3 elements of a planar point set of size n is at least $\Omega(n^{3/2})$ and at most $n^2/3 - O(n)$ [Ele84].

CONJECTURES OF ERDŐS

1. The number of times the unit distance can occur among n points in the plane does not exceed $n^{1+c/\log \log n}$.
2. Any set of n points in the plane determines at least $\Omega(n/\sqrt{\log n})$ distinct distances.
3. Any set of n points in convex position in the plane has a point from which there are at least $\lfloor n/2 \rfloor$ distinct distances.
4. There is an integer $k \geq 4$ such that any finite set in convex position in the plane has a point from which there are no k points at the same distance.
5. Any set of n points in the plane, not all on a line, contains at least $n - 2$ triples that determine distinct angles (Corrádi, Erdős, Hajnal).

6. The diameter of any set of n points in the plane with the property that the set of all distances determined by them is separated (on the line) is at least $\Omega(n)$. Perhaps it is at least $n - 1$, with equality when the points are collinear.
7. There is no set of n points everywhere dense in the plane such that all distances determined by them are rational (Erdős, Ulam).

1.3 COLORING PROBLEMS

If we partition a space into a small number of parts (i.e., we color its points with a small number of colors), at least one of these parts must contain certain “unavoidable” point configurations. In the simplest case, the configuration consists of a pair of points at a given distance. The prototype of such a question is the Hadwiger-Nelson problem: What is the minimum number of colors needed for coloring the plane so that no two points at unit distance receive the same color? The answer is known to be between 4 and 7.

FIGURE 1.3.1

The chromatic number of the plane is

(i) at most 7 and (ii) at least 4.

GLOSSARY

Chromatic number of a graph: The minimum number of colors, $\chi(G)$, needed to color all the vertices of G so that no two vertices of the same color are adjacent.

List-chromatic number of a graph: The minimum number k such that for any assignment of a list of k colors to every vertex of the graph, for each vertex it is possible to choose a single color from its list so that no two vertices adjacent to each other receive the same color.

Chromatic number of a metric space: The chromatic number of the unit distance graph of the space, i.e., the minimum number of colors needed to color all points of the space so that no two points of the same color are at unit distance.

Polychromatic number of metric space: The minimum number of colors, χ , needed to color all points of the space so that for each color class C_i , there is

a distance d_i such that no two points of C_i are at distance d_i . A sequence of “forbidden” distances, $(d_1, \dots, d_\chi)$, is called a **type** of the coloring. (The same coloring may have several types.)

Girth of a graph: The length of the shortest cycle in the graph.

A point configuration P is **k -Ramsey** in d -space if, for any coloring of the points of d -space with k colors, at least one of the color classes contains a congruent copy of P .

A point configuration P is **Ramsey** if, for every k , there exists $d(k)$ such that P is k -Ramsey in $d(k)$ -space.

Brick: The vertex set of a right parallelepiped.

FORBIDDEN DISTANCES

Table 1.3.1 contains the best bounds we know for the chromatic numbers of various spaces. All lower bounds can be established by showing that the corresponding unit distance graphs have some *finite* subgraphs of large chromatic number [dBE51]. $S^{d-1}(r)$ denotes the sphere of radius r in d -space, where the distance between two points is the length of the chord connecting them.

TABLE 1.3.1 Estimates for the chromatic numbers of metric spaces.

SPACE	LOWER BOUND	UPPER BOUND	SOURCE
Line	2	2	
Plane	4	7	Nelson, Isbell
Rational points of plane	2	2	[Woo73]
3-space	6	15	[Nec02, Cou02, RT03]
Rational points of 3-space	2	2	Benda, Perles
$S^2(r), \frac{1}{2} \leq r \leq \frac{\sqrt{3-\sqrt{3}}}{2}$	3	4	[Sim75]
$S^2(r), \frac{\sqrt{3-\sqrt{3}}}{2} \leq r \leq \frac{1}{\sqrt{3}}$	3	5	Straus
$S^2(r), r \geq \frac{1}{\sqrt{3}}$	4	7	[Sim76]
$S^2\left(\frac{1}{\sqrt{2}}\right)$	4	4	[Sim76]
Rational points of 4-space	4	4	Benda, Perles
Rational points of 5-space	6	?	[Chi90]
d -space	$(1 + o(1))(1.2)^d$	$(3 + o(1))^d$	[FW81, LR72]
$S^{d-1}(r), r \geq \frac{1}{2}$	d	?	[Lov83]

Next we list several problems and results strongly related to the Hadwiger-Nelson problem (quoted in the introduction to this section).

1. 4-chromatic unit distance graphs of large girth: O’Donnell [O’D00] answered a question of Erdős by exhibiting a series of unit distance graphs in the plane with arbitrary large girths and chromatic number 4.
2. Polychromatic number: Stechkin and Woodall [Woo73] showed that the polychromatic number of the plane is between 4 and 6. It is known that for any $r \in [\sqrt{2} - 1, 1/\sqrt{5}]$, there is a coloring of type $(1, 1, 1, 1, r)$ [Soi94]. However,

the list-chromatic number of the unit distance graph of the plane, which is at least as large as its polychromatic number, is infinite [Alo93].

3. Dense sets realizing no unit distance: The *lower* (resp. *upper*) *density* of an unbounded set in the plane is the $\liminf$ (resp. $\limsup$) of the ratio of the Lebesgue measure of its intersection with a disk of radius r around the origin to $r^2\pi$, as $r \rightarrow \infty$. If these two numbers coincide, their common value is called the ***density*** of the set. Let δ^d denote the maximum density of a planar set, no pair of points of which is at unit distance. Croft [Cro67] and Székely [Szé84] showed that $0.2293 \leq \delta^2 \leq 12/43$.
4. The graph of large distances: Let $G_i(P)$ denote the graph whose vertex set is a finite point set P , with two vertices connected by an edge if and only if their distance is one of the i largest distances determined by P . In the plane, $\chi(G_1(P)) \leq 3$ for every P ; see Borsuk's problem in the preceding section. It is also known that for any finite planar set, $G_i(P)$ has a vertex with fewer than $3i$ neighbors [ELV89]. Thus, $G_i(P)$ has fewer than $3in$ edges, and its chromatic number is at most $3i$. However, if $n > ci^2$ for a suitable constant $c > 0$, we have $\chi(G_i(P)) \leq 7$.

EUCLIDEAN RAMSEY THEORY

According to an old result of Gallai, for any finite d -dimensional point configuration P and for any coloring of d -space with finitely many colors, at least one of the color classes will contain a homothetic copy of P . The corresponding statement is false if, instead of a homothet, we want to find a *translate*, or even a *congruent copy*, of P . Nevertheless, for some special configurations, one can establish interesting positive results, provided that we color a sufficiently high-dimensional space with a sufficiently small number of colors. The Hadwiger-Nelson-type results discussed in the preceding subsection can also be regarded as very special cases of this problem, in which P consists of only two points. The field, known as “Euclidean Ramsey theory”, was started by a series of papers by Erdős, Graham, Montgomery, Rothschild, Spencer, and Straus [EGM⁺73, EGM⁺75a, EGM⁺75b].

For details, see [Chapter 11](#) of this Handbook.

OPEN PROBLEMS

1. (Erdős, Simmons) Is it true that the chromatic number of $S^{d-1}(r)$, the sphere of radius r in d -space, is equal to $d+1$, for every $r > 1/2$? In particular, does this hold for $d=3$ and $r=1/\sqrt{3}$?
2. (Sachs) What is the minimum number of colors, $\chi(d)$, sufficient to color any system of nonoverlapping unit balls in d -space so that no two balls that are tangent to each other receive the same color? Equivalently, what is the maximum chromatic number of a unit distance graph induced by a d -dimensional separated point set? It is easy to see [JR84] that $\chi(2)=4$, and we also know that $5 \leq \chi(3) \leq 9$.
3. (Ringel) Does there exist any finite upper bound on the number of colors needed to color any system of (possibly overlapping) disks (of not necessarily

equal radii) in the plane so that no two disks that are tangent to each other receive the same color, provided that no three disks touch one another at the same point? If such a number exists, it must be at least 5.

4. (Graham) Is it true that any 3-element point set P that does not induce an equilateral triangle is 2-Ramsey in the plane? This is known to be false for equilateral triangles, and correct for right triangles (Shader). Is every 3-element point set P 3-Ramsey in 3-space? The answer is again in the affirmative for right triangles [BT96].
5. (Solymosi) Is it true that, if n is sufficiently large, then for any 2-coloring of all the $\binom{n}{2}$ segments connecting any set of n points in general position in the plane, there exists a monochromatic empty triangle? Note that, if in the Erdős-Klein-Szekeres problem (discussed in section 1.1 above), we have $e(6) < \infty$, then the answer to this question is in the affirmative, because for any 2-coloring of the edges of a complete graph with 6 vertices, there is a monochromatic triangle.

1.4 SOURCES AND RELATED MATERIAL

SURVEYS

These surveys discuss and elaborate many of the results cited above.

[PA95, Mat02]: Monographs devoted to combinatorial geometry.

[BMP04]: A representative survey of results and open problems in discrete geometry, originally started by the Moser brothers.

[Pac93]: A collection of essays covering a large area of discrete and computational geometry, mostly of some combinatorial flavor.

[HDK64]: A classical treatise of problems and exercises in combinatorial geometry, complete with solutions.

[KW91]: A collection of beautiful open questions in geometry and number theory, together with some partial answers organized into challenging exercises.

[EP95]: A survey full of original problems raised by the “founding father” of combinatorial geometry.

[JT95]: A collection of more than two hundred unsolved problems about graph colorings, with an extensive list of references to related results.

[Grü72]: A monograph containing many results and conjectures on configurations and arrangements.

2 PACKING AND COVERING

Gábor Fejes Tóth

INTRODUCTION

The basic problems in the classical theory of packings and coverings, the development of which was strongly influenced by the geometry of numbers and by crystallography, are the determination of the densest packing and the thinnest covering with congruent copies of a given body K . Roughly speaking, the density of an arrangement is the ratio between the total volume of the members of the arrangement and the volume of the whole space. In Section 2.1 we define this notion rigorously and give an account of the known density bounds.

In Section 2.2 we consider packings in, and coverings of, bounded domains. Section 2.3 is devoted to multiple arrangements and their decomposability. In Section 2.4 we make a detour to spherical and hyperbolic spaces. In Section 2.5 we discuss problems concerning the number of neighbors in a packing, while in Section 2.6 we investigate some selected problems concerning lattice arrangements. We close in Section 2.7 with problems concerning packing and covering with sequences of convex sets.

2.1 DENSITY BOUNDS FOR ARRANGEMENTS IN $\mathbb{E}^d$

GLOSSARY

Convex body: A compact convex set with nonempty interior. A convex body in the plane is called a **convex disk**. The collection of all convex bodies in d -dimensional Euclidean space $\mathbb{E}^d$ is denoted by $\mathcal{K}(\mathbb{E}^d)$. The subfamily of $\mathcal{K}(\mathbb{E}^d)$ consisting of centrally symmetric bodies is denoted by $\mathcal{K}^*(\mathbb{E}^d)$.

Operations on $\mathcal{K}(\mathbb{E}^d)$: For a set A and a real number λ we set $\lambda A = \{x \mid x = \lambda a, a \in A\}$. λA is called a **homothetic copy** of A . The **Minkowski sum** $A + B$ of the sets A and B consists of all points $a + b$, $a \in A$, $b \in B$. The set $A - A = A + (-A)$ is called the **difference body** of A . B^d denotes the unit ball centered at the origin, and $A + rB^d$ is called the **parallel body** of A at distance r ($r > 0$). If $A \subset \mathbb{E}^d$ is a convex body with the origin in its interior, then the **polar body** A^* of A is $\{x \in \mathbb{E}^d \mid \langle x, a \rangle \leq 1 \text{ for all } a \in A\}$.

The **Hausdorff distance** between the sets A and B is defined by

$$d(A, B) = \inf \{ \varrho \mid A \subset B + \varrho B^d, B \subset A + \varrho B^d \}.$$

Lattice: The set of all integer linear combinations of a particular basis of $\mathbb{E}^d$.

Lattice arrangement: The set of translates of a given set in $\mathbb{E}^d$ by all vectors of a lattice.

Packing: A family of sets whose interiors are mutually disjoint.

Covering: A family of sets whose union is the whole space.

The **volume** (Lebesgue measure) of a measurable set A is denoted by $V(A)$. In the case of the plane we use the term **area** and the notation $a(A)$.

Density of an arrangement relative to a set: Let $\mathcal{A}$ be an arrangement (a family of sets each having finite volume) and D a set with finite volume. The **inner density** $d_{\text{inn}}(\mathcal{A}|D)$, **outer density** $d_{\text{out}}(\mathcal{A}|D)$, and **density** $d(\mathcal{A}|D)$ of $\mathcal{A}$ relative to D are defined by

$$d_{\text{inn}}(\mathcal{A}|D) = \frac{1}{V(D)} \sum_{A \in \mathcal{A}, A \subset D} V(A),$$

$$d_{\text{out}}(\mathcal{A}|D) = \frac{1}{V(D)} \sum_{A \in \mathcal{A}, A \cap D \neq \emptyset} V(A),$$

and

$$d(\mathcal{A}|D) = \frac{1}{V(D)} \sum_{A \in \mathcal{A}} V(A \cap D).$$

(If one of the sums on the right side is divergent, then the corresponding density is infinite.)

The **lower density** and **upper density** of an arrangement $\mathcal{A}$ are given by the limits $d_-(\mathcal{A}) = \liminf_{\lambda \rightarrow \infty} d_{\text{inn}}(\mathcal{A}|\lambda B^d)$, $d_+(\mathcal{A}) = \limsup_{\lambda \rightarrow \infty} d_{\text{out}}(\mathcal{A}|\lambda B^d)$. If $d_-(\mathcal{A}) = d_+(\mathcal{A})$, then we call the common value the **density** of $\mathcal{A}$ and denote it by $d(\mathcal{A})$. It is easily seen that these quantities are independent of the choice of the origin.

The **packing density** $\delta(K)$ and **covering density** $\vartheta(K)$ of a convex body (or more generally of a measurable set) K are defined by

$$\delta(K) = \sup \{d_+(\mathcal{P}) \mid \mathcal{P} \text{ is a packing of } \mathbb{E}^d \text{ with congruent copies of } K\}$$

and

$$\vartheta(K) = \inf \{d_-(\mathcal{C}) \mid \mathcal{C} \text{ is a covering of } \mathbb{E}^d \text{ with congruent copies of } K\}.$$

The **translational packing density** $\delta_T(K)$, **lattice packing density** $\delta_L(K)$, **translational covering density** $\vartheta_T(K)$, and **lattice covering density** $\vartheta_L(K)$ are defined analogously, by taking the supremum and infimum over arrangements consisting of translates of K and over lattice arrangements of K , respectively. It is obvious that in the definitions of $\delta_L(K)$ and $\vartheta_L(K)$ we can take maximum and minimum instead of supremum and infimum. By a theorem of Groemer, the same holds for the translational and for the general packing and covering densities.

Dirichlet cell: Given a set S of points in $\mathbb{E}^d$ such that the distances between the points of S have a positive lower bound, the Dirichlet cell, also known as the **Voronoi cell**, associated to an element s of S consists of those points of $\mathbb{E}^d$ that are closer to s than to any other element of S .

KNOWN VALUES OF PACKING AND COVERING DENSITIES

Apart from the obvious examples of space fillers, there are only a few specific bodies for which the packing or covering densities have been determined. The bodies for which the packing density is known are given in Table 2.1.1.

TABLE 2.1.1 Bodies K for which $\delta(K)$ is known.

BODY	AUTHOR	SEE
Circle	Thue	[Fej72, p. 58]
Parallel body of a rectangle	L. Fejes Tóth	[EGH89]
Intersection of two congruent circles	L. Fejes Tóth	[EGH89]
Centrally symmetric n -gon (algorithm in $O(n)$ time)	Mount and Silverman	[FK93c]
Ball in $\mathbb{E}^3$	Hales	[Hald]
Truncated rhombic dodecahedron	A. Bezdek	[Bez94]

We have $\delta(B^2) = \pi/\sqrt{12}$. The longstanding conjecture that $\delta(B^3) = \pi/\sqrt{18}$ has been confirmed recently by Hales. A packing of balls reaching this density is obtained by placing the centers at the vertices and face-centers of a cubic lattice. We discuss the sphere packing problem in the next section.

For the rest of the bodies in Table 2.1.1, the packing density can be given only by rather complicated formulas. We note that, with appropriate modification of the definition, the packing density of a set with infinite volume can also be defined. A. Bezdek and W. Kuperberg (see [FK93c]) showed that the packing density of an infinite circular cylinder is $\pi/\sqrt{12}$, that is, infinite circular cylinders cannot be packed more densely than their base. It is conjectured that the same statement holds for circular cylinders of any finite height.

A theorem of L. Fejes Tóth (see [Fej64, p. 163]) states that

$$\delta(K) \leq \frac{a(K)}{H(K)} \quad \text{for } K \in \mathcal{K}(\mathbb{E}^2), \tag{2.1.1}$$

where $H(K)$ denotes the minimum area of a hexagon containing K . This bound is best possible for centrally symmetric disks, and it implies that

$$\delta(K) = \delta_T(K) = \delta_L(K) = \frac{a(K)}{H(K)} \quad \text{for } K \in \mathcal{K}^*(\mathbb{E}^2).$$

The packing densities of the convex disks in Table 2.1.1 have been determined utilizing this relation.

It is conjectured that an inequality analogous to (2.1.1) holds for coverings, and this is supported by the following weaker result (see [Fej64, p. 167]):

Let $h(K)$ denote the maximum area of a hexagon contained in a convex disk K . Let $\mathcal{C}$ be a covering of the plane with congruent copies of K such that no two copies of K cross. Then

$$d_-(\mathcal{C}) \geq \frac{a(K)}{h(K)}.$$

The convex disks A and B **cross** if both $A \setminus B$ and $B \setminus A$ are disconnected. As translates of a convex disk do not cross, it follows that

$$\vartheta_T(K) \geq \frac{a(K)}{h(K)} \quad \text{for } K \in \mathcal{K}(\mathbb{E}^2).$$

Again, this bound is best possible for centrally symmetric disks, and it implies that

$$\vartheta_T(K) = \vartheta_L(K) = \frac{a(K)}{h(K)} \quad \text{for } K \in \mathcal{K}^*(\mathbb{E}^2). \quad (2.1.2)$$

Based on this, Mount and Silverman gave an algorithm that determines $\vartheta_T(K)$ for a centrally symmetric n -gon in $O(n)$ time. Also the classical result $\vartheta(B^2) = 2\pi/\sqrt{27}$ of Kershner (see [Fej72, p. 58]) follows from this relation.

One could expect that the restriction to arrangements of translates of a set means a considerable simplification. However, this apparent advantage has not been exploited so far in dimensions greater than 2. On the other hand, the lattice packing density of some special convex bodies in $\mathbb{E}^3$ has been determined; see Table 2.1.2.

Snub Dodecahedron	$0.7886401 \dots$	Betke and Henk

All results given in Table 2.1.2 are based on Minkowski's work on critical lattices of convex bodies and can be traced in [BH00]. We emphasize the following special

case: Gauss’s result that $\delta_L(B^3) = \pi/\sqrt{18}$ is the special case $\lambda = 1$ of Chalk’s theorem concerning the frustum of the ball. In [BH00] Betke and Henk gave an efficient algorithm for computing $\delta_L(K)$ for an arbitrary 3-polytope. As an application they calculated the lattice packing densities of all regular and Archimedean polytopes.

The list in Table 2.1.2 can be augmented by additional bodies using the following observations.

It has been noticed by Chalk and Rogers that the relation $\delta_T(K) = \delta_L(K)$ ($K \in \mathcal{K}(\mathbb{E}^2)$) readily implies that for a cylinder C in $\mathbb{E}^3$ based on a convex disk K we have $\delta_L(C) = \delta_L(K)$. Thus, $\delta_L(C)$ is known if the lattice packing density of its base is known.

Next, we recall the observation of Minkowski (see [Rog64, p. 69]) that an arrangement $\mathcal{A}$ of translates of a convex body K is a packing if and only if the arrangement of translates of the body $\frac{1}{2}(K - K)$ by the same vectors is a packing. This implies that, for $K \in \mathcal{K}(\mathbb{E}^d)$,

$$\delta_T(K) = 2^d \delta_T(K - K) \frac{V(K)}{V(K - K)} \quad \text{and} \quad \delta_L(K) = 2^d \delta_L(K - K) \frac{V(K)}{V(K - K)} \quad (2.1.3)$$

Generally, K is not uniquely determined by $K - K$; e.g., we have $K - K = B^d$ for every $K \subset \mathbb{E}^d$ that is a body of constant width 1, and the determination of $\delta_L(K)$ for such a body is reduced to the determination of $\delta_L(B^d)$, which is established for $d \leq 8$. We give the known values of $\delta_L(B^d)$, together with those of $\vartheta(B^d)$, in Table 2.1.3. All results given there can be traced in [CS93].

TABLE 2.1.3 Known values of $\delta_L(B^d)$ and $\vartheta_L(B^d)$.

THE KEPLER CONJECTURE

A remark of Kepler can be interpreted in modern terminology as the conjecture that $\delta(B^3) = \pi/\sqrt{18}$. Early research concerning Kepler’s conjecture concentrated on two easier problems: proving the conjecture for special arrangements and giving

upper bounds for $\delta(B^3)$.

We mentioned Gauss's result that $\delta_L(B^3) = \pi/\sqrt{18}$. A stronger result establishing Kepler's conjecture for a restricted class of packings is due to A. Bezdek, W. Kuperberg and Makai [BKM91]. They proved that the conjecture holds for packings consisting of parallel strings of balls. A string of balls is a collection of equal balls whose centers are collinear and such that each of them touches two others. The best upper bound for $\delta(B^3)$ was given by Muder [Mud93], who proved that $\delta(B^3) \leq 0.773055$.

The first step toward the solution of Kepler's conjecture in its full generality was made in the early 1950's by L. Fejes Tóth (see [Fej72]). He considered weighted averages of the volumes of Dirichlet cells of a finite collection of balls in a packing. He showed that the Kepler conjecture holds if a particular weighted average of volumes involving not more than 13 cells is greater than or equal the volume of the rhombic dodecahedron circumscribed around a ball (this being the Dirichlet cell of a ball in the face-centered cubic lattice). His argument constitutes a program that, if realizable in principle, reduces Kepler's conjecture to an optimization problem in a finite number of variables. Later, in [Fej64], he suggested that with the use of computers $\delta(B^3)$ could be "approximated with great exactitude."

In 1990 W.-Y. Hsiang announced the solution of the Kepler conjecture. His approach is very similar to the program proposed by L. Fejes Tóth. Unfortunately, Hsiang's paper [Hsi93] contains significant gaps, so it cannot be accepted as a proof. Hsiang maintains his claim of having a proof. He gave more detail in [Hsi01]. The mathematical community lost interest in checking those details, however.

About the same time as Hsiang, Tom Hales also attacked the Kepler conjecture. His first attempt [Hal92] was a program based on the Delone subdivision of space, which is dual to the subdivision by Dirichlet cells. He modified his approach in several steps [Hal93, Hal97, Hal98, FH]. His final version, worked out in collaboration with his graduate student Ferguson in [FH], uses a subdivision that is a hybrid of certain Delone-type simplices and Dirichlet cells. With each ball B in a saturated packing of unit balls, an object, called a *decomposition star*, is associated, consisting of certain tetrahedra having the center of B as a common vertex together with parts of a modified Dirichlet cell of B . A complicated scoring rule is introduced that takes into account the volumes of the different parts of the decomposition star with appropriate weights. The score of a decomposition star in the face-centered cubic lattice is a certain number, which Hales takes to be 8 pts. The key property of the decomposition stars and the scoring rule is that the decomposition star of a ball B , as well as its score, depends only on balls lying in a certain neighborhood of B . From the mathematical point of view, the main step of the proof is the theorem that

The Kepler conjecture holds, provided the score of each decomposition star in a saturated packing of unit balls is at most 8 pts.

The task of proving this, which is an optimization problem in finitely many variables, has been carried out with the aid of computers. As Hales points out, there is hope that in the future such a problem "might eventually become an instance of a general family of optimization problems for which general optimization techniques exist". In the absence of such general techniques, manual procedures had to be used to guide the work of computers.

Computers are used in the proof in several ways. The topological structure of the decomposition stars is described by planar maps. A computer program enu-

merates around 5000 planar maps that have to be examined as potential counterexamples to the conjecture. Interval arithmetic is used to prove various inequalities. Nonlinear optimization problems are replaced by linear problems that dominate the original ones in order to apply linear programming methods. Even the organization of the few gigabites of data is a difficult task.

It is safe to say that the 300-page proof, aided by computer calculations taking months, is one of the most complex proofs in the history of mathematics. Lagarias, who in [Lag02] extracts the common ideas of the programs of L. Fejes Tóth, W.-Y. Hsiang, and Hales and puts them into a general framework, finds that “the Hales–Ferguson proof, assumed correct, is a tour de force of nonlinear optimization.” No one has checked all details of the proof, and possibly no human being will ever check them. However, the general framework of the proof is sound and no errors have been detected so far; thus, it is largely accepted by the mathematical community.

EXISTENCE OF ECONOMICAL ARRANGEMENTS

Table 2.1.4 lists the known bounds establishing the existence of reasonably dense packings and thin coverings. When c appears in a bound without specification, it means a suitable constant characteristic of the specific bound. The proofs of most of these are nonconstructive. For constructive methods yielding slightly weaker bounds, as well as improvements for special convex bodies, see Chapter 61.

TABLE 2.1.4 Bounds establishing the existence of dense packings and thin coverings.

No.	BOUND	AUTHOR	SEE
Bounds for general convex bodies in $\mathbb{E}^d$			
1	$\delta_L(K) \geq cd^{3/2}/4^d \quad (d \text{ large})$	Schmidt, Rogers, and Shephard	[Rog64]
2	$\vartheta_T(K) \leq d \ln d + d \ln \ln d + 5d$	Rogers	[Rog64, Theorem 3.2]
3	$\vartheta_L(K) \leq d^{\log_2 \ln d + c}$	Rogers	[Rog64]
4	$\vartheta_L(B^d) \leq cd(\ln d)^{\log_2 \sqrt{2\pi e}}$	Rogers	[Rog64]
Bounds for centrally symmetric convex bodies in $\mathbb{E}^d$			
5	$\delta_L(K) \geq \zeta(d)/2^{d-1}$	Minkowski-Hlawka	[PA95, Theorem 7.7]
6	$\delta_L(K) \geq cd/2^d \quad (d \text{ large})$	Schmidt	[Rog64]
Bounds for general convex bodies in $\mathbb{E}^2$			
7	$\delta(K) \geq \sqrt{3}/2 = 0.8660 \dots$	G. Kuperberg and W. Kuperberg	[PA95, Theorem 4.5]
8	$\vartheta(K) \leq 1.2281771 \dots$	Ismailescu	[Ism98]
9	$\delta_L(K) \geq 2/3$	Fáry	[Fej72, p. 100]
10	$\vartheta_L(K) \leq 3/2$	Fáry	[Fej72, p. 100]
Bounds for centrally symmetric convex bodies in $\mathbb{E}^2$			
11	$\delta_L(K) \geq 0.892656 \dots$	Tammela	[PA95]
12	$\vartheta_L(K) \leq 2\pi/\sqrt{27}$	L. Fejes Tóth	[Fej72, p. 103]

Bound 1 for the packing density of general convex bodies follows by combining Bound 6 with the relation (2.1.3) and the inequality $V(K - K) \leq \binom{2d}{d}V(K)$ of

Rogers and Shephard (see [Rog64, Theorem 2.4]). For $d \geq 3$ all methods establishing the existence of dense packings rely on the theory of lattices, thus providing the same lower bounds for $\delta(K)$ and $\delta_T(K)$ as for $\delta_L(K)$.

Gritzmann (see [PA95]) proved a bound similar to Bound 4 for a larger class of convex bodies:

$$\vartheta_L(K) \leq cd(\ln d)^{1+\log_2 e}$$

holds for a suitable constant c and for every convex body K in $\mathbb{E}^d$ that has an affine image symmetric about at least $\log_2 \ln d + 4$ coordinate hyperplanes.

UPPER BOUNDS FOR $\delta(B^d)$ AND LOWER BOUNDS FOR $\vartheta(B^d)$

The packing and covering density of B^d is not known for $d \geq 3$. Asymptotically, the best upper bound known for $\delta(B^d)$ is

$$\delta(B^d) \leq 2^{-0.599d+o(d)} \quad (\text{as } d \rightarrow \infty), \quad (2.1.4)$$

given by Kabatjanskiĭ and Levenšteĭn (see [CS93]). This bound is not obtained directly by the investigation of packings in $\mathbb{E}^d$ but rather through studying the analogous problem in spherical geometry, where the powerful technique of linear programming bounds can be used (see Section 2.4). For low dimensions, Rogers's simplex bound

$$\delta(B^d) \leq \sigma_d \quad (2.1.5)$$

gives a better estimate (see [Rog64, Theorem 7.1]). Here, σ_d is the ratio between the total volume of the sectors of $d+1$ unit balls centered at the vertices of a regular simplex of edge 2 and the volume of the simplex.

Recently, Rogers's bound has been improved in low dimensions as well. On one hand, K. Bezdek [Bez02] extended the method of Rogers by investigating the surface area of the Voronoi regions, rather than their volume; on the other hand, Cohn and Elkies [CE03, Coh02] developed linear programming bounds that apply directly to sphere packings in $\mathbb{E}^d$. This latter method seems to be more powerful. In dimensions 8 and 24 the bounds in [CE03] differ from the conjectured values of $\delta(B^8)$ and $\delta(B^{24})$ only by factors of 1.000001 and 1.0007071, respectively. There is hope that the exact values of $\delta(B^8)$ and $\delta(B^{24})$ can be found using these methods.

Coxeter, Few, and Rogers (see [Rog64, Theorem 8.1]) proved a dual counterpart to Rogers's simplex bound:

$$\vartheta(B^d) \geq \tau_d,$$

where τ_d is the ratio between the total volume of the intersections of $d+1$ unit balls with the regular simplex of edge $\sqrt{2(d+1)/d}$ if their centers lie at the vertices of the simplex, and the volume of the simplex. Asymptotically,

$$\tau_d \sim d/e^{3/2}.$$

In contrast to packings, where there is a sizable gap between bound (2.1.4) and the bound from the other direction (Bound 6 in Table 2.1.4), this bound compares quite favorably with the corresponding Bound 2 in Table 2.1.4.

According to a result of W. Schmidt (see [FK93c]), we have $\delta(K) < 1$ and $\vartheta(K) > 1$ for every smooth convex body; but the method of proof does not allow one to derive any explicit bound. There is a general upper bound for $\delta(K)$ that is

nontrivial (smaller than 1) for a wide class of convex bodies [FK93a]. It is quite reasonable for “longish” bodies. For cylinders in $\mathbb{E}^d$, the bound is asymptotically equal to the Kabatjanskiĭ and Levenstein bound for B^d (as $d \rightarrow \infty$). We note that no nontrivial bound is known for $\vartheta(K)$ for any K other than a ball.

REGULARITY OF OPTIMAL ARRANGEMENTS

The packings and coverings attaining the packing and covering densities of a set are, of course, not uniquely determined, but it is a natural question whether there exist among the optimal arrangements some that satisfy certain regularity properties. Of particular interest are those bodies for which the densest packing and/or thinnest covering with congruent copies can be realized by a lattice arrangement. As mentioned above, $\delta(K) = \delta_L(K)$ for $K \in \mathcal{K}^*(\mathbb{E}^2)$. A plausible interpretation of this result is that the assumption of maximum density creates from a chaotic structure a regular one. Unfortunately, certain results indicate that such bodies are rather exceptional.

Let $\mathcal{L}_p$ and $\mathcal{L}_c$ be the classes of those convex disks $K \in \mathcal{K}(\mathbb{E}^2)$ for which $\delta(K) = \delta_L(K)$ and $\vartheta(K) = \vartheta_L(K)$, respectively. Then, in the topology induced by the Hausdorff metric on $\mathcal{K}(\mathbb{E}^2)$, the sets $\mathcal{L}_p$ and $\mathcal{L}_c$ are nowhere dense [FZ94, Fej95]. It is conjectured that an analogous statement holds also in higher dimensions.

Rogers [Rog64, p. 15] conjectures that for sufficiently large d we have $\delta(B^d) > \delta_L(B^d)$. The following result of A. Bezdek and W. Kuperberg (see [FK93c]) supports this conjecture: For $d \geq 3$ there are ellipsoids E in $\mathbb{E}^d$ for which $\delta(E) > \delta_L(E)$. An even more surprising result holds for coverings [FK95]: For $d \geq 3$ every strictly convex body K in $\mathbb{E}^d$ has an affine image K' such that $\vartheta(K') < \vartheta_L(K')$. In particular, there is an ellipsoid E in $\mathbb{E}^3$ for which

$$\vartheta(E) < 1.394 < \frac{3\sqrt{3}}{2}(3 \arccos \frac{1}{3} - \pi) = \tau_3 \leq \vartheta_T(E) \leq \vartheta_L(E).$$

We note that no example of a convex body K is known for which $\delta_L(K) < \delta_T(K)$ or $\vartheta_L(K) > \vartheta_T(K)$.

Schmitt [Sch88] constructed a star-shaped prototile for a monohedral tiling in $\mathbb{E}^3$ such that no tiling with its replicas is periodic. It is not known whether a convex body with this property exists; however, with a slight modification of Schmitt's construction, Conway produced a convex prototile that admits only nonperiodic tilings if no mirror-image is allowed (see Section 3.4). Another result of Schmitt's [Sch91] is that there are star-shaped sets in the plane whose densest packing cannot be realized in a periodic arrangement.

2.2 FINITE ARRANGEMENTS

PACKING IN AND COVERING OF A BODY WITH GIVEN SHAPE

What is the size of the smallest square tray that can hold n given glasses? Thue's result gives a bound that is asymptotically sharp as $n \rightarrow \infty$; however, for practical reasons, small values of n are of interest.

Generally, for given sets K and C and a positive integer n one can ask for the quantities

$$M_p(K, C, n) = \inf\{\lambda \mid n \text{ congruent copies of } C \text{ can be packed in } \lambda K\}$$

and

$$M_c(K, C, n) = \sup\{\lambda \mid n \text{ congruent copies of } C \text{ can cover } \lambda K\}.$$

Tables 2.2.1 and 2.2.2 contain the known results about the cases when C is a circle and K is a circle, square, or regular triangle. In addition, economical circle packings and circle coverings have been constructed for many special values of n . All of these results can be traced in [Fod99, Fod00, Fod, HM97, Mel93, Mel94, Mel97, Pei94]. Concerning the thinnest covering of a circle with congruent circles, we mention the conjecture that $M_c(K, B^2, n) = 1 + 2 \cos \frac{2\pi}{n-1}$ for $8 \leq n \leq 10$. The paper of Krotoszyński [Kro93] claims this as a theorem even for $n \leq 11$; however, his proof contains a gap. In fact, Melissen and Schuur have found an example showing that the result does not hold for $n = 11$.

Most of these results were obtained by ad hoc methods. Recently, however, Peikert described a heuristic algorithm for the determination of $M_p(K, B^2, n)$ and the corresponding optimal arrangements in the case where K is the unit square. His algorithm consists of the following steps:

Step 1. Find a good upper bound m for $M_p(K, B^2, n)$. This requires the construction of a reasonably good arrangement, which can be established, e.g., by the Monte Carlo method.

Step 2. Iterate an elimination process on a successively refined grid to restrict possible locations for the centers of a packing of unit circles in mK .

Step 3. Based on the result of Step 2, guess the nerve graph of the packing, then determine the optimal packing with the given graph.

Step 4. Verify that the arrangement obtained in Step 3 is indeed optimal.

Peikert does not prove that these steps always provide the optimal arrangement in finite time, but he implemented the method successfully for $n \leq 20$. The best arrangements are shown in Figure 2.2.1. Observe that quite often an optimal arrangement can contain a freely movable circle.

The sequence $M_p(K, B^2, n)$ seems to be strictly increasing when K is a square or when K is a circle and $n \geq 7$. In contrast to this, it is conjectured that in

the case where K is a triangle, we have $M_p(K, B^2, n) = M_p(K, B^2, n - 1)$ for all triangular numbers $n = k(k + 1)/2$ ($k > 1$).

The problem of finding the densest packing of n congruent circles in a circle has been considered also in the Minkowski plane. In terms of Euclidean geometry, this is the same as asking for the smallest number $\varrho(n, K)$ such that n mutually disjoint translates of the centrally symmetric convex disk K (the unit circle in the Minkowski metric) can be contained in $\varrho(n, K)K$. Doyle, Lagarias, and Randell [DLR92] solved the problem for all $K \in \mathcal{K}^*(\mathbb{E}^2)$ and $n \leq 7$. There is an n -gon inscribed in K having equal sides in the Minkowski metric (generated by K) and having a vertex at an arbitrary boundary point of K . Let $\alpha(n, K)$ be the maximum Minkowski side-length of such an n -gon. Then we have $\varrho(n, K) = 1 + 2/\alpha(n, K)$ for $2 \leq n \leq 6$ and $\varrho(7, K) = \varrho(6, K) = 3$.

The densest packing of n congruent balls in a cube is known for $n \leq 10$ (see [Sch94]). The problem of finding the densest packing of congruent balls in other regular polytopes has been investigated by K. Bezdek (see [CFG91]).

SAUSAGE CONJECTURES

Intensive research on another type of finite packing and covering problem has been generated by the sausage conjectures of L. Fejes Tóth and Wills (see [GW93]):

What is the convex body of minimum volume in $\mathbb{E}^d$ that can accommodate k nonoverlapping unit balls?

What is the convex body of maximum volume in $\mathbb{E}^d$ that can be covered by k unit balls?

According to the conjectures mentioned above, for $d \geq 5$ the extreme bodies are “sausages” and in the optimal arrangements the centers of the balls are equally spaced on a line segment (Figure 2.2.2).

FIGURE 2.2.2

Sausage-like arrangements of circles.

After several partial results supporting these conjectures (see [GW93]) the breakthrough concerning the sausage conjecture for ball packings was achieved by Betke, Henk, and Wills [BHW94]: they proved that the conjecture holds for dimensions $d \geq 13387$. Later, Betke and Henk [BH98] improved the bound on d to $d \geq 42$.

Several generalizations of the problems mentioned above have been considered. Connections of these types of problems to the classical theory of packing and coverings, as well as to crystallography, have been observed. For details we refer to [Bör].

THE COVERING PROBLEMS OF BORSUK AND HADWIGER-LEVI

In 1933, Borsuk formulated the conjecture that any bounded set in $\mathbb{E}^d$ can be partitioned into $d + 1$ subsets of smaller diameter. Borsuk verified the conjecture for $d = 2$, and the three-dimensional case was settled independently by Eggleston, Grünbaum, and Heppes. The conjecture is known to be true also for many special cases: for smooth convex bodies (Hadwiger), for centrally symmetric sets (Rissling), as well as for sets having the symmetry group of the regular simplex (Rogers). Quite recently, however, Kahn and Kalai [KK93] showed that Borsuk's conjecture is false in the following very strong sense: Let $b(d)$ denote the smallest integer such that every bounded set in $\mathbb{E}^d$ can be partitioned into $b(d)$ subsets of smaller diameter. Then $b(d) \geq (1.2)^{\sqrt{d}}$ for every sufficiently large value of d .

In the 1950s, Hadwiger and Levi, independently of each other, asked for the smallest integer $h(K)$ such that the convex body K can be covered by $h(K)$ smaller positively homothetic copies of K . Hadwiger conjectured that $h(K) \leq 2^d$ for all $K \in \mathcal{K}(\mathbb{E}^d)$ and that equality holds only for parallelotopes. Levi verified the conjecture for the plane, but it is open for $d \geq 3$. Lassak proved Hadwiger's conjecture for centrally symmetric convex bodies in $\mathbb{E}^3$, and K. Bezdek extended Lassak's result to convex polytopes with any affine symmetry.

Boltjanskiĭ observed that the Hadwiger-Levi covering problem for convex bodies is equivalent to an illumination problem. We say that a boundary point x of the convex body K is *illuminated from the direction u* if the ray issuing from x in the direction u intersects the interior of K . Let $i(K)$ be the minimum number of directions from which the boundary of K can be illuminated. Then $h(K) = i(K)$ for every convex body. For literature and further results concerning the Hadwiger-Levi problem, we refer to [Bez93].

2.3 MULTIPLE ARRANGEMENTS

GLOSSARY

***k*-fold packing:** An arrangement $\mathcal{A}$ such that each point of the space belongs to the interior of at most k members of $\mathcal{A}$.

***k*-fold covering:** An arrangement $\mathcal{A}$ such that each point of the space belongs to at least k members of $\mathcal{A}$.

Densities: In analogy to the packing and covering densities of a body K , we define the quantities $\delta^k(K)$, $\delta_T^k(K)$, $\delta_L^k(K)$, $\vartheta^k(K)$, $\vartheta_T^k(K)$, and $\vartheta_L^k(K)$ as the suprema of the densities of all k -fold packings and the infima of the densities of all k -fold coverings with congruent copies, translates, and lattice translates of K , respectively.

TABLE 2.3.1 Bounds for k -fold packing and covering densities.

BOUND	AUTHOR
$\delta_T^k(K) \geq ck \quad K \in \mathcal{K}(\mathbb{E}^d)$	Erdős and Rogers
$\vartheta_L^k(K) \leq ((k+1)^{1/d} + 8d)^d \quad K \in \mathcal{K}(\mathbb{E}^d)$	Cohn
$\delta_L^k(K) \geq k - ck^{2/5} \quad K \in \mathcal{K}(\mathbb{E}^2)$	Bolle
$\vartheta_L^k(K) \leq k + ck^{2/5} \quad K \in \mathcal{K}(\mathbb{E}^2)$	Bolle
$\delta^k(B^d) \geq (2k/(k+1))^{d/2} \delta(B^d)$	Few
$\delta_L^k(B^d) \geq (2k/(k+1))^{d/2} \delta_L(B^d)$	Few
$\delta^k(B^d) \leq (1 + d^{-1})((d+1)^k - 1)(k/(k+1))^{d/2}$	Few
$\delta^2(B^d) \leq \frac{4}{3}(d+2)(\frac{2}{3})^{d/2}$	Few
$\vartheta^k(B^d) \geq ck \quad c = c_d > 1$	G. Fejes Tóth
$\delta^k(B^2) \leq \frac{\pi}{6} \cot \frac{\pi}{6k}$	G. Fejes Tóth
$\vartheta^k(B^2) \geq \frac{\pi}{3} \csc \frac{\pi}{3k}$	G. Fejes Tóth

The information known about the asymptotic behavior of k -fold packing and covering densities is summarized in Table 2.3.1. There, in the various bounds, different constants appear, all of which we denote by c . All results given in the table can be traced in [EGH89] and [Fej83].

The known values of $\delta_L^k(B^d)$ and $\vartheta_L^k(B^d)$ (for $k \geq 2$) are given in Table 2.3.2 and can be traced in [EGH89, Fej83, FK93c, Tem94a, Tem94b].

Recently, general methods for the determination of the densest k -fold lattice packings and the thinnest k -fold lattice coverings with circles have been developed by Horváth, Temesvári, and Yakovlev and by Temesvári, respectively (see [FK93c]).

These methods reduce both problems to the determination of the optima of finitely many well-defined functions of one variable. The proofs readily provide algorithms for finding the optimal arrangements; however, the authors did not try to implement them. Only the values of $\delta_L^9(B^2)$ and $\vartheta_L^8(B^2)$ have been added in this way to the list of values of $\delta_L^k(B^2)$ and $\vartheta_L^k(B^2)$ that had been determined previously by ad hoc methods.

We note that we have $\delta_L^k(B^2) = k\delta_L(B^2)$ for $k \leq 4$ and $\vartheta_L^2(B^2) = 2\vartheta_L(B^2)$. These are the only cases where the extreme multiple arrangements of circles are not better than repeated simple arrangements. These relations have been extended to arbitrary centrally symmetric convex disks by Dumir and Hans-Gill and by G. Fejes Tóth (see [FK93c]). There is a simple reason for the relations $\delta_L^3(K) = 3\delta_L(K)$ and $\delta_L^4(K) = 4\delta_L(K)$ ($K \in \mathcal{K}^*(\mathbb{E}^2)$): Every 3-fold lattice packing of the plane with a centrally symmetric disk is the union of 3 simple lattice packings and every 4-fold packing is the union of two 2-fold packings.

This last observation brings us to the topic of decompositions of multiple arrangements. Our goal here is to find insight into the structure of multiple arrangements by decomposing them into possibly a few simple ones. Pach showed (see [FK93c]) that any double packing with positively homothetic copies of a convex disk can be decomposed into 4 simple packings. Further, if $\mathcal{P}$ is a k -fold packing with convex disks such that for some integer L the inradius $r(K)$ and the area $a(K)$ of each member K of $\mathcal{P}$ satisfy the inequality $9\pi^2kr^2(K)/a(K) \leq L$, then $\mathcal{P}$ can be decomposed into L simple packings.

Concerning the decomposition of multiple coverings, Pach proved (see [FK93c]) that for any centrally symmetric polygon P and positive integer r there exists an integer $k = k(P, r)$ such that every k -fold covering with translates of P can be decomposed into r coverings. The attempt to extend this result by an approximation argument to all centrally symmetric disks fails, since, for fixed r , $k(P, r)$ approaches

infinity as the number of sides of P tends to infinity. For circle coverings, however, Mani and Pach (see [FK93c]) were able to establish a decomposition theorem: Every 33-fold covering with congruent circles can be decomposed into two coverings. In 3-space, results analogous to the two theorems above do not hold.

2.4 PROBLEMS IN NONEUCLIDEAN SPACES

Research on packing and covering in spherical and hyperbolic spaces has been concentrated on arrangements of balls. In contrast to spherical geometry, where the finite, combinatorial nature of the problems, as well as applications, have inspired research, investigations in hyperbolic geometry have been hampered by the lack of a reasonable notion of density relative to the whole hyperbolic space.

SPHERICAL SPACE

Let $M(d, \varphi)$ be the maximum number of caps of spherical diameter φ forming a packing on the d -dimensional spherical space $\mathbb{S}^d$, that is, on the boundary of B^{d+1} , and let $m(d, \varphi)$ be the minimum number of caps of spherical diameter φ covering $\mathbb{S}^d$. An upper bound for $M(d, \varphi)$, which is sharp for certain values of d and φ and yields the best estimate known as $d \rightarrow \infty$, is the so-called **linear programming bound** (see [CS93, pp. 257–266]). It establishes a surprising connection between $M(d, \varphi)$ and the expansion of real polynomials in terms of certain Jacobi polynomials. The Jacobi polynomials, $P_i^{(\alpha, \beta)}(x)$, $i = 0, 1, \dots$, $\alpha > -1$, $\beta > -1$, form a complete system of orthogonal polynomials on $[-1, 1]$ with respect to the weight function $(1-x)^\alpha(1+x)^\beta$. Set $\alpha = \beta = (d-1)/2$ and let

$$f(t) = \sum_{i=0}^k f_i P_i^{(\alpha, \alpha)}(t)$$

be a real polynomial such that $f_0 > 0$, $f_i \geq 0$ ($i = 1, 2, \dots, k$), and $f(t) \leq 0$ for $-1 \leq t \leq \cos \varphi$. Then

$$M(d, \varphi) \leq f(1)/f_0.$$

With the use of appropriate polynomials Kabatjanskiĭ and Levenšteĭn (see [CS93]) obtained the asymptotic bound:

$$\frac{1}{d} \ln M(d, \varphi) \leq \frac{1 + \sin \varphi}{2 \sin \varphi} \ln \frac{1 + \sin \varphi}{2 \sin \varphi} - \frac{1 - \sin \varphi}{2 \sin \varphi} \ln \frac{1 - \sin \varphi}{2 \sin \varphi} + o(1).$$

This implies the simpler bound

$$M(d, \varphi) \leq (1 - \cos \varphi)^{-d/2} 2^{-0.099d + o(d)} \quad (\text{as } d \rightarrow \infty, \varphi \leq \varphi^* = 62.9974\dots).$$

Bound (2.1.4) for $\delta(B^d)$ follows in the limiting case when $\varphi \rightarrow 0$.

The following is a list of some special values of d and φ for which the linear programming bound turns out to be exact (see [CS93]).

$M(2, \arccos 1/\sqrt{5}) = 12$	$M(4, \arccos 1/5) = 16$	$M(5, \arccos 1/4) = 27$
$M(6, \arccos 1/3) = 56$	$M(7, \pi/3) = 240$	$M(20, \arccos 1/9) = 112$
$M(20, \arccos 1/7) = 162$	$M(21, \arccos 1/11) = 100$	$M(21, \arccos 1/6) = 275$
$M(21, \arccos 1/4) = 891$	$M(22, \arccos 1/5) = 552$	$M(22, \arccos 1/3) = 4600$
$M(23, \pi/3) = 196560$		

For small values of d and specific values of φ the linear programming bound is superseded by the “simplex bound” of Böröczky (see [FK93c]), which is the generalization of Rogers’s bound (2.1.5) for ball packings in $\mathbb{S}^d$.

The value of $M(d, \varphi)$ has been determined for all d and $\varphi \geq \pi/2$ (see [CS93]). We have

$$M(d, \varphi) = i + 1 \quad \text{for } \frac{1}{2}\pi + \arcsin \frac{1}{i+1} < \varphi \leq \frac{1}{2}\pi + \arcsin \frac{1}{i}, \quad i = 1, \dots, d,$$

$$M(d, \varphi) = d + 2 \quad \text{for } \frac{1}{2}\pi < \varphi \leq \frac{1}{2}\pi + \arcsin \frac{1}{d+1},$$

and

$$M(d, \frac{1}{2}\pi) = 2(d+1).$$

Except for an upper bound on $m(d, \varphi)$ establishing the existence of reasonably economic coverings of $\mathbb{S}^d$ by equal balls due to Rogers (see [Fej83]), no results on coverings in spherical spaces of high dimensions are known.

Extensive research has been done on circle packings and circle coverings on $\mathbb{S}^2$. Traditionally, here the inverse functions of $M(2, \varphi)$ and $m(2, \varphi)$ are considered. Let a_n be the maximum number such that n caps of spherical diameter a_n can form a packing and let A_n be the minimum number such that n caps of spherical diameter A_n can form a covering on $\mathbb{S}^2$. The known values of a_n and A_n are given in Table 2.4.1. All the results mentioned in the table can be traced in [Fej72]. In addition, conjecturally best circle packings and circle coverings for $n \leq 130$, as well as good arrangements with icosahedral symmetry for $n \leq 55000$, have been constructed [HSS]. The ad hoc methods of the earlier constructions have recently been replaced by different computer algorithms, but none of them has been shown to give the optimum.

Observe that $a_5 = a_6$ and $a_{11} = a_{12}$. Also, $A_2 = A_3$. It is conjectured that $a_n > a_{n+1}$ and $A_n > A_{n+1}$ in all other cases.

HYPERBOLIC SPACE

The density of a general arrangement of sets in d -dimensional hyperbolic space $\mathbb{H}^d$ cannot be defined by a limit as in $\mathbb{E}^d$ (see [FK93c]). The main difficulty is that in hyperbolic geometry the volume and the surface area of a ball of radius r are of the same order of magnitude as $r \rightarrow \infty$. In the absence of a reasonable definition of density with respect to the whole space, two natural problems arise:

- (i) Estimate the density of an arrangement relative to a bounded domain;
- (ii) Find substitutes for the notions of densest packing and thinnest covering.

Concerning the first problem, we mention the following result of K. Bezdek (see [FK93c]). Consider a packing of finitely many, but at least two, circles of radius

TABLE 2.4.1 Densest packing and thinnest covering with congruent circles on a sphere.

r in the hyperbolic plane $\mathbb{H}^2$. Then the density of the circles relative to the outer parallel domain of radius r of the convex hull of their centers is at most $\pi/\sqrt{12}$.

As a corollary it follows that if at least two congruent circles are packed in a circular domain in $\mathbb{H}^2$, then the density of the packing relative to the domain is at most $\pi/\sqrt{12}$. We note that the density of such a finite packing relative to the convex hull of the circles can be arbitrarily close to 1 as $r \rightarrow \infty$. K. Böröczky, Jr. (see [Bör]) proved a dual counterpart to the above-mentioned theorem of K. Bezdek, a corollary of which is that if at least two congruent circles cover a circular domain in $\mathbb{H}^2$, then the density of the covering relative to the domain is at most $2\pi/\sqrt{27}$.

Rogers’s simplex bound (2.1.5) for ball packings in $\mathbb{E}^d$ has been extended by Böröczky (see [FK93b]) to $\mathbb{H}^d$ as follows. If balls of radius r are packed in $\mathbb{H}^d$ then the density of each ball relative to its Dirichlet cell is less than or equal to the density of $d + 1$ balls of radius r centered at the vertices of a regular simplex of side-length $2r$ relative to this simplex. Of course, we should not interpret this result as a global density bound. The impossibility of such an interpretation is shown by an ingenious example of Böröczky (see [FK93b]). He constructed a packing $\mathcal{P}$ of congruent circles in $\mathbb{H}^2$ and two tilings, $\mathcal{T}_1$ and $\mathcal{T}_2$, both consisting of congruent tiles, such that each tile of $\mathcal{T}_1$, as well as each tile of $\mathcal{T}_2$, contains exactly one circle from $\mathcal{P}$, but such that the tiles of $\mathcal{T}_1$ and $\mathcal{T}_2$ have different areas.

The first notion that has been suggested as a substitute for densest packing and thinnest covering is “solidity.” $\mathcal{P}$ is a **solid packing** if no finite subset of $\mathcal{P}$ can be rearranged so as to form, together with the rest of $\mathcal{P}$, a packing not congruent to $\mathcal{P}$. Analogously, $\mathcal{C}$ is a **solid covering** if no finite subset of $\mathcal{C}$ can be rearranged so as to form, together with the rest of $\mathcal{C}$, a covering not congruent to $\mathcal{C}$. Obviously, in $\mathbb{E}^d$ a solid packing with congruent copies of a body K has density $\delta(K)$, and a solid covering with congruent copies of K has density $\vartheta(K)$. This justifies the use of solidity as a natural substitute for “densest packing” and “thinnest covering” in hyperbolic space.

The tiling with Schläfli symbol $\{p, 3\}$ (see Chapters 19 or 21 of this Handbook) has regular p -gonal faces such that at each vertex of the tiling three faces meet. There exists such a tiling for each $p \geq 2$: for $p \leq 5$ on the sphere, for $p \geq 7$ on the hyperbolic plane, while for $p = 6$ we have the well-known hexagonal tiling on

the Euclidean plane. The incircles of such a tiling form a solid packing and the circumcircles form a solid covering. In addition, several packings and coverings by incongruent circles, including the the incircles and the circumcircles of certain trihedral Archimedean tilings have been confirmed to be solid (see [FK93c] and [Flo00, Flo01, FH00] for recent results).

Other substitutes for the notion of densest packing and thinnest covering have been proposed in [FKK98] and [Kup00]. A packing $\mathcal{P}$ with congruent copies of a body K is **completely saturated** if no finite subset of $\mathcal{P}$ can be replaced by a greater number of congruent copies of K that, together with the rest of $\mathcal{P}$, form a packing. Analogously, a covering $\mathcal{C}$ with congruent copies of K is **completely reduced** if no finite subset of $\mathcal{C}$ can be replaced by a smaller number of congruent copies of K that, together with the rest of $\mathcal{C}$, form a covering. While there are convex bodies that do not admit a solid packing or solid covering, it has been conjectured that each body in $\mathbb{E}^d$ or $\mathbb{H}^d$ admits a completely saturated packing and a completely reduced covering. By a body we mean a compact connected set that is the closure of its interior. The conjecture has been established for convex bodies in $\mathbb{E}^d$ [FKK98] and recently in full generality in [Bow03]. However, the following rather counterintuitive result of Bowen makes it doubtful whether complete saturatedness and complete reducedness are good substitutes for the notions of densest packing and thinnest covering in hyperbolic space. For any positive number ε there is a body K in $\mathbb{H}^d$ that admits a tiling and at the same time a completely saturated packing $\mathcal{P}$ with the following property. For every point p in $\mathbb{H}^d$, the limit

$$\lim_{\lambda \rightarrow \infty} \frac{1}{V(B_\lambda(p))} \sum_{P \in \mathcal{P}} V(P \cap (B_\lambda(p)))$$

exists, is independent of p , and is less than ε . Here $V(\cdot)$ denotes the volume in $\mathbb{H}^d$ and $B_\lambda(p)$ denotes the ball of radius λ centered at p .

In [BR03] and [BR04] Bowen and Radin proposed a probabilistic approach to analyze the efficiency of packings in hyperbolic geometry. Their approach can be sketched as follows.

Instead of studying individual arrangements, one considers the space Σ_K consisting of all saturated packings of $\mathbb{H}^d$ by congruent copies of K . A suitable metric on Σ_K is introduced that makes Σ_K compact and makes the natural action of the group $\mathcal{G}^d$ of rigid motions of $\mathbb{H}^d$ on Σ_K continuous. We consider Borel probability measures on Σ_K that are invariant under $\mathcal{G}^d$. For such an invariant measure μ the **density** $d(\mu)$ of μ is defined as $d(\mu) = \mu(A)$, where A is the set of packings $\mathcal{P} \in \Sigma_K$ for which the origin of $\mathbb{H}^d$ is contained in some member of $\mathcal{P}$. It follows easily from the invariance of μ that this definition is independent of the choice of the origin. The connection of density of measures to density of packings is established by the following theorem.

If μ is an ergodic invariant Borel probability measure on Σ_K , then—with the exception of a set of μ -measure zero—for every packing $\mathcal{P} \in \Sigma_K$, and for all $p \in \mathbb{H}^d$,

$$\lim_{\lambda \rightarrow \infty} \frac{1}{V(B_\lambda(p))} \sum_{P \in \mathcal{P}} V(P \cap (B_\lambda(p))) = d(\mu). \quad (2.4.1)$$

(A measure μ is ergodic if it cannot be expressed as the positive linear combination of two invariant measures.)

The **packing density** $\delta(K)$ of K can now be defined as the supremum of $d(\mu)$ for all ergodic invariant measures on Σ_K . A packing $\mathcal{P} \in \Sigma_K$ is **optimally dense**

if there is an ergodic invariant measure μ such that the orbit of $\mathcal{P}$ under $\mathcal{G}^d$ is dense in the support of μ and, for all $p \in \mathbb{H}^d$, (2.4.1) holds.

It is shown in [BR03] and [BR04] that there exists an ergodic invariant measure μ with $d(\mu) = \delta(K)$ and a subset of the support of μ of full μ -measure of optimally dense packings. Bowen and Radin prove several results justifying that this is a workable notion of optimal density and optimally dense packings. In particular, the definitions carry over without any change to $\mathbb{E}^d$, and there they coincide with the usual notions. The advantage of this probabilistic approach is that it neglects pathological packings such as the example by Böröczky. As for packings of balls, it is shown in [BR03] that there are only countably many radii for which there exists an optimally dense packing of balls of the given radius that is periodic.

2.5 NEIGHBORS

GLOSSARY

Neighbors: Two members of a packing whose closures intersect.

Newton number $N(K)$ of a convex body K : The maximum number of neighbors of K in all packings with congruent copies of K .

Hadwiger number $H(K)$ of a convex body K : The maximum number of neighbors of K in all packings with translates of K .

n -neighbor packing: A packing in which each member has exactly n neighbors.

n^+ -neighbor packing: A packing in which each member has at least n neighbors.

Table 2.5.1 contains the results known about Newton numbers and Hadwiger numbers (see [CS93, FK93c, Tal98a, Tal99a, Tal99b, Tal00]).

It seems that the maximum number of neighbors of one body in a lattice packing with congruent copies of K is considerably smaller than $H(K)$. While $H(B^d)$ is of exponential order of magnitude, the highest known number of neighbors in a lattice packing with B^d occurs in the Barnes-Wall lattice and is $c^{O(\log d)}$ [CS93]. Moreover, Gruber showed that, in the sense of Baire categories, most convex bodies in $\mathbb{E}^d$ have no more than $2d^2$ neighbors in their densest lattice packing. Talata [Tal98b] gave examples of convex bodies in $\mathbb{E}^d$ for which the difference between the Hadwiger number and the maximum number of neighbors in a lattice packing is 2^{d-1} . Alon [Alo97] constructed a finite ball packing in $\mathbb{E}^d$ in which each ball has $c^{O(\sqrt{d})}$ neighbors.

A problem related to the determination of the Hadwiger number concerns the maximum number $C(K)$ of mutually nonoverlapping translates of a set K that have a common point. No more than four nonoverlapping translates of a topological disk in the plane can share a point [BKK95], while for $d \geq 3$ there are starlike bodies in $\mathbb{E}^d$ for which $C(K)$ is arbitrarily large.

For a given convex body K , let $M(K)$ denote the maximum natural number with the property that an $M(K)$ -neighbor packing with finitely many congruent copies of K exists. For $n \leq M(K)$, let $L(n, K)$ denote the minimum cardinality, and, for $n > M(K)$, let $\lambda(n, K)$ denote the minimum density, of an n -neighbor packing with congruent copies of K . The quantities $M_T(K)$, $M^+(K)$, $M_T^+(K)$,

$L_T(n, K)$, $L^+(n, K)$, $L_T^+(n, K)$, $\lambda_T(n, K)$, $\lambda^+(n, K)$, and $\lambda_T^+(n, K)$ are defined analogously.

Österreicher and Linhart showed (see [FK93b]) that for a smooth convex disk K we have $L(2, K) \geq 3$, $L(3, K) \geq 6$, $L(4, K) \geq 8$, and $L(5, K) \geq 16$. All of these inequalities are sharp. We have $M_T^+(K) = 3$ for all convex disks, and there exists a 4-neighbor packing of density 0 with translates of any convex disk. There exists a 5-neighbor packing of density 0 with translates of a parallelogram, but Makai proved (see [FK93b]) that $\lambda_T^+(5, K) \geq 3/7$ and $\lambda_T^+(6, K) \geq 1/2$ for every $K \in \mathcal{K}(\mathbb{E}^2)$ that is not a parallelogram, and that $\lambda_T^+(5, K) \geq 9/14$ and $\lambda_T^+(6, K) \geq 3/4$ for every $K \in \mathcal{K}^*(\mathbb{E}^2)$ that is not a parallelogram. The case of equality characterizes triangles and affinely regular hexagons, respectively. According to a result of Chvátal (see [FK93c]), $\lambda_T^+(6, P) = 11/15$ for a parallelogram P .

A construction of Wegner (see [FK93c]) shows that $M(B^3) \geq 6$ and $L(6, B^3) \leq 240$, while Kertész [Ker94] proved that $M(B^3) \leq 8$. It is an open problem whether an n -neighbor or n^+ -neighbor packing of finitely many congruent balls exists for $n = 7$ and $n = 8$.

For 6^+ -neighbor packings with (not necessarily equal) circles, the following nice theorem of Bárány, Füredi, and Pach (see [FK93b]) holds:

In a 6^+ -neighbor packing with circles, either all circles are congruent or arbitrarily small circles occur.

2.6 SELECTED PROBLEMS ON LATTICE ARRANGEMENTS

In this section we discuss, from the vast literature on lattices, some special problems concerning arrangements of convex bodies in which the restriction to lattice arrangements is automatically imposed by the nature of the problem.

GLOSSARY

Point-trapping arrangement: An arrangement $\mathcal{A}$ such that every component of the complement of the union of the members of $\mathcal{A}$ is bounded.

Connected arrangement: An arrangement $\mathcal{A}$ such that the union of the members of $\mathcal{A}$ is connected.

j -impassable arrangement: An arrangement $\mathcal{A}$ such that every j -dimensional flat intersects the interior of a member of $\mathcal{A}$.

Obviously, a point-trapping arrangement of congruent copies of a body can be arbitrarily thin. On the other hand, Bárány, Böröczky, Makai, and Pach showed that the density of a point-trapping *lattice* arrangement of any convex body in $\mathbb{E}^d$ is greater than or equal to $1/2$. For $d \geq 3$, equality is attained only in the “checkerboard” arrangement of parallelotopes (see [FK93c]).

Bleicher (see [FK93c]) showed that the minimum density of a point-trapping lattice of unit balls in $\mathbb{E}^3$ is equal to

$$32\sqrt{(7142 + 1802\sqrt{17})^{-1}} = 0.265\dots$$

The extreme lattice is generated by three vectors of length $\frac{1}{2}\sqrt{7 + \sqrt{17}}$, any two of which make an angle of $\arccos \frac{\sqrt{17}-1}{8} = 67.021\dots^\circ$.

For a convex body K , let $c(K)$ denote the minimum density of a connected lattice arrangement of congruent copies of K . According to a theorem of Groemer (see [FK93c]),

$$\frac{1}{d!} \leq c(K) \leq \frac{\pi^{d/2}}{2^d \Gamma(1 + d/2)} \quad \text{for } K \in \mathcal{K}^d.$$

The lower bound is attained when K is a simplex or cross-polytope, and the upper bound is attained for a ball.

For a given convex body K in $\mathbb{E}^d$, let $\varrho_j(K)$ denote the infimum of the densities of all j -impassable lattice arrangements of copies of K . Obviously, $\varrho_0(K) = \vartheta_L(K)$. Let $\widehat{K} = (K - K)^*$ denote the polar body of the difference body of K . Between $\varrho_{d-1}(K)$ and $\delta_L(\widehat{K})$ Makai (see [FK93c]) found the following surprising connection:

$$\varrho_{d-1}(K)\delta_L(\widehat{K}) = 2^d V(K)V(\widehat{K}).$$

Little is known about $\varrho_j(K)$ for $0 < j < d - 1$. The value of $\varrho_1(B^3)$ has been determined recently [BW94]. We have

$$\varrho_1(B^3) = 9\pi/32 = 0.8835\dots$$

An extreme lattice is generated by the vectors $\frac{4}{3}(1, 1, 0)$, $\frac{4}{3}(0, 1, 1)$, and $\frac{4}{3}(1, 0, 1)$.

2.7 PACKING AND COVERING WITH SEQUENCES OF CONVEX BODIES

In this section we consider the following problem: Given a convex set K and a sequence $\{C_i\}$ of convex bodies in $\mathbb{E}^d$, is it possible to find rigid motions σ_i such

that $\{\sigma_i C_i\}$ covers K , or forms a packing in K ? If there are such motions σ_i , then we say that the sequence $\{C_i\}$ permits an **isometric covering** of K , or an **isometric packing** in K , respectively. If there are not only rigid motions but even translations τ_i so that $\{\tau_i C_i\}$ is a covering of K , or a packing in K , then we say that $\{C_i\}$ permits a **translative covering** of K , or a **translative packing** in K , respectively.

First we consider translative packings and coverings of cubes by sequences of boxes. By a **box** we mean an orthogonal parallelotope whose sides are parallel to the coordinate axes. We let $I^d(s)$ denote a cube of side s in $\mathbb{E}^d$.

Groemer (see [Gro85]) proved that a sequence $\{C_i\}$ of boxes whose edge lengths are at most 1 permits a translative covering of $I^d(s)$ if

$$\sum V(C_i) \geq (s+1)^d - 1,$$

and that it permits a translative packing in $I^d(s)$ if

$$\sum V(C_i) \leq (s-1)^d - \frac{s-1}{s-2}((s-1)^{d-2} - 1).$$

Slightly stronger conditions (see [Las97]) guarantee even the existence of on-line algorithms for the determination of the translations τ_i . This means that the determination of τ_i is based only on C_i and the previously fixed sets $\tau_i C_i$.

We recall (see [Las97]) that to any convex body K in $\mathbb{E}^d$ there exist two boxes, say Q_1 and Q_2 , with $V(Q_1) \geq 2d^{-d}V(K)$ and $V(Q_2) \leq d!V(K)$, such that $Q_1 \subset K \subset Q_2$. It follows immediately that if $\{C_i\}$ is a sequence of convex bodies in $\mathbb{E}^d$ whose diameters are at most 1 and

$$\sum V(C_i) \geq \frac{1}{2}d^d((s+1)^d - 1),$$

then $\{C_i\}$ permits an isometric covering of $I^d(s)$; and that if

$$\sum V(C_i) \leq \frac{1}{d!} \left((s-1)^d - \frac{s-1}{s-2}((s-1)^{d-2} - 1) \right),$$

then it permits an isometric packing in $I^d(s)$.

The sequence $\{C_i\}$ of convex bodies is **bounded** if the set of the diameters of the bodies is bounded. As further consequences of the results above we mention the following. If $\{C_i\}$ is a bounded sequence of convex bodies such that $\sum V(C_i) = \infty$, then it permits an isometric covering of $\mathbb{E}^d$ with density $\frac{1}{2}d^d$ and an isometric packing in $\mathbb{E}^d$ with density $\frac{1}{d!}$. Moreover, if all the sets C_i are boxes, then $\{C_i\}$ permits a translative covering of $\mathbb{E}^d$ and a translative packing in $\mathbb{E}^d$ with density 1.

In $\mathbb{E}^2$, any bounded sequence $\{C_i\}$ of convex disks with $\sum a(C_i) = \infty$ permits even a translative packing and covering with density $\frac{1}{2}$ and 2, respectively. It is an open problem whether for $d > 2$ any bounded sequence $\{C_i\}$ of convex bodies in $\mathbb{E}^d$ with $\sum V(C_i) = \infty$ permits a translative covering. If the sequence $\{C_i\}$ is unbounded, then the condition $\sum V(C_i) = \infty$ no longer suffices for $\{C_i\}$ to permit even an isometric covering of the space. For example, if C_i is the rectangle of side lengths i and $\frac{1}{i^2}$, then $\sum a(C_i) = \infty$ but $\{C_i\}$ does not permit an isometric covering of $\mathbb{E}^2$. There is a simple reason for this, which brings us to one of the most interesting topics of this subject, namely Tarski's plank problem.

A *plank* is a region between two parallel hyperplanes. Tarski conjectured that if a convex body of minimum width w is covered by a collection of planks in $\mathbb{E}^d$, then the sum of the widths of the planks is at least w . Tarski's conjecture was first proved by Bang. Bang's theorem immediately implies that the sequence of rectangles above does not permit an isometric covering of $\mathbb{E}^2$, not even of $(\frac{\pi^2}{12} + \epsilon)B^2$.

There is a nice account of the history of Tarski's plank problem and its generalizations in [Gro85]. In his paper, Bang asked whether his theorem can be generalized so that the width of each plank is measured relative to the width of the convex body being covered, in the direction normal to the plank. Bang's problem has been solved for centrally symmetric bodies by Ball [Bal91]. This case has a particularly appealing formulation in terms of normed spaces:

If the unit ball in a Banach space is covered by a countable collection of planks, then the total width of the planks is at least 2.

2.8 SOURCES AND RELATED MATERIAL

SURVEYS

The monographs [Fej72, Rog64, Zon99] are devoted solely to packing and covering; also the books [CS93, CFG91, EGH89, Fej64, GL87, PA95, Zon96] contain results relevant to this chapter. Additional material and bibliography can be found in the following surveys: [Bar69, Fej83, Fej84, Fej99, FK93b, FK93c, FK01, Few67, Flo87, Flo02, GW93, Gro85, Gru79, MP93, SA75].

3 TILINGS

Doris Schattschneider and Marjorie Senechal

INTRODUCTION

Tilings of surfaces and packings of space have been of interest to artisans and manufacturers throughout history; they are a means of artistic expression and lend economy and strength to modular constructions. Today scientists and mathematicians study tilings because they pose interesting mathematical questions and provide mathematical models for such diverse structures as the molecular anatomy of crystals, cell packings of viruses, n -dimensional algebraic codes, and “nearest neighbor” regions for a set of discrete points. The basic questions are: What bodies can tile space? In what ways do they tile? However, in this generality such questions are intractable. To study tiles and tilings, we must impose constraints.

Even with constraints the subject is unmanageably large. In this chapter we restrict ourselves, for the most part, to tilings of unbounded spaces. In the next section we present some general results that are fundamental to the subject as a whole. Section 3.2 addresses tilings with congruent tiles. In Section 3.3 we discuss the classical subject of periodic tilings, which continues to be enriched with new results. Next, we briefly describe the newer theory of nonperiodic and aperiodic tilings, both of which are discussed in more detail in [Chapter 62](#). We conclude with a very brief description of some kinds of tilings not considered here.

3.1 GENERAL CONSIDERATIONS

In this section we define terms that will be used throughout the chapter and state some basic results. Taken together, these results state that although there is no algorithm for deciding which bodies are tiles, there are criteria for deciding the question in certain cases. We can obtain some quantitative information about the tiling in particularly well-behaved cases.

Unless otherwise stated, we assume that S is an n -dimensional space, either Euclidean ($\mathbb{E}^n$) or hyperbolic. We also assume that the tiles are bounded and the tilings are locally finite (see the Glossary below). Throughout this chapter, n is the dimension of the space in which we are working.

GLOSSARY

Body: A bounded region (of S) that is the closure of its (nonempty) interior.

Tiling (of S): A decomposition of S into a countable number of n -dimensional bodies whose interiors are pairwise disjoint. In this context, the bodies are also called n -cells and are the tiles of the tiling (see below). Synonyms: *tessellation*, *parquetry* (when $n = 2$), *honeycomb* (for $n \geq 2$).

Tile: A body that is an n -cell of one or more tilings of S . To say that a body **tiles** a region $R \subseteq S$ means that R can be covered exactly by copies of the body without gaps or overlaps.

Locally finite tiling: Every n -ball of finite radius in S meets only finitely many tiles of the tiling.

Prototile set (for a tiling $\mathcal{T}$ of S): A minimal subset of tiles in $\mathcal{T}$ such that each tile in the tiling $\mathcal{T}$ is the congruent image of one of those in the prototile set. The tiles in the set are called prototiles and the prototile set is said to admit $\mathcal{T}$.

k -face (of a tiling): An intersection of at least $n - k + 1$ tiles of the tiling that is not contained in a j -face for $j < k$. (The 0-faces are the **vertices** and 1-faces the **edges**; the $(n-1)$ -faces are simply called the **faces** of the tiling.)

Patch (in a tiling): A set of tiles whose union is homeomorphic to an n -ball. See Figure 3.1.1. A spherical patch $P(r, s)$ is the set of tiles whose intersection with the ball of radius r centered at s is nonempty, together with any additional tiles needed to complete the patch (that is, to make it homeomorphic to an n -ball).

FIGURE 3.1.1
Three patches in a tiling of the plane by squares.

Normal tiling: A tiling in which (i) each prototile is homeomorphic to an n -ball, and (ii) the prototiles are uniformly bounded (there exist $r > 0$ and $R > 0$ such that each prototile contains a ball of radius r and is contained in a ball of radius R). It is technically convenient to include a third condition: (iii) the intersection of every pair of tiles is a connected set. (A normal tiling is necessarily locally finite.)

Face-to-face tiling (by polytopes): A tiling in which the faces of the tiling are also the $(n-1)$ -dimensional faces of the polytopes. (A face-to-face tiling by convex polytopes is also k -face-to- k -face for $0 \leq k \leq n-1$.) In dimension 2, this is an **edge-to-edge** tiling by polygons, and in dimension 3, a face-to-face tiling by polyhedra.

Dual tiling: Two tilings $\mathcal{T}$ and $\mathcal{T}^*$ are dual if there is an incidence-reversing bijection between the k -faces of $\mathcal{T}$ and the $(n-k)$ -faces of $\mathcal{T}^*$ (see Figure 3.1.2).

Voronoi (Dirichlet) tiling: A tiling whose tiles are the Voronoi cells of a discrete set Λ of points in S . The Voronoi cell of a point $p \in \Lambda$ is the set of all points in S that are at least as close to p as to any other point in Λ (see Chapter 23).

Delaunay (or Delone) tiling: A face-to-face tiling by convex circumscribable polytopes (i.e., the vertices of each polytope lie on a sphere).

FIGURE 3.1.2

A Voronoi tiling (solid lines) and its Delaunay dual (dashed lines).

Isometry: A distance-preserving self-map of S .

Symmetry group (of a tiling): The set of isometries of S that map the tiling to itself.

MAIN RESULTS

1. **The Undecidability Theorem.** There is no algorithm for deciding whether or not an arbitrary body or set of bodies admits a tiling of S [Ber66].
2. **The Extension Theorem (for $\mathbb{E}^n$).** Let A be any finite set of bodies, each homeomorphic to a closed n -ball. If A tiles regions that contain arbitrarily large n -balls, then A admits a tiling of $\mathbb{E}^n$. (These regions need not be nested, nor need any of the tilings of the regions be extendable!) The proof for $n = 2$ in [GS87] extends to $\mathbb{E}^n$ with minor changes.
3. **The Normality Lemma (for $\mathbb{E}^n$).** In a normal tiling, the ratio of the number of tiles that meet the boundary of a spherical patch to the number of tiles in the patch tends to zero as the radius of the patch tends to infinity. In fact, a stronger statement can be made: For $s \in S$ let $t(r, s)$ be the number of tiles in the spherical patch $P(r, s)$. Then, in a normal tiling, for every $x > 0$,

$$\lim_{r \rightarrow \infty} \frac{t(r+x, s) - t(r, s)}{t(r, s)} = 0.$$

The proof for $n = 2$ in [GS87] extends to $\mathbb{E}^n$ with minor changes.

4. **Euler's Theorem for tilings of $\mathbb{E}^2$.** Let $\mathcal{T}$ be a normal tiling of $\mathbb{E}^2$, and let $t(r, s)$, $e(r, s)$, and $v(r, s)$ be the numbers of tiles, edges, and vertices, respectively, in the circular patch $P(r, s)$. Then if one of the limits $e(\mathcal{T}) = \lim_{r \rightarrow \infty} e(r, s)/t(r, s)$ or $v(\mathcal{T}) = \lim_{r \rightarrow \infty} v(r, s)/t(r, s)$ exists, so does the other, and $v(\mathcal{T}) - e(\mathcal{T}) + 1 = 0$. Like Euler's Theorem for Planar Maps, on which the proof of this theorem is based, this result can be extended in various ways [GS87].
5. **Voronoi Dual.** Every Voronoi tiling has a Delaunay dual and conversely (see Figure 3.1.2) [Vor09].

3.2 TILINGS BY ONE TILE

To say that a body tiles $\mathbb{E}^n$ usually means that there is a tiling all of whose tiles are copies of this body. The artist M.C. Escher has demonstrated how intricate such tiles can be even when $n = 2$. But in higher dimensions the simplest tiles—for example, cubes—can produce surprises, as the recent counterexample to Keller's conjecture attests (see below).

GLOSSARY

Monohedral tiling: A tiling with a single prototile.

r -morphoric tile: A prototile that admits exactly r distinct monohedral tilings.

Figure 3.2.1 shows a 5-morphoric tile and all its tilings, and Figure 3.2.3 shows a 1-morphoric tile and its tiling.

FIGURE 3.2.1
A pentamorphic tile.

k -rep tile: A body for which k copies can be assembled into a larger, similar body. (Or, equivalently, a body that can be partitioned into k congruent bodies, each similar to the original.) More formally, a k -rep tile is a closed set A_1 in S with nonempty interior such that there are sets $A_2, \dots, A_k$ congruent to A_1 that satisfy

$$\text{Int } A_i \cap \text{Int } A_j = \emptyset$$

for all $i \neq j$ and $A_1 \cup \dots \cup A_k = g(A_1)$, where g is a similarity mapping. (Figure 3.2.2 shows a 3-dimensional chair rep tile and the second-level chair. An n -dimensional chair rep tile can be formed in a similar manner.)

Transitive action: A group G is said to act transitively on a set $\{A_1, A_2, \dots\}$ if the set is an orbit for G . (That is, for every pair A_i, A_j of elements of the set, there is a $g_{ij} \in G$ such that $g_{ij}A_i = A_j$.)

Regular system of points: A discrete set of points on which an infinite group of isometries acts transitively.

Isohedral (tiling): A tiling whose symmetry group acts transitively on its tiles.

Anisohedral tile: A prototile that admits monohedral tilings but no isohedral tilings. In Figure 3.2.3, the prototile admits a unique nonisohedral tiling; the shaded tiles are each surrounded differently, from which it follows that no isom-

FIGURE 3.2.2

A 3-dimensional chair rep tile and a second-level chair in which seven copies surround the first.

etry can map one to the other (and the tiling to itself). This tiling is periodic, however (see [Section 3.3](#)).

FIGURE 3.2.3

An anisohedral tile (due to R. Penrose) and its unique tiling in which tiles are surrounded in two different ways.

Corona (of a tile P in a tiling $\mathcal{T}$): Define $C^0(P) = P$. Then $C^k(P)$, the k th corona of P , is the set of all tiles $Q \in T$ for which there exists a path of tiles $P = P_0, P_1, \dots, P_m = Q$ with $m \leq k$ in which $P_i \cap P_{i+1} \neq \emptyset$, $i = 0, 1, \dots, m-1$.

Lattice: The group of integral linear combinations of n linearly independent vectors in S . A point orbit of a lattice, often called a **point lattice**, is a particular case of a regular system of points.

Translation tiling: A monohedral tiling of S in which every tile is a translate of a fixed prototile. See [Figure 3.2.4](#).

Lattice tiling: A monohedral tiling on whose tiles a lattice of translation vectors acts transitively. Figure 3.2.4 is not a lattice tiling since it is invariant by multiples of just one vector.

n -parallelotope: A convex n -polytope that tiles $\mathbb{E}^n$ by translation.

FIGURE 3.2.4

A translation non-lattice tiling.

Belt (of an n -parallelotope): A maximal subset of parallel $(n-2)$ -faces of a parallelotope in $\mathbb{E}^n$. The number of $(n-2)$ -faces in a belt is its length.

Center of symmetry (for a set A in $\mathbb{E}^n$): A point $a \in A$ such that A is invariant under the mapping $x \rightarrow 2a - x$; the mapping is called **central inversion** and an object that has a center of symmetry is said to be **centrosymmetric**.

Stereohedron: A convex polytope that is the prototile of an isohedral tiling. A Voronoi cell of a regular system of points is a stereohedron.

Linear expansive map: A linear transformation all of whose eigenvalues have modulus greater than one.

MAIN RESULTS

1. **The Local Theorem.** Let $\mathcal{T}$ be a monohedral tiling of S , and for $P \in \mathcal{T}$, let $S_i(P)$ be the subgroup of the symmetry group of P that leaves invariant $C^i(P)$, the i th corona of P . $\mathcal{T}$ is isohedral if and only if there exists an integer $k > 0$ for which the following two conditions hold: (a) for all $P \in \mathcal{T}$, $S_{k-1}(P) = S_k(P)$ and (b) For every pair of tiles P, P' in $\mathcal{T}$, there exists an isometry γ such that $\gamma(P) = P'$ and $\gamma(C^k(P)) = C^k(P')$. In particular, if P is asymmetric, then $\mathcal{T}$ is isohedral if and only if condition (b) holds for $k = 1$ [DS98].
2. A convex polytope is a parallelotope if and only if it is centrosymmetric, its faces are centrosymmetric, and its belts have lengths four or six. First proved by Venkov, this theorem was rediscovered independently by McMullen [Ven54, McM80].
3. The number $|F|$ of faces of a convex parallelotope in $\mathbb{E}^n$ satisfies Minkowski's inequality, $2n \leq |F| \leq 2(2^n - 1)$. Both upper and lower bounds are realized in every dimension [Min97].
4. The number of faces of an n -dimensional stereohedron in $\mathbb{E}^n$ is bounded. In fact, if a is the number of translation classes of the stereohedron in an isohedral tiling, then the number of faces is at most the Delaunay bound $2^n(1 + a) - 2$ [Del61].
5. Using a classification system that takes into account the symmetry groups of the tilings and their tiles, the combinatorial structure of the tiling, and the ways in which the tiles are related to adjacent tiles, Grünbaum and Shephard proved that there are 81 classes of isohedral tilings of $\mathbb{E}^2$, 93 classes if the tiles are **marked** (that is, they have decorative markings to express symmetry in

addition to the tile shape) [GS77]. There is an infinite number of classes of isohedral tilings of $\mathbb{E}^n$, $n > 2$.

6. Anisohedral tiles exist in $\mathbb{E}^n$ for every $n \geq 2$ [GS80]. (The first example, given for $n = 3$ by Reinhardt [Rei28], was the solution to part of Hilbert's 18th problem.) H. Heesch gave the first example for $n = 2$ [Hee35] and R. Kershner the first convex examples [Ker68].
7. Every n -parallelotope admits a lattice tiling. However, for $n \geq 3$, there are nonconvex tiles that tile by translation but do not admit lattice tilings [SS94].
8. A lattice tiling of $\mathbb{E}^n$ by unit cubes must have a pair of cubes sharing a whole face [Min07, Haj42]. However, a famous conjecture of Keller, which stated that for every n , any tiling of $\mathbb{E}^n$ by congruent cubes must contain at least one pair of cubes sharing a whole face, is false: for $n \geq 10$, there are translation tilings by unit cubes in which no two cubes share a whole face [LS92].
9. Every linear expansive map that transforms the lattice $\mathbb{Z}^n$ of integer vectors into itself defines a family of k -rep tiles; these tiles, which usually have fractal boundaries, admit lattice tilings [Ban91].

OPEN PROBLEMS

1. Which convex n -polytopes in $\mathbb{E}^n$ are prototiles for monohedral tilings of $\mathbb{E}^n$? This is unsolved for all $n \geq 2$ (see [GS87] for the case $n = 2$; the list of convex pentagons that tile has not been proved complete). For higher dimensions, little is known; it is not even known which tetrahedra tile $\mathbb{E}^3$ [GS80, Sen81].
2. **Heesch's Problem.** Is there an integer k_n , depending only on the dimension n of the space S , such that if a body A can be completely surrounded k_n times by tiles congruent to A , then A is a prototile for a monohedral tiling of S ? (A is completely surrounded once if A , together with congruent copies that have nonempty intersection with A , tile a patch containing A in its interior.) When $S = \mathbb{E}^2$, $k_2 > 5$. The body shown in Figure 3.2.5 can be completely surrounded three times but not four; William Rex Marshall and, independently, Casey Mann, found 4-corona tiles, and Mann 5-corona tiles [Man01]. This problem is unsolved for all n .
3. **Keller's conjecture** is true for $n \leq 6$ and false for $n \geq 10$ (see Result 8 above). The cases $n = 7, 8$, and 9 are still open.
4. Do r -morphic tiles exist for every positive integer r ? Fontaine and Martin have shown the answer is yes in $\mathbb{E}^2$ for $r \leq 10$ [FM84].
5. Find a good upper bound for the number of faces of an n -dimensional stereohedron. Delaunay's bound, stated above, is evidently much too high; for example, it gives 390 as the bound in $\mathbb{E}^3$, while the maximal known number of faces of a three-dimensional stereohedron (found by P. Engel [Eng81]) is 38.
6. For monohedral (face-to-face) tilings by convex polytopes there is an integer k_n , depending only on the dimension n of S , that is an upper bound for the constant k in the Local Theorem [DS98]. Find the value of this k_n . For the

FIGURE 3.2.5

Ammann's 3-corona tile cannot be surrounded by a fourth corona. 4-corona and 5-corona tiles also exist.

Euclidean plane $\mathbb{E}^2$ it is known that $k_2 = 1$ (convexity of the tiles is not necessary) [SD98], but for the hyperbolic plane, $k_2 \geq 2$ [Mak92]. For $\mathbb{E}^3$, it is known that $2 \leq k_3 \leq 5$.

3.3 PERIODIC TILINGS

Periodic tilings have been studied intensely, in part because their applications range from ornamental design to crystallography, and in part because many techniques (algebraic, geometric, and combinatorial) are available for studying them.

GLOSSARY

Periodic tiling of $\mathbb{E}^n$: A tiling, not necessarily monohedral, whose symmetry group contains an n -dimensional lattice. This definition can be adapted to include “subperiodic” tilings (those whose symmetry groups contain $1 \leq k < n$ linearly independent vectors) and tilings of other spaces (for example, cylinders). Tilings in Figures 3.2.1, 3.2.3, 3.3.1, and 3.3.3 are periodic.

Fundamental domain (generating region) for a periodic tiling: A minimal subset of S whose orbit under the symmetry group of the tiling is the whole tiling. A fundamental domain may be a tile (Figure 3.2.1), a subset of a single tile (Figure 3.3.1), or a subset of tiles (two shaded tiles in Figure 3.2.3).

Orbifold (of a tiling of S): The manifold obtained by identifying points of S that are in the same orbit under the action of the symmetry group of the tiling.

Free tiling: A tiling whose symmetry group acts freely and transitively on the tiles.

k -isohedral (tiling): A tiling whose tiles belong to k transitivity classes under the action of its symmetry group. Isohedral means 1-isohedral (Figures 3.2.1, 3.3.1, and 3.3.3). The tiling in Figure 3.2.3 is 2-isohedral.

Equitransitive (tiling by polytopes): A tiling in which each combinatorial class of tiles forms a single transitivity class under the action of the symmetry group of the tiling.

k-isogonal (tiling): A tiling whose vertices belong to k transitivity classes under the action of its symmetry group. Isogonal means 1-isogonal.

k-uniform (tiling of a 2-dimensional surface): A k -isogonal tiling by regular polygons.

Uniform (tiling for $n > 2$): An isogonal tiling with congruent edges and uniform faces.

Flag of a tiling (of S): An ordered $(n+1)$ -tuple $(X_0, X_1, \dots, X_n)$, with X_n a tile and X_k a k -face for $0 \leq k \leq n-1$, in which $X_{i-1} \subset X_i$ for $i = 1, \dots, n$.

Regular tiling (of S): A tiling $\mathcal{T}$ whose symmetry group is transitive on the flags of $\mathcal{T}$. (For $n > 2$, these are also called regular honeycombs.) See Figure 3.3.3.

k-colored tiling: A tiling in which each tile has a single color, and k different colors are used. Unlike the case of map colorings, in a colored tiling adjacent tiles may have the same color.

Perfectly k-colored tiling: A k -colored tiling for which each element of the symmetry group G of the uncolored tiling effects a permutation of the colors. The ordered pair (G, Π) , where Π is the corresponding permutation group, is called a k -color symmetry group.

CLASSIFICATION OF PERIODIC TILINGS

The mathematical study of tilings (like most mathematical investigations) has been accompanied by the development and use of a variety of notations for classification of different “types” of tilings and tiles. Far from being merely names by which to distinguish types, these notations tell us the investigators’ point of view and the questions they ask. Notation may tell us the global symmetries of the tiling, or how each tile is surrounded, or the topology of its orbifold. Notation makes possible the computer implementation of investigations of combinatorial questions about tilings.

Periodic tilings are classified by symmetry groups and, sometimes, by their skeletons (of vertices, edges, ..., $(n-1)$ -faces). The groups are known as ***crystallographic groups***; up to isomorphism, there are 17 in $\mathbb{E}^2$ and 219 in $\mathbb{E}^3$. For $\mathbb{E}^2$ and $\mathbb{E}^3$, the most common notation for the groups has been that of the International Union of Crystallography (IUCr) [Hah83]. This is cross-referenced to earlier notations in [Sch78]. Recently developed notations include Delaney-Dress symbols [Dre87] and orbifold notation for $n = 2$ [Con92, CH02] and for $n = 3$ [CDHT01].

GLOSSARY

International symbol (for periodic tilings of $\mathbb{E}^2$ and $\mathbb{E}^3$): Encodes lattice type and particular symmetries of the tiling. In Figure 3.3.1, the lattice unit diagram at the right encodes the symmetries of the tiling and the IUCr symbol p31m indicates that the highest-order rotation symmetry in the tiling is 3-fold, that there is no mirror normal to the edge of the lattice unit, and that there is a mirror at 60° to the edge of the lattice unit. These symbols are augmented to denote symmetry groups of perfectly 2-colored tilings.

Delaney-Dress symbol (for tilings of Euclidean, hyperbolic, or spherical space of any dimension): Associates an edge-colored and vertex-labeled

FIGURE 3.3.1
An isohedral tiling with standard IUCr lattice unit shaded; a half-leaf is a fundamental domain. The classification symbols are for the symmetry group of the tiling.

graph derived from a **chamber system** (a formal barycentric subdivision) of the tiling. In Figure 3.3.2, the nodes of the graph represent distinct triangles A, B, C, D in the chamber system, and colored edges (dashed, thick, or thin) indicate their adjacency relations. Numbers on the nodes of the graph show the degree of the tile that contains that triangle and the degree of the vertex of the tiling that is also a vertex of that triangle.

FIGURE 3.3.2
A chamber system of the tiling in Figure 3.3.1 determines the graph that is its Delaney-Dress symbol.

Orbifold notation (for symmetry groups of tilings of 2-dimensional surfaces of constant curvature): Encodes properties of the orbifold induced by the symmetry group of a periodic tiling of the Euclidean plane or hyperbolic plane, or a finite tiling of the surface of a sphere; introduced by Conway. In Figure 3.3.1, the first 3 in the orbifold symbol 3^*3 for the symmetry group of the tiling indicates there is a 3-fold rotation center (gyration point) that becomes a cone point in the orbifold, while ^{*3} indicates that the boundary of the orbifold is a mirror with a corner where three mirrors intersect.

See Table 3.3.1 for the IUCr and orbifold notations for $\mathbb{E}^2$.

TABLE 3.3.1 IUCr and orbifold notations for the 17 symmetry groups of periodic tilings of $\mathbb{E}^2$.

IUCr	ORBIFOLD	IUCr	ORBIFOLD
p1	o or o1	p3	333
pg	$\times \times$ or $1 \times \times$	p31m	3^*3
cm	$^* \times$ or $1^* \times$	p3m1	^{*333}
pm	$**$ or 1^{**}	p4	442
p2	2222	p4g	4^*2
pgg	$22 \times$	p4m	^{*442}
pmg	22^*	p6	632
cmm	2^*22	p6m	^{*632}
pmm	^{*2222}		

Isohedral tilings of $\mathbb{E}^2$ fall into 11 combinatorial classes, typified by the Laves nets (Figure 3.3.3). The Laves net for the tiling in Figure 3.3.1 is [3.6.3.6]; this gives the vertex degree sequence for each tile. In an isohedral tiling, every tile is surrounded in the same way. Grünbaum and Shephard provide an *incidence symbol* for each isohedral type by labeling and orienting the edges of each tile [GS79]. Figure 3.3.4 gives the incidence symbol for the tiling in Figure 3.3.1. The tile symbol $a^+a^-b^+b^-$ records the cycle of edges of a tile and their orientations with respect to the (arrowed) first edge (+ indicates the same, – indicates opposite orientation). The adjacency symbol b^-a^- records for each different letter edge of a single tile, beginning with the first, the edge it abuts in the adjacent tile and their relative orientations (now – indicates same, + opposite). These symbols can be augmented

FIGURE 3.3.3

The 11 Laves nets. The three regular tilings of $\mathbb{E}^2$ are at the top of the illustration.

to adjacency symbols to denote k -color symmetry groups. Earlier, Heesch devised signatures for the 28 types of tiles that could be fundamental domains of isohedral tilings without reflection symmetry [HK63]; this signature system was extended in [BW94].

FIGURE 3.3.4
Labeling and orienting the edges of the isohedral tiling in Figure 3.3.1 determines its Grünbaum-Shephard incidence symbol.

MAIN RESULTS

1. If a finite prototile set of polygons admits an edge-to-edge tiling of the plane that has translational symmetry, then the prototile set also admits a periodic tiling [GS87].
2. The number of symmetry groups of periodic tilings in $\mathbb{E}^n$ is finite (this is a famous theorem of Bieberbach [Bie10] that partially solved Hilbert's 18th problem: see also Chapter 62); the number of symmetry groups of corresponding tilings in hyperbolic n -space, for $n = 2$ and $n = 3$, is infinite.
3. Every k -isohedral tiling of the Euclidean plane, hyperbolic plane, or sphere can be obtained from a $(k-1)$ -isohedral tiling by a process of *splitting* (splitting an asymmetric prototile) and *gluing* (amalgamating two or more equivalent asymmetric tiles adjacent in the tiling into one new tile) [Hus93]; there are 1270 classes of normal 2-isohedral tilings and 48,231 classes of normal 3-isohedral tilings of $\mathbb{E}^2$.
4. Classifying isogonal tilings in a manner analogous to isohedral ones, Grünbaum and Shephard have shown [GS78a] that there are 91 classes of normal isogonal tilings of $\mathbb{E}^2$ (93 classes if the tiles are marked). Similarly [GS78b], there are 26 classes of normal tilings of $\mathbb{E}^2$ for which the symmetry group acts transitively on the edges (30 if the tiles are marked); these tilings are called *isotoxal*. See also [GS87].
5. There are 88 combinatorial classes of periodic tilings of $\mathbb{E}^3$ for which the symmetry group acts transitively on the faces of the tiling [DHM93].
6. For every k , the number of k -uniform tilings of $\mathbb{E}^2$ is finite. There are 11 uniform tilings of $\mathbb{E}^2$ (also called *Archimedean*, or *semiregular*), of which 3 are regular. The Laves nets in Figure 3.3.3 are duals of these 11 uniform tilings [GS87, Sections 2.1, 2.2]. There are 28 uniform tilings of $\mathbb{E}^3$ [Grü94] and 20

- 2-uniform tilings of $\mathbb{E}^2$ [Krö69]; see also [GS87, Section 2.2]. In the hyperbolic plane, uniform tilings with vertex valence 3 and 4 have been classified [GS79].
7. In any equitransitive tiling of $\mathbb{E}^2$ by convex polygons, the maximum number of edges of any tile is 66 [DGS87].
 8. There are finitely many regular tilings of $\mathbb{E}^n$ (three for $n = 2$, one for $n = 3$, three for $n = 4$, and one for each $n > 4$) [Cox63]. There are infinitely many normal regular tilings of the hyperbolic plane, four of hyperbolic 3-space, five of hyperbolic 4-space, and none of hyperbolic n -space if $n > 4$ [Sch83, Cox54].
 9. If two orbifold symbols for a tiling of the Euclidean or hyperbolic plane look exactly the same except for the numerical values of their digits, which may differ by a permutation of the natural numbers (such as *632 and *532), then the number of k -isohedral tilings for each of these orbifold types is the same [BH96].
 10. There is a one-to-one correspondence between perfect k -colorings of a free tiling and the subgroups of index k of its symmetry group. See [Sen79].

OPEN PROBLEMS

1. Does every convex pentagon that tiles $\mathbb{E}^2$ admit a k -isohedral tiling for some $k \geq 1$, and if so, is there an upper bound on k ? (All pentagons known to tile the plane admit k -isohedral tilings, with $k \leq 3$.)
2. Classify uniform tilings of the hyperbolic plane for the cases of vertex valences greater than 4.
3. Enumerate the uniform tilings of $\mathbb{E}^n$ for $n > 3$. (Some uniform tilings for $\mathbb{E}^n$, $n > 3$, are discussed in [Joh04].)
4. Delaney-Dress symbols and orbifold notations have made progress possible on the classification of k -isohedral tilings in all three 2-dimensional spaces of constant curvature; extend this work to higher-dimensional spaces.

3.4 NONPERIODIC AND APERIODIC TILINGS

Nonperiodic tilings are found everywhere in nature, from cracked glazes to biological tissues to real crystals. In a remarkable number of cases, such tilings exhibit strong regularities. For example, many such tilings have simplicial duals. Others repeat on increasingly larger scales. An even larger class of tilings are those now called repetitive, in which every bounded configuration appearing anywhere in the tiling is repeated infinitely many times throughout it (see below). Aperiodic tilings—those whose prototile sets admit only nonperiodic tilings—are particularly interesting. They were first introduced to prove the Undecidability Theorem (Section 3.1). Later, after Penrose found pairs of aperiodic prototiles (see [Figure 3.4.1](#)), they became popular in recreational mathematical circles. Their deep mathematical

FIGURE 3.4.1

Portions of Penrose tilings of the plane
 (a) by rhombs; (b) by kites and darts.
 The matching rules that force nonperiodicity are not shown (see Chapter 62).

properties were first studied by Penrose, Conway, de Bruijn, and others. After the discovery of “quasicrystals” in 1984, aperiodic tilings became the focus of intense research. The basic ideas of this rapidly developing subject are only introduced here; they are discussed in more detail in Chapter 62.

GLOSSARY

Nonperiodic tiling: A tiling with no translation symmetry.

Hierarchical tiling: A tiling whose tiles can be composed into larger tiles, called *level-one* tiles, whose level-one tiles can be composed into level-two tiles, and so on *ad infinitum*. In some cases it is necessary to partition the original tiles before composition.

Self-similar tiling: A hierarchical tiling for which the larger tiles are copies of the prototiles (all enlarged by a constant expansion factor λ). *k*-rep tiles are the special case when there is just one prototile (Figure 3.2.2).

Uniquely hierarchical tiling: A tiling whose *j*-level tiles can be composed into (*j*+1)-level tiles in only one way ($j = 0, 1, \dots$).

Composition rule (for a hierarchical tiling): The equations $T'_i = m_{i1}T_1 \cup \dots \cup m_{ik}T_k$, $i = 1, \dots, k$, that describe the numbers m_{ij} of each prototile T_j in the next higher level prototile T'_i . These equations define a linear map whose matrix has *i, j* entry m_{ij} .

Relatively dense configuration: A configuration *C* of tiles in a tiling for which there exists a radius r_C such that every ball of radius r_C in the tiling contains a copy of *C*.

Repetitive: A tiling in which every bounded configuration of tiles is relatively dense in the tiling.

Local isomorphism class: A family of tilings such that every bounded configuration of tiles that appears in any of them appears in all of the others. (For example, the uncountably many Penrose tilings with the same prototile set form a single local isomorphism class.)

Projected tiling: A tiling obtained by the canonical projection method (see Chapter 62).

Aperiodic prototile set: A prototile set that admits only nonperiodic tilings; see Figure 3.4.1.

Aperiodic tiling: A tiling with an aperiodic prototile set.

Matching rules: A list of rules for fitting together the prototiles of a given prototile set.

Mutually locally derivable tilings: Two tilings are mutually locally derivable if the tiles in either tiling can, through a process of decomposition into smaller tiles, or regrouping with adjacent tiles, or a combination of both processes, form the tiles of the other (see Figure 3.4.2).

Complex Perron number: An algebraic integer that is strictly larger in modulus than its Galois conjugates (except for its complex conjugate).

FIGURE 3.4.2

The Penrose tilings by kites and darts and by rhombs are mutually locally derivable.

MAIN RESULTS

1. Self-similar and projected tilings are repetitive (see [Sen95]).
2. Uniquely hierarchical tilings are nonperiodic (the proof given in [GS87] for $n = 2$ extends immediately to all n). Conversely, nonperiodic self-similar tilings have the unique composition property [Sol98].
3. For each complex Perron number λ there is a self-similar tiling with expansion λ [Ken95].
4. “Irrational” projected tilings are nonperiodic (see [Chapter 62](#)).
5. The prototile sets of certain irrational projected tilings can be equipped with matching rules so that all tilings admitted by the prototile set belong to a single local isomorphism class (see [Chapter 62](#)).
6. Mutual local derivability is an equivalence relation on the set of all tilings. The existence or nonexistence of hierarchical structure and matching rules is a class property [KSB93].
7. Certain convex *biprisms* admit only nonperiodic monohedral tilings of $\mathbb{E}^3$ if no mirror-image copies of the tiles are allowed [Sch88]; see [Figure 3.4.3](#). These tiles can be altered to produce nonconvex aperiodic prototiles for $\mathbb{E}^3$ [Dan95].

8. The prototile set of every uniquely hierarchical tiling can be equipped with matching rules that force the hierarchical structure [Goo98].

FIGURE 3.4.3

Conway's biprism consists of two prisms fused at a common rhombus face. Small angle of rhombus is $\arccos(3/4) \approx 41.4^\circ$; diagonal of prism ≈ 2.87 . When assembled, the vertices of the rhombus that is a common face of the two prisms are the poles of two 2-fold rotation axes.

OPEN PROBLEMS

Does there exist a prototile in $\mathbb{E}^2$ that is aperiodic? Does there exist a convex prototile for $\mathbb{E}^3$ that is aperiodic without restriction?

3.5 OTHER TILINGS

There is a vast literature on tilings (or dissections) of bounded regions (such as rectangles and boxes, polygons, and polytopes) by tiles to satisfy particular conditions. This and much of the recreational literature focuses on tilings by tiles of a particular type, such as tilings by rectangles, tilings by clusters of n -cubes (polyominoes—see Chapter 15—and polycubes) or n -simplices (polyiamonds in $\mathbb{E}^2$), or tilings by recognizable animate figures. In the search for new ways to produce tiles and tilings, both mathematicians (such as P.A. MacMahon [Mac21]) and amateurs (such as M.C. Escher [Sch90]) have contributed to the subject. Recently the search for new shapes that tile a given bounded region S has produced knotted tiles, toroidal tiles, and twisted tiles. Kuperberg and Adams have shown that for any given knot K ,

there is a monohedral tiling of $\mathbb{E}^3$ (or of hyperbolic 3-space, or of spherical 3-space) whose prototile is a solid torus that is knotted as K . Also, Adams has shown that, given any polyhedral submanifold M with one boundary component in $\mathbb{E}^n$, a monohedral tiling of $\mathbb{E}^n$ can be constructed whose prototile has the same topological type as M [Ada95].

Other directions of research seek to broaden the definition of prototile set: in new contexts, the tiles in a tiling may be homothetic (rather than congruent) images of tiles in a prototile set, or be topological images of tiles in a prototile set. For example, a tiling of $\mathbb{E}^n$ by polytopes in which every tile is combinatorially isomorphic to a fixed convex n -polytope (the combinatorial prototile) is said to be **monotypic**. It has been shown that in $\mathbb{E}^2$, there exist monotypic face-to-face tilings by convex n -gons for all $n \geq 3$; in $\mathbb{E}^3$, every convex 3-polytope is the combinatorial prototile of a monotypic tiling [Sch84a]. Many (but not all) classes of convex 3-polytopes admit monotypic face-to-face tilings [DGS83, Sch84b].

SURVEYS

The following surveys are useful, in addition to the references below.

[GS87]: The definitive, comprehensive treatise on tilings of $\mathbb{E}^2$, state of the art as of the mid-1980s. All subsequent work (in any dimension) has taken this as its starting point for terminology, notation, and basic results. The Main Results of our Section 3.1 can be found here.

[Joh04]: A comprehensive and detailed account of uniform polytopes and honeycombs in Euclidean and non-Euclidean spaces of n dimensions.

[Moo97]: The proceedings of the NATO Advanced Study Institute on the Mathematics of Aperiodic Order, held in Waterloo, Canada in August 1995.

[Sch93]: A contemporary survey of tiling theory, especially useful for its accounts of monotypic and other kinds of tilings more general than those discussed in this chapter.

[Sch02]: A recent brief survey of tiling.

[Sen95]: [Chapters 5 – 8](#) form an introduction to the emerging theory of aperiodic tilings.

[SS94]: This book is especially useful for its account of tilings in $\mathbb{E}^n$ by clusters of cubes.

4 HELLY-TYPE THEOREMS AND GEOMETRIC TRANSVERSALS⁷³

Rephael Wenger

INTRODUCTION

A geometric transversal is an affine subspace of $\mathbb{R}^d$, such as a point, line, plane, or hyperplane, that intersects every member of a family of convex sets. Eduard Helly's celebrated theorem gives conditions for the members of a family of convex sets to have a point in common, i.e., a point transversal. In Section 4.1 we highlight some of the more notable theorems related to Helly's theorem and point transversals. Section 4.2 is devoted to geometric transversal theory.

4.1 HELLY-TYPE THEOREMS

In 1913, Eduard Helly proved the following theorem:

THEOREM 4.1.1 *Helly's Theorem* [Hel23]

Let $\mathcal{A}$ be a finite family of at least $d + 1$ convex sets in $\mathbb{R}^d$. If every $d + 1$ members of $\mathcal{A}$ have a point in common, then there is a point common to all members of $\mathcal{A}$.

The theorem also holds for infinite families of compact convex sets.

Helly's theorem spawned numerous generalizations and variants. These theorems usually have the form: If every m members of a family of objects have property $\mathcal{P}$ then the entire family has property $\mathcal{Q}$. When $\mathcal{P}$ equals $\mathcal{Q}$, theorems of this form are sometimes referred to as **Helly-type** theorems. In Helly's theorem the objects are convex sets in $\mathbb{R}^d$, properties $\mathcal{P}$ and $\mathcal{Q}$ are the properties of having a point in common, and m equals $d + 1$. Most generalizations of Helly's theorem take four forms: replacing convex sets by other objects in $\mathbb{R}^d$, strengthening properties $\mathcal{P}$ and $\mathcal{Q}$, replacing $m = d + 1$ by some other number or condition, and replacing $\mathbb{R}^d$ by the d -dimensional sphere, $\mathbb{S}^d$.

The first five parts of this section discuss various generalizations of Helly's theorem. The sixth and seventh part discuss some theorems and algorithms related to Helly's theorem. The last part contains some open problems. The theorems will all be stated for finite families of convex sets. As with Helly's theorem, many of them extend to infinite families of compact convex sets by standard topological arguments.

GLOSSARY

Convex: A set $a \subseteq \mathbb{R}^d$ is convex if $x, y \in a$ implies that line segment $xy \subseteq a$.

Convex hull: The convex hull of a set of points $X \subseteq \mathbb{R}^d$ is the smallest (inclusionwise) convex set containing X .

Homology cell: Metric space a is a homology cell if it is nonempty and homologically trivial (acyclic) in all dimensions.

Translate: Set $a \subseteq \mathbb{R}^d$ is a translate of set $b \subseteq \mathbb{R}^d$ if $a = \{v + x \mid x \in b\}$ for some vector $v \in \mathbb{R}^d$.

Homothet: Set $a \subseteq \mathbb{R}^d$ is a (positive) homothet of set $b \subseteq \mathbb{R}^d$ if $a = \{v + tx \mid x \in b\}$ for some vector $v \in \mathbb{R}^d$ and scalar $t > 0$.

Flat: An affine subspace of dimension k .

Support: Hyperplane h supports convex set a if a intersects h and is contained in one of the closed halfspaces bounded by h ; k -flat f supports convex set a if a intersects f and f is contained in some supporting hyperplane of a .

Diameter: The diameter of a point set a is the supremum of the distances between pairs of points in a .

Width: The width of a closed convex set a is the smallest distance between parallel supporting hyperplanes of a .

Piercing number: The piercing number of a family $\mathcal{A}$ of convex sets in $\mathbb{R}^d$ is the minimum number of points needed to intersect every member of $\mathcal{A}$.

NOTATION

$\text{conv}(X)$: The convex hull of point set X .

$f_i(\mathcal{A})$: The number of subfamilies $\mathcal{A}'$ of size $i + 1$ of a family $\mathcal{A}$ of point sets such that $\bigcap_{a \in \mathcal{A}'} a \neq \emptyset$.

$\mathcal{C}_j^d$: The family of all sets of $\mathbb{R}^d$ that are the unions of j or fewer convex sets.

$\mathcal{K}_j^d$: The family of all sets of $\mathbb{R}^d$ that are the unions of j or fewer pairwise disjoint closed convex sets.

4.1.1 GENERALIZATIONS TO NONCONVEX SETS

In 1930, Helly himself gave the following topological generalization of his theorem:

THEOREM 4.1.2 [Hel30]

Let $\mathcal{A}$ be a finite family of closed homology cells in $\mathbb{R}^d$. If the intersection of every $d + 1$ or fewer members of $\mathcal{A}$ is a homology cell, then the intersection of all the members of $\mathcal{A}$ is a homology cell.

Since the intersection of convex sets is a convex set and nonempty convex sets are homology cells, Theorem 4.1.2 implies Helly's theorem. Other proofs are available in [AH35, Deb70].

Helly's theorem can also be generalized to objects that are the unions of convex sets. Let $\mathcal{C}_j^d$ be the family of all sets of $\mathbb{R}^d$ that are the unions of j or fewer convex sets. The intersection of members of $\mathcal{C}_j^d$ is not necessarily in $\mathcal{C}_j^d$.

THEOREM 4.1.3 [AK95, Mat97]

For every $j, d \geq 1$ there exists an integer $c(j, d) < \infty$ such that: If $\mathcal{A}$ is a finite subfamily of $\mathcal{C}_j^d$ of size at least $c(j, d)$, such that the intersection of every subfamily of $\mathcal{A}$ is also in $\mathcal{C}_j^d$ and such that every $c(j, d)$ members of $\mathcal{A}$ have a point in common, then there is a point common to all the members of $\mathcal{A}$.

A tight version of Theorem 4.1.3 is known for objects that are the unions of pairwise disjoint closed convex sets. Let $\mathcal{K}_j^d$ be the family of all sets of $\mathbb{R}^d$ that are the unions of j or fewer pairwise disjoint closed convex sets.

THEOREM 4.1.4 [Mor73]

Let $\mathcal{A}$ be a finite subfamily of $\mathcal{K}_j^d$ of size at least $j(d+1)$ such that the intersection of every j members of $\mathcal{A}$ is also in $\mathcal{K}_j^d$. If every $j(d+1)$ members of $\mathcal{A}$ have a point in common, then there is a point common to all the members of $\mathcal{A}$.

The value $j(d+1)$ cannot be reduced. An elegant proof of this theorem appears in [Ame96].

4.1.2 INTERSECTIONS IN MORE THAN A POINT

The following generalizations of Helly's theorem apply to families of convex sets but strengthen both the hypothesis and the conclusion of the theorem, usually by assuming that the sets intersect in more than a single point.

THEOREM 4.1.5 [San57]

Let $\mathcal{A}$ be a finite family of convex sets in $\mathbb{R}^d$. If every $d-k+1$ or fewer members of $\mathcal{A}$ contain a k -flat in common, then there is a k -flat contained in all the members of $\mathcal{A}$.

THEOREM 4.1.6 [Kat71]

Let $\mathcal{A}$ be a finite family of convex sets in $\mathbb{R}^d$. Let $\psi(0, d) = d+1$ and $\psi(k, d) = \max(d+1, 2(d-k+1))$ for $1 \leq k \leq d$. If the intersection of every $\psi(k, d)$ or fewer members of $\mathcal{A}$ has dimension at least k , then the intersection of all the members of $\mathcal{A}$ is a set of dimension at least k .

The values of $\psi(k, d)$ are tight and cannot be reduced.

THEOREM 4.1.7 [Vin39, Kle53]

Let $\mathcal{A}$ be a finite family of at least $d+1$ convex sets in $\mathbb{R}^d$ and let b be some convex set in $\mathbb{R}^d$. If every $d+1$ members of $\mathcal{A}$ contain [intersect; are contained in] some translate of b , then some translate of b is contained in [intersects; contains] all the members of $\mathcal{A}$.

THEOREM 4.1.8 [BV82]

Let $\mathcal{A}$ be a finite family of at least $d+1$ closed convex sets in $\mathbb{R}^d$. If the intersection of every $d+1$ members of $\mathcal{A}$ has width at least w , then the intersection of all the members of $\mathcal{A}$ has width at least w .

THEOREM 4.1.9 [BKP84]

Let $\mathcal{A}$ be a finite family of at least $2d$ convex sets in $\mathbb{R}^d$. If the intersection of every $2d$ members of $\mathcal{A}$ has diameter at least 1, then the intersection of all the members of $\mathcal{A}$ has diameter at least $d^{-2d}/2$.

THEOREM 4.1.10 [BKP84]

Let $\mathcal{A}$ be a finite family of at least $2d$ convex sets in $\mathbb{R}^d$. If the intersection of every $2d$ members of $\mathcal{A}$ has volume at least 1, then the intersection of all the members of $\mathcal{A}$ has volume at least d^{-2d^2} .

The value $2d$ in Theorems 4.1.9 and 4.1.10 is tight and cannot be reduced. The values $d^{-2d}/2$ and d^{-2d^2} are not tight and can be increased. Bárány, Katchalski, and Pach [BKP84] conjecture that the correct values are approximately $c_1 d^{-1/2}$ and $d^{-c_2 d}$ for some c_1 and c_2 .

4.1.3 REDUCING $d+1$

Reducing the number of intersecting convex sets in the hypothesis of Helly's theorem gives:

THEOREM 4.1.11 [Kle51]

Let $\mathcal{A}$ be a finite family of convex sets in $\mathbb{R}^d$. For any $m \leq d+1$, if every m or fewer members of $\mathcal{A}$ have a point in common, then every $(d-m+1)$ -flat in $\mathbb{R}^d$ has some translate that intersects every member of $\mathcal{A}$ and every $(d-m)$ -flat in $\mathbb{R}^d$ is contained in a $(d-m+1)$ -flat that intersects every member of $\mathcal{A}$.

It is also true that if every $(d-m+1)$ -flat in $\mathbb{R}^d$ has some translate that intersects every member of $\mathcal{A}$ or every $(d-m)$ -flat in $\mathbb{R}^d$ is contained in a $(d-m+1)$ -flat that intersects every member of $\mathcal{A}$, then every m members of $\mathcal{A}$ have a point in common.

Theorem 4.1.11 also has a variant giving the topological structure of the set of $(d-m+1)$ -flats intersecting $\mathcal{A}$ [BM02].

For a family $\mathcal{A}$ of n convex sets, let $f_i(\mathcal{A})$ be the number of subfamilies $\mathcal{A}'$ of $\mathcal{A}$ of size $i+1$ such that the $i+1$ members of $\mathcal{A}'$ have a point in common. ($f_i(\mathcal{A})$ is the number of faces of dimension i in the *nerve* of $\mathcal{A}$.) Helly's theorem states that if $f_d(\mathcal{A})$ equals $\binom{n}{d+1}$, then there is a point common to all the members of $\mathcal{A}$. What if $f_d(\mathcal{A})$ is some value less than $\binom{n}{d+1}$?

THEOREM 4.1.12 [Kal84, Eck85]

Let $\mathcal{A}$ be a finite family of $n \geq d+1$ convex sets in $\mathbb{R}^d$. For any r where $0 \leq r \leq n-d-1$, if $f_d(\mathcal{A}) > \binom{n}{d+1} - \binom{n-r}{d+1}$, then some $d+r+1$ members of $\mathcal{A}$ have a point in common.

THEOREM 4.1.13 [Kal84]

Let $\mathcal{A}$ be a finite family of $n \geq d+1$ convex sets in $\mathbb{R}^d$. For any ρ where $0 \leq \rho \leq 1$, if $f_d(\mathcal{A}) > (1 - (1-\rho)^{d+1})\binom{n}{d+1}$, then some $\lfloor \rho n \rfloor + 1$ members of $\mathcal{A}$ have a point in common.

The values given in Theorems 4.1.12 and 4.1.13 are tight and cannot be reduced. Tight versions of these theorems are also known when $f_d(\mathcal{A})$ is replaced by $f_i(\mathcal{A})$ for any $i > d$. Theorem 4.1.13 is sometimes called a **fractional Helly theorem**.

The hypothesis that every $d + 1$ members of $\mathcal{A}$ have a point in common can also be replaced by the hypothesis that out of every p members of $\mathcal{A}$ some q have a point in common, where $p \geq q \geq d + 1$. For certain values of p and q , Hadwiger and Debrunner proved the following result on their so-called (p, q) -problem:

THEOREM 4.1.14 [HD57]

Let $\mathcal{A}$ be a finite family of at least p convex sets in $\mathbb{R}^d$. If out of every p members of $\mathcal{A}$ some q have a point in common, where $p \geq q \geq d + 1$ and $p(d - 1) < (q - 1)d$, then some set of $p - q + 1$ points intersects every member of $\mathcal{A}$.

The value of $p - q + 1$ is tight and cannot be reduced.

A similar theorem holds for general values of p and q , but tight bounds are not known:

THEOREM 4.1.15 [AK92]

For every $p \geq q \geq d + 1$, there exists a positive integer $c(p, q, d) < \infty$ such that: If $\mathcal{A}$ is a finite family of at least p convex sets in $\mathbb{R}^d$ and out of every p members of $\mathcal{A}$ some q have a point in common, then some set of $c(p, q, d)$ points intersects every member of $\mathcal{A}$.

For the special case of homothets, the intersection of every two members of $\mathcal{A}$ suffices.

THEOREM 4.1.16 [Grü59]

For every d there exists a positive integer $c(d) < \infty$ such that: If $\mathcal{A}$ is a finite family of homothets of a convex set in $\mathbb{R}^d$ and every two members of $\mathcal{A}$ intersect, then some set of $c(d)$ points intersects every member of $\mathcal{A}$.

Tight bounds are known for circular disks in $\mathbb{R}^2$.

THEOREM 4.1.17 [Dan86]

Let $\mathcal{A}$ be a finite family of circular disks in $\mathbb{R}^2$. If every two members of $\mathcal{A}$ intersect, then some set of four points intersects every member of $\mathcal{A}$.

THEOREM 4.1.18 [HDK64]

Let $\mathcal{A}$ be a finite family of circular unit disks in $\mathbb{R}^2$. If every two members of $\mathcal{A}$ intersect, then some set of three points intersects every member of $\mathcal{A}$.

Danzer proved Theorem 4.1.17, settling a question by Gallai on the minimum number of points needed to intersect all the members of any family of pairwise intersecting circular disks in $\mathbb{R}^2$. Such problems are often called Gallai-type problems.

Theorem 4.1.13 generalizes to objects that are unions of convex sets. Let $\mathcal{C}_j^d$ be as above.

THEOREM 4.1.19 [AK95]

For every α , $0 \leq \alpha \leq 1$, and every $j, d > 0$, there exists a constant $c(j, \alpha, d) > 0$ such that: If $\mathcal{A}$ is a finite subfamily of $\mathcal{C}_j^d$ of size $n \geq d + 1$ and $f_d(\mathcal{A}) > \alpha \binom{n}{d+1}$, then some $c(j, \alpha, d)n$ members of $\mathcal{A}$ have a point in common.

Similarly, Theorem 4.1.15 generalizes to subfamilies of $\mathcal{C}_j^d$:

THEOREM 4.1.20 [AK95]

For every $p \geq q \geq d+1$ and every $j > 0$, there exists a positive integer $c(j, p, q, d) < \infty$ such that: If $\mathcal{A}$ is a finite subfamily of $\mathcal{C}_j^d$ of size at least p and out of every p members of $\mathcal{A}$ some q have a point in common, then some set of $c(j, p, q, d)$ points intersects every member of $\mathcal{A}$.

4.1.4 SPHERICAL HELLY-TYPE THEOREMS

Various generalizations of convexity to a convexity structure on the d -sphere, $\mathbb{S}^d$, give rise to various Helly-type theorems.

GLOSSARY

Robinson-convex: A set $a \subseteq \mathbb{S}^d$ is Robinson-convex if for every $x, y \in a$ where x and y are not antipodal points, the small arc of the great circle joining x and y is contained in a .

Strongly convex: A set $a \subseteq \mathbb{S}^d$ is strongly convex if a is Robinson-convex and does not contain any antipodal points.

Convex cone: A set $a \subseteq \mathbb{R}^d$ is a convex cone centered at the origin if $x, y \in a$ implies $t_x x + t_y y \in a$ for any scalars $t_x, t_y \geq 0$.

NOTATION

$-a$: The set of points antipodal to the points in $a \subseteq \mathbb{S}^d$.

$\dim(a)$: The dimension of a manifold a with boundary. (By convention, the dimension of the empty set is -1 .)

RESULTS**THEOREM 4.1.21**

Let $\mathcal{A}$ be a finite family of at least $d+2$ strongly convex sets in $\mathbb{S}^d$. If every $d+2$ members of $\mathcal{A}$ have a point in common, then there is a point common to all the members of $\mathcal{A}$.

THEOREM 4.1.22 [Rob42]

Let $\mathcal{A}$ be a finite family of Robinson-convex sets in $\mathbb{S}^d$. If every $2d+2$ or fewer members of $\mathcal{A}$ have a point in common, then there is a point common to all the members of $\mathcal{A}$.

Theorems 4.1.21 and 4.1.22 generalize to:

THEOREM 4.1.23 [SS75]

Let $\mathcal{A}$ be a finite family of Robinson-convex sets in $\mathbb{S}^d$. Let m equal $\min_{a \in \mathcal{A}} [\dim(a) + \dim(a \cap -a)]$. If every $m+3$ or fewer members of $\mathcal{A}$ have a point in common, then there is a point common to all the members of $\mathcal{A}$.

The values $d+2$, $2d+2$, and $m+3$ in Theorems 4.1.21, 4.1.22, and 4.1.23 can be reduced by one under certain suitable circumstances. A subset of $\mathbb{S}^d$ is Robinson-convex if and only if it is the intersection of $\mathbb{S}^d$ with some convex cone centered at the origin. Thus Theorems 4.1.22 and 4.1.23 can be formulated in terms of convex cones.

Weakening the hypothesis of Theorem 4.1.22 by replacing $2d+2$ by $d+1$ gives the following theorem:

THEOREM 4.1.24 [Kat77]

Let $\mathcal{A}$ be a finite family of at least $d+n+1$ Robinson-convex sets in $\mathbb{S}^d$, $n > 0$. If every $d+1$ members of $\mathcal{A}$ have a point in common, then some $d + \lfloor n/2 \rfloor + 1$ members of $\mathcal{A}$ have a point in common.

A spherical variant of the topological Helly theorem (Theorem 4.1.2) generalizes Theorem 4.1.21.

THEOREM 4.1.25 [Deb70]

Let $\mathcal{A}$ be a finite family of closed homology cells in $\mathbb{S}^d$. If the intersection of every $d+2$ or fewer members of $\mathcal{A}$ is a homology cell, then the intersection of all the members of $\mathcal{A}$ is a homology cell.

4.1.5 OTHER GENERALIZATIONS

Helly's theorem generalizes to multiple families of convex sets:

THEOREM 4.1.26 [Bár82]

Let $\mathcal{A}_1, \mathcal{A}_2, \dots, \mathcal{A}_{d+1}$ be nonempty finite families of convex sets in $\mathbb{R}^d$. If $\bigcap_{i=1}^{d+1} \mathcal{A}_i \neq \emptyset$ for each choice of $a_i \in \mathcal{A}_i$, then $\bigcap_{a \in \mathcal{A}_i} a \neq \emptyset$ for some $\mathcal{A}_i$.

Setting $\mathcal{A}_1 = \mathcal{A}_2 = \dots = \mathcal{A}_{d+1}$ gives Helly's original theorem.

Dol'nikov gave a variation of Theorem 4.1.11 for multiple families of convex sets:

THEOREM 4.1.27 [Dol88]

Let $\mathcal{A}_1, \mathcal{A}_2, \dots, \mathcal{A}_{d-m+2}$ be $d-m+2$ finite families of convex sets in $\mathbb{R}^d$, $2 \leq m \leq d+1$. If every m or fewer members of each family $\mathcal{A}_i$ have a point in common, then there is some $(d-m+1)$ -flat in $\mathbb{R}^d$ that intersects every member of $\mathcal{A} = \bigcup_{i=1}^{d-m+2} \mathcal{A}_i$.

Theorem 4.1.27 is a special case of a much more general theorem by Dol'nikov that gives conditions for an algebraic surface of dimension $d-m+1$ to intersect every member of $\mathcal{A} = \bigcup_{i=1}^{d-m+2} \mathcal{A}_i$.

4.1.6 RELATED THEOREMS

Helly's theorem implies and/or is implied by some notable theorems.

THEOREM 4.1.28 *Carathéodory's Theorem*

Each point of $\text{conv}(X)$, $X \subseteq \mathbb{R}^d$, is a convex combination of $d + 1$ or fewer points of X .

THEOREM 4.1.29 *Radon's Theorem*

Each set of $d + 2$ or more points in $\mathbb{R}^d$ can be partitioned into two disjoint sets whose convex hulls have a point in common.

THEOREM 4.1.30 *Kirchberger's Theorem*

For point sets $X, Y \subseteq \mathbb{R}^d$, $\text{conv}(X) \cap \text{conv}(Y) \neq \emptyset$ if and only if $\text{conv}(X') \cap \text{conv}(Y') \neq \emptyset$ for some $X' \subseteq X$ and $Y' \subseteq Y$ where $|X'| + |Y'| \leq d + 2$.

A theorem similar to Carathéodory's theorem gives conditions for a point to lie in the interior of the convex hull of a set of points.

THEOREM 4.1.31 *Steinitz's Theorem*

Each point in the interior of $\text{conv}(X)$, $X \subseteq \mathbb{R}^d$, is in the interior of $\text{conv}(X')$ for some $X' \subseteq X$ and $|X'| \leq 2d$.

Theorem 4.1.26 is a generalization of Helly's theorem to multiple families of convex sets. Carathéodory's theorem has a similar, related generalization:

THEOREM 4.1.32

Let $X_1, X_2, \dots, X_{d+1}$ be subsets of $\mathbb{R}^d$. If $x \in \text{conv}(X_i)$ for each X_i , then there exist points $x_i \in X_i$ such that $x \in \text{conv}(\{x_1, \dots, x_{d+1}\})$.

Finally, Radon's theorem has the following generalization:

THEOREM 4.1.33 *Tverberg's Theorem* [Tve66]

Each set of $(r - 1)(d + 1) + 1$ or more points in $\mathbb{R}^d$ can be partitioned into r subsets whose convex hulls have a point in common.

The theorem is tight and the number $(r - 1)(d + 1) + 1$ cannot be reduced. For more details, see [Chapter 14](#).

4.1.7 RELATED ALGORITHMS

Helly's theorem provokes the following algorithmic problem: Given a family $\mathcal{A}$ of n convex sets, find a point common to all the sets or, if there is no such point, find $d + 1$ members of $\mathcal{A}$ that have no point in common. When $\mathcal{A}$ is a family of n halfspaces, this problem is simply a specialized version of linear programming. Sharir and Welzl have generalized linear programming to a more abstract framework that they call *generalized linear programming*. The problem of finding a point common to n convex sets can be formulated and solved as a generalized linear programming problem. In addition, other Helly-type theorems have related algorithmic questions that can be formulated and solved as generalized linear programming problems [Ame94]. For more on linear programming and generalized linear programming, see [Chapters 45](#) and [46](#).

4.1.8 OPEN PROBLEMS

PROBLEM 4.1.34

Prove or disprove that there exists some constant c such that: If the intersection of every $2d$ members of a family $\mathcal{A}$ of at least $2d$ convex sets in $\mathbb{R}^d$ has diameter at least 1, then the intersection of all the members of $\mathcal{A}$ has diameter at least $cd^{-1/2}$.

PROBLEM 4.1.35

Prove or disprove that there exists some constant c such that: If the intersection of every $2d$ members of a family $\mathcal{A}$ of at least $2d$ convex sets in $\mathbb{R}^d$ has volume at least 1, then the intersection of all the members of $\mathcal{A}$ has volume at least d^{-cd} .

PROBLEM 4.1.36

Let $\mathcal{A}$ be a finite family of translates of a convex set in $\mathbb{R}^2$. Prove or disprove that if every two members of $\mathcal{A}$ intersect, then some set of three points intersects every member of $\mathcal{A}$.

4.2 GEOMETRIC TRANSVERSALS

Much research on geometric transversals focuses on necessary and sufficient conditions for the existence of line, plane, or hyperplane transversals to a family $\mathcal{A}$ of convex sets. This research includes conditions on the existence of transversals to special families of convex sets, such as translates or homothets. Most of the results apply either to line transversals in $\mathbb{R}^2$ or to hyperplane transversals in $\mathbb{R}^d$. The “order” in which a transversal intersects $\mathcal{A}$ plays an important role in stating and proving such theorems. Given a family $\mathcal{A}$ of convex sets, in how many different orders can $\mathcal{A}$ be intersected by transversals?

The set of transversals to a family $\mathcal{A}$ of convex sets forms a topological space with the usual topology associated with affine subspaces in $\mathbb{R}^d$, i.e., the topology inherited from the Grassmannian. What is the combinatorial structure and complexity of this space? What are efficient algorithms for constructing this space? Under what conditions does a set of k -flats form the space of transversals to some family of convex sets?

GLOSSARY

Transversal: An affine subspace $f \subseteq \mathbb{R}^d$ of dimension k is a k -transversal to a family $\mathcal{A}$ of convex sets if f intersects every member of $\mathcal{A}$.

Line transversal: A 1-transversal to a family of convex sets in $\mathbb{R}^d$.

Hyperplane transversal: A $(d-1)$ -transversal to a family of convex sets in $\mathbb{R}^d$.

Separated: A family $\mathcal{A}$ of convex sets is k -separated if no $k+2$ members of $\mathcal{A}$ have a k -transversal.

Ordering: A k -ordering of a family $\mathcal{A} = \{a_1, \dots, a_n\}$ of convex sets is a family of orientations of $(k+1)$ -tuples of $\mathcal{A}$ defined by a mapping $\chi : \mathcal{A}^{k+1} \rightarrow \{-1, 0, 1\}$

corresponding to the orientations of some family of points $X = \{x_1, \dots, x_n\}$ in $\mathbb{R}^k$. The orientation of $(a_{i_0}, a_{i_1}, \dots, a_{i_k})$ is the orientation of the corresponding points $(x_{i_0}, x_{i_1}, \dots, x_{i_k})$, i.e.,

$$\left(\operatorname{sgn} \det \begin{pmatrix} 1 & x_{i_0}^1 & \cdots & x_{i_0}^k \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{i_k}^1 & \cdots & x_{i_k}^k \end{pmatrix} \right).$$

Nontrivial ordering: A k -ordering is nontrivial if at least one of its orientations is nonzero.

Acyclic oriented matroid: A rank r acyclic oriented matroid on a set $\mathcal{A}$ is a family of orientations of r -tuples of $\mathcal{A}$ defined by a mapping $\chi: \mathcal{A}^r \rightarrow \{-1, 0, 1\}$ satisfying certain “chirotope” axioms and a condition of “acyclicity”; for more details, see [Chapter 6](#).

Realizable acyclic oriented matroid: An acyclic oriented matroid of rank r is *realizable* if it can be represented as the family of orientations of a set of points in $\mathbb{R}^{r-1}$.

Geometric permutation: A geometric permutation of a $(k-1)$ -separated family $\mathcal{A}$ of convex sets in $\mathbb{R}^d$ is the pair of k -orderings induced by some k -transversal of $\mathcal{A}$.

Ackermann function: The extremely rapidly growing function defined recursively by $A(n) = A_n(n)$, where $A_1(n) = 2n$ and $A_k(n) = A_{k-1}^{(n)}(1)$, $k \geq 2$.

Davenport-Schinzel sequence: An (n, s) Davenport-Schinzel sequence is a sequence of integers, $(u_1, \dots, u_m)$, where $1 \leq u_i \leq n$ and $u_i \neq u_{i+1}$, that does not contain any alternating subsequence $(u_{i_1}, u_{i_2}, \dots, u_{i_{s+2}})$ of length $s+2$ such that $u_{i_1} = u_{i_3} = u_{i_5} = \dots$ and $u_{i_2} = u_{i_4} = u_{i_6} = \dots$ and $u_{i_1} \neq u_{i_2}$; for more details, see Section 46.4 of this Handbook.

Constant description complexity: A convex set has constant description complexity if it is defined by a constant number of algebraic equalities and inequalities of constant maximum degree.

Strictly convex: A compact convex set a is strictly convex if its boundary contains no line segments.

Fat: Convex set a is ρ -fat, $\rho \geq 1$, if the ratio between the radius of the smallest ball containing a and the largest ball containing a is at most ρ .

Stubby: Convex set a is ρ -stubby, $\rho \geq 1$, if it is contained in a ball of radius ρ and contains a ball of radius one.

NOTATION

$\mathcal{T}_k^d(\mathcal{A})$: The space of k -transversals to a family $\mathcal{A}$ of convex sets in $\mathbb{R}^d$.

$g_k^d(n)$: The maximum number of geometric permutations induced by k -transversals of $(k-1)$ -separated families of n compact convex sets in $\mathbb{R}^d$.

$\alpha(n)$: The inverse of the Ackermann function.

$\lambda_s(n)$: The maximum length of an (n, s) Davenport-Schinzel sequence.

4.2.1 HADWIGER'S TRANSVERSAL THEOREM

In 1935, Vincensini asked if there is a Helly-type theorem for line transversals to a family $\mathcal{A}$ of convex sets in $\mathbb{R}^2$. In other words, is there a number m such that if every m members of $\mathcal{A}$ are simultaneously intersected by a line then there exists a single line intersecting all the members of $\mathcal{A}$? The answer is no, even for line transversals to families of pairwise disjoint line segments. Figure 4.2.1 illustrates a counterexample for m equal to four.

FIGURE 4.2.1

A counterexample to a Helly-type theorem for line transversals to families of convex sets in $\mathbb{R}^2$: Five convex sets, four line segments and a point, where every four sets have a line transversal but all five do not.

However, in 1957 Hadwiger added a condition about the order in which every m members of $\mathcal{A}$ are intersected by a line to give the following theorem:

THEOREM 4.2.1 *Hadwiger's Transversal Theorem* [Had57]

Let $\mathcal{A}$ be a finite family of pairwise disjoint convex sets in $\mathbb{R}^2$. If there exists a linear ordering of $\mathcal{A}$ such that every three members of $\mathcal{A}$ are intersected by a directed line in the given order, then $\mathcal{A}$ has a line transversal.

As with Helly's theorem, Hadwiger's transversal theorem and most of the similar theorems in this section also apply to infinite families of compact convex sets.

Hadwiger's transversal theorem generalizes to hyperplane transversals in $\mathbb{R}^d$ as follows:

THEOREM 4.2.2 [PW90]

Let $\mathcal{A}$ be a finite family of connected sets in $\mathbb{R}^d$. If, for some k , $0 \leq k < d$, there exists a nontrivial k -ordering of $\mathcal{A}$ such that every $k+2$ members of $\mathcal{A}$ are intersected by an oriented k -flat consistently with that k -ordering, then $\mathcal{A}$ has a hyperplane transversal.

An oriented k -flat f meets $\mathcal{A}' \subseteq \mathcal{A}$ consistently with a given k -ordering of $\mathcal{A}$ if one can choose a point y_i from the intersection of each set $a_i \in \mathcal{A}'$ and f such that the orientation of every $(k+1)$ -tuple, $(y_{i_0}, y_{i_1}, \dots, y_{i_k})$, of points in f matches the orientation of the corresponding $(k+1)$ -tuple, $(a_{i_0}, a_{i_1}, \dots, a_{i_k})$, of the k -ordering. Note that Theorem 4.2.2 eliminates the assumption of pairwise disjointness in Theorem 4.2.1.

Hadwiger's transversal theorem can be generalized even further in the language of oriented matroid theory:

THEOREM 4.2.3 [AW96]

Let $\mathcal{A}$ be a finite family of connected sets in $\mathbb{R}^d$. If, for some k , $0 \leq k < d$, there exists an acyclic oriented matroid of rank $k+1$ on $\mathcal{A}$ such that every $k+2$ members of $\mathcal{A}$ are intersected by an oriented k -flat consistently with that oriented matroid, then $\mathcal{A}$ has a hyperplane transversal.

An oriented k -flat f meets $\mathcal{A}' \subseteq \mathcal{A}$ consistently with a given acyclic oriented matroid on $\mathcal{A}$ if one can choose a point y_i from the intersection of each set $a_i \in \mathcal{A}'$ and f such that the orientation of every $(k+1)$ -tuple, $(y_{i_0}, y_{i_1}, \dots, y_{i_k})$, of points in f matches the orientation of the corresponding $(k+1)$ -tuple, $(a_{i_0}, a_{i_1}, \dots, a_{i_k})$, of the oriented matroid. Theorem 4.2.2 is a restriction of Theorem 4.2.3 to realizable oriented matroids.

Theorem 4.2.3 can be generalized to give the topological structure of the space of hyperplane transversals [ABM⁺02]. Essentially, if every $k+2$ members of $\mathcal{A}$ are intersected by an oriented k -flat consistent with the given oriented matroid, then the space of hyperplane transversals has “homologically” as many hyperplanes as the set of hyperplanes containing a k -flat in $\mathbb{R}^d$.

Hadwiger's theorem does not generalize to line transversals in $\mathbb{R}^3$ even for families of pairwise disjoint convex translates [HM]. For each $m \geq 2$, there is a finite family $\mathcal{A}$ of pairwise disjoint convex translates in $\mathbb{R}^3$ and a linear ordering of $\mathcal{A}$ such that every $m-1$ members of $\mathcal{A}$ are met by a directed line in the given order, but $\mathcal{A}$ has no line transversal.

4.2.2 HELLY-TYPE THEOREMS

Helly-type theorems are known for infinite families and for families with some minimum separation between sets.

GLOSSARY

Limiting direction: A unit vector u is a limiting direction of an unbounded family $\mathcal{A}$ of compact convex sets of bounded diameter if the unit vectors from the origin toward an unbounded sequence of members of $\mathcal{A}$ approach the limit u .

Unbounded: An unbounded family of compact convex sets of bounded diameter is k -unbounded if the linear subspace spanning the set of limiting directions of $\mathcal{A}$ has dimension at least k .

Separated: A finite family $\mathcal{A}$ of convex sets in $\mathbb{R}^d$ is ϵ -separated if, for every $0 < k < d$, any k of the sets can be separated from any other $d-k$ of the sets by a hyperplane more than $\epsilon D(\mathcal{A})/2$ away from all d of the sets, where $D(\mathcal{A})$ is the largest diameter of any member of $\mathcal{A}$.

THEOREM 4.2.4 [AGP02]

If $\mathcal{A}$ is a k -unbounded family of compact convex sets with bounded diameter in $\mathbb{R}^d$, where $k < d$, and every $d+1$ members of $\mathcal{A}$ have a k -transversal, then $\mathcal{A}$ has a k -transversal.

THEOREM 4.2.5 [AGPW01]

For every real $\epsilon > 0$ and integer $d > 1$, there exists a constant $N_d(\epsilon)$, such that: If $\mathcal{A}$ is an ϵ -separated family of at least $N_d(\epsilon)$ compact convex sets in $\mathbb{R}^d$ and every $2d+2$ members of $\mathcal{A}$ have a hyperplane transversal, then $\mathcal{A}$ has a hyperplane transversal.

4.2.3 GALLAI-TYPE PROBLEMS

Under certain conditions a family $\mathcal{A}$ may not have a k -transversal but there may be some small set of k -flats whose union intersects every member of $\mathcal{A}$.

Theorem 4.1.15 has a variant for hyperplane transversals:

THEOREM 4.2.6 [AK95]

For every $p \geq q \geq d + 1$ there exists a positive integer $c(p, q, d) < \infty$ such that: If $\mathcal{A}$ is a finite family of at least p convex sets in $\mathbb{R}^d$ and out of every p members of $\mathcal{A}$ some q have a hyperplane transversal, then there are $c(p, q, d)$ hyperplanes whose union intersects every member of $\mathcal{A}$.

In $\mathbb{R}^2$ almost exact minimal values of $c(p, p, 2)$ are known.

THEOREM 4.2.7 [Eck73]

Let $\mathcal{A}$ be a finite family of convex sets in $\mathbb{R}^2$. If every four members of $\mathcal{A}$ have a line transversal, then there are two lines whose union intersects every member of $\mathcal{A}$.

THEOREM 4.2.8 [Eck93a]

Let $\mathcal{A}$ be a finite family of convex sets in $\mathbb{R}^2$. If every three members of $\mathcal{A}$ have a line transversal, then there are four lines whose union intersects every member of $\mathcal{A}$.

It is conjectured, but not proven, that the number four in the conclusion of Theorem 4.2.8 can be reduced to three. It cannot be reduced to two.

Theorem 4.2.6 generalizes to subfamilies of $\mathcal{C}_j^d$, i.e., families whose members are the unions of convex sets:

THEOREM 4.2.9 [AK95]

For every $p \geq q \geq d + 1$ and every j there exists a positive integer $c(j, p, q, d) < \infty$ such that: If $\mathcal{A}$ is a finite subfamily of $\mathcal{C}_j^d$ of size at least p and out of every p members of $\mathcal{A}$ some q have a hyperplane transversal, then there are $c(j, p, q, d)$ hyperplanes whose union intersects every member of $\mathcal{A}$.

4.2.4 TRANSLATES

Many special theorems apply to transversals of families of translates. Most noteworthy is the following Helly-type theorem conjectured by Grünbaum in 1958 and proved by Tverberg in 1989:

THEOREM 4.2.10 [Tve89]

Let $\mathcal{A}$ be a family of pairwise disjoint translates of a compact convex set in $\mathbb{R}^2$. If every five or fewer members of $\mathcal{A}$ have a line transversal, then $\mathcal{A}$ has a line transversal.

The number five cannot be reduced, even for unit disks [AGPW00].

Under the weaker condition that every three members of $\mathcal{A}$ have a line transversal, the following theorem holds:

THEOREM 4.2.11 [Hol03]

Let $\mathcal{A}$ be a family of pairwise disjoint translates of a compact convex set in $\mathbb{R}^2$. If every three members of $\mathcal{A}$ have a line transversal, then some subfamily $\mathcal{A}' \subseteq \mathcal{A}$ containing all but 22 members of $\mathcal{A}$ has a line transversal.

Katchalski and Lewis [KL80] proved this theorem with looser bounds, which were later improved by Tverberg. The current bound of 22 is a recent result by Holmsen [Hol03]. The number 22 is not known to be tight and can possibly be reduced. Katchalski and Lewis conjectured that the correct number is two, but Holmsen [Hol03] gave an example showing that the number is at least four.

Versions of Theorems 4.2.10 and 4.2.11 exist for families of pairwise disjoint ρ -stubby convex sets where the constants are replaced by functions of ρ .

The condition that the members of $\mathcal{A}$ are pairwise disjoint can also be weakened.

THEOREM 4.2.12 [Rob97]

For every $j > 0$ there exists a number $c(j)$ such that: If $\mathcal{A}$ is a family of translates of a compact convex set in $\mathbb{R}^2$ such that the intersection of any j members of $\mathcal{A}$ is empty and such that every $c(j)$ or fewer members of $\mathcal{A}$ have a line transversal, then $\mathcal{A}$ has a line transversal.

Recently, Holmsen and Matoušek [HM] showed that Theorem 4.2.10 does not generalize to line transversals of pairwise disjoint convex translates in $\mathbb{R}^3$. For any integer $n > 2$, there exists a family $\mathcal{A}$ of pairwise disjoint translates of n compact convex sets such that every $n - 1$ members of $\mathcal{A}$ have a line transversal, but $\mathcal{A}$ does not have a line transversal. Theorem 4.2.11 also does not generalize to line transversals in $\mathbb{R}^3$.

In another recent result, Holmsen, Katchalski, and Lewis proved that there is a Helly-type theorem for line transversals of disjoint unit balls in $\mathbb{R}^3$:

THEOREM 4.2.13 [HKL03]

There exists an integer $m \leq 46$ such that: If $\mathcal{A}$ is a family of pairwise disjoint unit balls in $\mathbb{R}^3$ and every m or fewer members of $\mathcal{A}$ have a line transversal, then $\mathcal{A}$ has a line transversal.

Helly-type theorems are also known for hyperplane transversals of families of translates of convex polytopes:

THEOREM 4.2.14 [Grü64]

Let $\mathcal{A}$ be a family of translates of a convex polytope in $\mathbb{R}^d$ with n vertices. If every $\binom{n}{2}(d + 1)$ or fewer members of $\mathcal{A}$ have a hyperplane transversal, then $\mathcal{A}$ has a hyperplane transversal.

THEOREM 4.2.15 [Grü64]

Let $\mathcal{A}$ be a family of translates of a centrally symmetric convex polytope in $\mathbb{R}^d$ with n vertices. If every $\lfloor \frac{n}{2} \rfloor (d+1)$ or fewer members of $\mathcal{A}$ have a hyperplane transversal, then $\mathcal{A}$ has a hyperplane transversal.

The number $\lfloor \frac{n}{2} \rfloor (d+1)$ is tight and cannot be reduced.

4.2.5 GALLAI-TYPE PROBLEMS ON TRANSLATES

Eckhoff established Gallai-type results for line transversals of translates in $\mathbb{R}^2$:

THEOREM 4.2.16 [Eck73]

Let $\mathcal{A}$ be a finite family of translates of a convex set in $\mathbb{R}^2$. If every three members of $\mathcal{A}$ have a line transversal, then there are two parallel lines whose union intersects every member of $\mathcal{A}$.

In higher dimensions, Eckhoff showed:

THEOREM 4.2.17 [Eck69]

For every $k \geq 0$ there exists a number $c(k)$ such that: If $\mathcal{A}$ is a finite family of translates of a convex set in $\mathbb{R}^d$ and every $k+2$ members of $\mathcal{A}$ have a k -transversal, then there are $c(k)$ parallel k -flats whose union intersects every member of $\mathcal{A}$.

4.2.6 SPACE OF TRANSVERSALS

Given a family $\mathcal{A}$ of convex sets in $\mathbb{R}^d$, let $\mathcal{T}_k^d(\mathcal{A})$ be the space of all k -transversals of $\mathcal{A}$. If the members of $\mathcal{A}$ are closed, then the boundary of $\mathcal{T}_k^d(\mathcal{A})$ consists of k -flats that support one or more members of $\mathcal{A}$. This boundary can be partitioned into subspaces of k -flats that support the same subfamily of $\mathcal{A}$. Each of these subspaces can be further partitioned into connected components. The combinatorial complexity of $\mathcal{T}_k^d(\mathcal{A})$ is the number of such connected components.

Even in $\mathbb{R}^2$, the boundaries of two convex sets can intersect in an arbitrarily large number of points and have an arbitrarily large number of common supporting lines. Thus the space of line transversals to two convex sets in $\mathbb{R}^2$ can have arbitrarily large combinatorial complexity. However, if $\mathcal{A}$ consists of pairwise disjoint convex sets in $\mathbb{R}^2$ or, more generally, suitably separated convex sets in $\mathbb{R}^d$, then the complexity is bounded. If the convex sets have constant description complexity, then again the transversal space complexity is bounded. Finally, if the sets are convex polytopes, then the transversal space is bounded by the total number of polytope faces. Table 4.2.1 gives bounds on the transversal space complexity for various families of sets.

The function $\alpha(n)$ is the very slowly growing inverse of the Ackermann function. The function $\lambda_s(n)$ is the maximum length of an (n, s) Davenport-Schinzel sequence. Function $\lambda_s(n)$ equals $n\alpha(n)^{O(\alpha(n)^{s-3})}$.

In $\mathbb{R}^2$ the bounds are based on the maximum number s of common supporting lines per pair of convex sets, i.e., on the number of lines tangent to both sets that do not separate the sets. For sets of constant description complexity, this maximum s is bounded. Note that $\lambda_s(n) \in O(n^{1+\epsilon})$ for any $\epsilon > 0$.

TABLE 4.2.1 Bounds on $\mathcal{T}_k^d(\mathcal{A})$.

FAMILY	k	d	COMPLEXITY OF $\mathcal{T}_k^d(\mathcal{A})$	SOURCE
$(d-2)$ -separated family of n compact and strictly convex sets	$d-1$	d	$O(n^{d-1})$	[CGP ⁺ 94]
n connected sets such that any two sets have at most s common supporting lines	1	2	$O(\lambda_s(n))$	[AB87]
n convex sets with const. description complexity	1	3	$O(n^{3+\epsilon})$ for any $\epsilon > 0$	[KS]
n convex sets with const. description complexity	2	3	$O(n^{2+\epsilon})$ for any $\epsilon > 0$	[ASS96]
n convex sets with const. description complexity	3	4	$O(n^{3+\epsilon})$ for any $\epsilon > 0$	[KS]
n line segments	$d-1$	d	$O(n^{d-1})$	[PS89]
Convex polytopes with a total of n_f faces	$d-1$	d	$O(n_f^{d-1} \alpha(n_f))$	[PS89]
Convex polytopes with a total of n_f faces	1	3	$O(n_f^{3+\epsilon})$ for any $\epsilon > 0$	[Aga94]
n $(d-1)$ -balls	$d-1$	d	$O(n^{\lceil d/2 \rceil})$	[HII ⁺ 93]

The asymptotic bounds on the worst case complexity of hyperplane transversals ($k = d - 1$) to line segments and convex polytopes are tight. There are examples of families $\mathcal{A}$ of convex polytopes where the complexity of $\mathcal{T}_1^3(\mathcal{A})$ is $\Omega(n_f^3)$.

4.2.7 GEOMETRIC PERMUTATIONS

A directed line intersects a family $\mathcal{A}$ of pairwise disjoint convex sets in a well-defined order. Thus an undirected line transversal to $\mathcal{A}$ induces a pair of linear orderings or “permutations” on $\mathcal{A}$ consisting of the two orders in which oriented versions of the line intersect $\mathcal{A}$. Similarly an oriented k -transversal f intersects a $(k-1)$ -separated family $\mathcal{A} = \{a_1, \dots, a_n\}$ of convex sets in a well-defined k -ordering. The orientation of $(a_{i_0}, a_{i_1}, \dots, a_{i_k})$ is the orientation in f of any corresponding set of points $(x_{i_0}, x_{i_1}, \dots, x_{i_k})$, where $x_{i_j} \in a_{i_j} \cap f$. An unoriented k -transversal to a $(k-1)$ -separated family $\mathcal{A}$ of convex sets induces a pair of k -orderings on $\mathcal{A}$, consisting of the two k -orderings in which oriented versions of the k -transversal intersect $\mathcal{A}$. Each such pair of k -orderings is called a *geometric permutation* of $\mathcal{A}$.

If $\mathcal{A}$ is $(k-1)$ -separated, then two k -transversals that induce different geometric permutations on $\mathcal{A}$ must lie in different connected components of $\mathcal{T}_k^d(\mathcal{A})$. The converse also holds for hyperplane transversals.

THEOREM 4.2.18 [Wen90b]

Let $\mathcal{A}$ be a $(d-2)$ -separated family of compact convex sets in $\mathbb{R}^d$. Two hyperplane transversals induce the same geometric permutation on $\mathcal{A}$ if and only if they lie in the same connected component of $\mathcal{T}_{d-1}^d(\mathcal{A})$.

Consider geometric permutations induced by k -transversals of $(k-1)$ -separated families of compact convex sets in $\mathbb{R}^d$. Let $g_k^d(n)$ be the maximum number of such geometric permutations over all such families $\mathcal{A}$ of size n . The following is known about $g_k^d(n)$:

FIGURE 4.2.2

An example of n convex sets, two quarter circles and $n - 2$ line segments, that have $2n - 2$ geometric permutations. (From [GPW93], with permission.)

THEOREM 4.2.19

1. $g_1^2(n) = 2n - 2$ [ES90]. (See Figure 4.2.2.)
2. $g_1^d(n) = \Omega(n^{d-1})$ [KLL92].
3. $g_{d-1}^d(n) = O(n^{d-1})$ [Wen90a].
4. $g_k^d(n) = O(k)^{d^2} \left(\binom{2^{k+1}-2}{k} \binom{n}{k+1} \right)^{k(d-k)}$ (or $g_k^d(n) = O(n^{k(k+1)(d-k)})$ for fixed k and d) [GPW96].

For families of pairwise disjoint translates, special bounds hold. Note that such families also have a special Helly-type transversal theorem (Theorem 4.2.10).

THEOREM 4.2.20 [KLL87, KLL92]

A family of pairwise disjoint translates of a compact convex set in $\mathbb{R}^2$ has at most three geometric permutations.

A family of pairwise disjoint ρ -stubby compact convex sets in $\mathbb{R}^2$ has at most c_ρ geometric permutations, where the constant c_ρ depends upon ρ .

Starting with work by Smorodinsky, Mitchell and Sharir [SMS00], there has been substantial recent progress on geometric permutations of line transversals to balls.

THEOREM 4.2.21 [SMS00]

The maximum number of geometric permutations induced by line transversals to a family of n pairwise disjoint balls in $\mathbb{R}^d$ is $\Theta(n^{d-1})$.

THEOREM 4.2.22 [HXC01, KSZ03]

The maximum number of geometric permutations induced by line transversals to a sufficiently large, finite family of pairwise disjoint unit balls in $\mathbb{R}^d$ is four.

THEOREM 4.2.23 [SMS00]

The maximum number of geometric permutations induced by line transversals to a sufficiently large, finite family of pairwise disjoint unit disks in $\mathbb{R}^2$ is two.

Theorem 4.2.21 generalizes to families of ρ -fat convex sets. The constant of proportionality depends on ρ and d .

THEOREM 4.2.24 [KV01]

The maximum number of geometric permutations induced by line transversals to a family of n ρ -fat convex sets $\Theta(n^{d-1})$.

4.2.8 TRANSVERSAL ALGORITHMS

As may be expected, the time to construct a representation of $\mathcal{T}_k^d(\mathcal{A})$ is directly related to the complexity of $\mathcal{T}_k^d(\mathcal{A})$. Most algorithms use upper and lower envelopes to represent and construct $\mathcal{T}_k^d(\mathcal{A})$. (See [Chapter 24](#).) Table 4.2.2 gives known bounds on the worst case time to construct a representation of the space $\mathcal{T}_k^d(\mathcal{A})$ for various families of convex sets. All sets are assumed to be compact. As noted, for $\mathcal{T}_1^3(\mathcal{A})$ and $\mathcal{T}_3^4(\mathcal{A})$, the bound is for expected running time, not worst case time.

TABLE 4.2.2 Algorithms to construct $\mathcal{T}_k^d(\mathcal{A})$.

FAMILY	k	d	TIME COMPLEXITY	SOURCE
$(d-2)$ -separated family of n strictly convex sets with constant description complexity	$d-1$	d	$O(n^{d-1} \log^2(n))$	[CGP+94]
n convex sets with const. description complexity s.t. any two sets have at most s common supporting lines	1	2	$O(\lambda_s(n) \log n)$	[AB87]
n convex sets with const. description complexity	1	3	$O(n^{3+\epsilon}) \forall \epsilon > 0$ (exp'd.)	[KS]
n convex sets with const. description complexity	2	3	$O(n^{2+\epsilon}) \forall \epsilon > 0$	[ASS96]
n convex sets with const. description complexity	3	4	$O(n^{3+\epsilon}) \forall \epsilon > 0$ (exp'd.)	[KS]
Convex polygons with a total of n_f faces	1	2	$\Theta(n_f \log(n_f))$	[Her89]
Convex polytopes with a total of n_f faces	1	3	$O(n_f^{3+\epsilon}) \forall \epsilon > 0$	[PS92]
Convex polytopes with a total of n_f faces	2	3	$\Theta(n_f^2 \alpha(n_f))$	[EGS89]
Convex polytopes with a total of n_f faces	$d-1$	d	$O(n_f^d), d > 3$	[PS89]
n $(d-1)$ -balls	$d-1$	d	$O(n^{\lceil d/2 \rceil + 1})$	[HII ⁺ 93]
n convex homothets	1	2	$O(n \log(n))$	[Ede85]
n pairwise disjoint translates of a convex set with constant description complexity	1	2	$O(n)$	[EW89]

The model of computation used in the lower bound for the time to construct $\mathcal{T}_1^2(\mathcal{A})$ is an algebraic decision tree. In the worst case, $\mathcal{T}_2^3(\mathcal{A})$ may have $\Omega(n_f^2 \alpha(n_f))$ complexity, which gives the lower bound on constructing $\mathcal{T}_2^3(\mathcal{A})$. Similarly, $\mathcal{T}_1^3(\mathcal{A})$ may have $\Omega(n_f^3)$ complexity, giving an $\Omega(n_f^3)$ lower bound on the time to construct $\mathcal{T}_1^3(\mathcal{A})$.

4.2.9 CONVEXITY ON THE AFFINE GRASSMANNIAN

Goodman and Pollack in [GP95] extend the notion of point set convexity to convexity of a set of k -flats in $\mathbb{R}^d$, giving several alternate and equivalent formulations

of this convexity structure. In one such formulation, a set $\mathcal{F}$ of k -flats is *convex* if $\mathcal{F}$ is the transversal space of some family of convex point sets. They explore the conditions for $\mathcal{F}$ to be such a transversal space.

GLOSSARY

Convex (set of k -flats): A set $\mathcal{F}$ of k -flats is convex if $\mathcal{F}$ is the space of k -transversals to some (possibly infinite) family of convex sets in $\mathbb{R}^d$.

Surround: A set $\mathcal{F}$ of k -flats surrounds a k -flat f if there is some j -flat g containing f such that every $(j-1)$ -flat containing f and lying in g strictly separates two members of $\mathcal{F}$ also lying in g .

Convex hull (of a set of k -flats): The convex hull of a set $\mathcal{F}$ of k -flats in $\mathbb{R}^d$ is the set of all k -flats surrounded by $\mathcal{F}$ in $\mathbb{R}^d$.

THEOREM 4.2.25 [GP95]

A set $\mathcal{F}$ of k -flats in $\mathbb{R}^d$ is the space of k -transversals to some (possibly infinite) family of convex point sets in $\mathbb{R}^d$ if and only if every k -flat surrounded by $\mathcal{F}$ is in $\mathcal{F}$.

There is no Helly-type theorem for convex sets of k -flats in $\mathbb{R}^d$ since such a theorem would be equivalent to a Helly-type theorem for k -transversals in $\mathbb{R}^d$. Such convex sets may have many connected components and may even have arbitrarily complex homology. Under suitable conditions in $\mathbb{R}^3$, however, each such connected component is itself convex.

THEOREM 4.2.26 [GPW95]

Let $\mathcal{F}$ be the space of all line transversals to a finite family of pairwise disjoint compact convex sets in $\mathbb{R}^3$. Each connected component of $\mathcal{F}$ can itself be represented as the space of line transversals to some finite family of pairwise disjoint compact convex sets in $\mathbb{R}^3$.

The theorem does not hold for line transversals to infinite families of noncompact convex sets.

4.2.10 OPEN PROBLEMS

PROBLEM 4.2.27

Let $\mathcal{A}$ be a finite family of convex sets in $\mathbb{R}^2$. Prove or disprove that if every three members of $\mathcal{A}$ have a line transversal, then there are three lines whose union intersects every member of $\mathcal{A}$.

PROBLEM 4.2.28

Let $\mathcal{A}$ be a family of pairwise disjoint translates of a compact convex set in $\mathbb{R}^2$. Prove or disprove that if every three members of $\mathcal{A}$ have a line transversal, then some subfamily $\mathcal{A}' \subseteq \mathcal{A}$ containing all but four members of $\mathcal{A}$ has a line transversal.

PROBLEM 4.2.29

Prove or disprove that there exists some m such that: If every m or fewer members of a finite 1-separated family $\mathcal{A}$ of unit balls have a plane transversal, then $\mathcal{A}$ has a plane transversal. (A family is 1-separated if no three members have a line transversal.) Prove or disprove the same for a 1-separated family $\mathcal{A}$ of convex translates.

PROBLEM 4.2.30

Prove or disprove that there exist some m and r such that: If every m members of a finite family $\mathcal{A}$ of at least m convex sets in $\mathbb{R}^3$ have a line transversal, then there are r lines whose union intersects every member of $\mathcal{A}$. Prove a similar result under the conditions that out of every p members of $\mathcal{A}$ some q have a line transversal, for suitably large p and q . Generalize to k -transversals in $\mathbb{R}^d$.

PROBLEM 4.2.31

Let $\mathcal{F}$ be the space of all k -transversals to a finite $(k-1)$ -separated family of compact convex sets in $\mathbb{R}^d$. Prove or disprove that each connected component of $\mathcal{F}$ can itself be represented as the space of k -transversals to some family of convex sets in $\mathbb{R}^d$.

4.3 SOURCES AND RELATED MATERIAL

SURVEYS

The following surveys and books are excellent sources for many of the results in this chapter.

[DGK63]: The classical survey of Helly's theorem and related results.

[Eck93b]: A more recent survey of Helly's theorem and related results, updating the material in [DGK63].

[GPW93]: A survey of geometric transversal theory.

[SA95]: Contains applications of Davenport-Schinzel sequences and upper and lower envelopes to geometric transversals.

[Mat02]: A recent text covering many aspects of discrete geometry including the fractional Helly theorem and the (p, q) -problem.

5 PSEUDOLINE ARRANGEMENTS

Jacob E. Goodman

INTRODUCTION

Pseudoline arrangements generalize in a natural way arrangements of straight lines, discarding the straightness aspect, but preserving their basic topological and combinatorial properties. Elementary and intuitive in nature, at the same time, by the Folkman-Lawrence topological representation theorem (see [Chapter 6](#)), they provide a concrete geometric model for oriented matroids of rank 3.

After their explicit description by Levi in the 1920's, and the subsequent development of the theory by Ringel in the 1950's, the major impetus was given in the 1970's by Grünbaum's monograph *Arrangements and Spreads*, in which a number of results were collected and a great many problems and conjectures posed about arrangements of both lines and pseudolines. The connection with oriented matroids discovered several years later led to further work. The theory is by now very well developed, with many combinatorial and topological results and relations to other areas, as well as an increasing number of applications in computational geometry.

Section 5.1 is devoted to the basic properties of pseudoline arrangements, and Section 5.2 to related structures, such as arrangements of straight lines, configurations (and generalized configurations) of points, and allowable sequences of permutations. (We do not discuss the connection with oriented matroids, however; that is included in Chapter 6.) In Section 5.3 we discuss the stretchability problem and in Section 5.4 summarize some of the (many) combinatorial results known about line and pseudoline arrangements. Section 5.5 deals with results of a topological nature, Section 5.6 with issues of combinatorial and computational complexity, and Section 5.7 with several applications, including sweeping arrangements and visibility graphs.

Unless otherwise noted, we work in the real projective plane $\mathbf{P}^2$.

5.1 BASIC PROPERTIES

GLOSSARY

Arrangement of lines: A labeled set of lines not all passing through the same point (the latter is called a *pencil*).

Pseudoline: A simple closed curve whose removal does not disconnect $\mathbf{P}^2$.

Arrangement of pseudolines: A labeled set of pseudolines not a pencil, every pair meeting no more than once (hence exactly once and crossing).

Isomorphic arrangements: Two arrangements such that the mapping induced by their labelings is an isomorphism of the cell complexes into which they parti-

tion $\mathbf{P}^2$. (Isomorphism classes of pseudoline arrangements correspond to reorientation classes of oriented matroids of rank 3; see [Chapter 6](#).)

Stretchable: A pseudoline arrangement isomorphic to an arrangement of straight lines. Figure 5.1.1 illustrates what was once believed to be an arrangement of straight lines, but which was later proven not to be stretchable. We will see in [Section 5.6](#) that most pseudoline arrangements, in fact, are not stretchable.

FIGURE 5.1.1

An arrangement of 10 pseudolines, each containing 3 triple points; the arrangement is nonstretchable.

Vertex: The intersection of two or more pseudolines in an arrangement.

Ordinary vertex: A vertex at which only two pseudolines meet.

Simple arrangement: An arrangement (of lines or pseudolines) in which each vertex is ordinary.

Euclidean arrangement of pseudolines: An arrangement of x -monotone curves in the Euclidean plane, every pair meeting exactly once and crossing there.

Wiring diagram: A Euclidean arrangement of pseudolines consisting of piecewise linear “wires,” each horizontal except for a short segment where it crosses another wire; see Figure 5.1.2, which shows a wiring diagram labeled $1, \dots, n$ in upward order on the left and in downward order on the right.

FIGURE 5.1.2

A wiring diagram.

p -convex hull: If $\mathcal{A}$ is an arrangement of pseudolines and p is a point not contained in any member of $\mathcal{A}$, $L \in \mathcal{A}$ is in the p -convex hull of $\mathcal{B} \subset \mathcal{A}$ if every path from p to a point of L meets some member of $\mathcal{B}$.

A fundamental tool in working with arrangements of pseudolines, which takes the place of the fact that two points determine a line, is the following.

THEOREM 5.1.1 *Levi Enlargement Lemma* [Lev26]

If $\mathcal{A} = \{L_1, \dots, L_n\}$ is an arrangement of pseudolines and $p, q \in \mathbf{P}^2$ are two distinct points not on the same member of $\mathcal{A}$, there is a pseudoline L passing through p and q such that $\mathcal{A} \cup \{L\}$ is an arrangement.

Theorem 5.1.1 has been shown by Goodman and Pollack [GP81b] not to extend to arrangements of pseudohyperplanes. It has, however, been extended by Snoeyink and Hershberger to the case of “2-intersecting curves” (where three points are given) [SH91], and shown by them not to extend to k -intersecting curves and $k + 1$ points for $k > 2$.

The Levi Enlargement Lemma is used to prove extensions to pseudoline arrangements of a number of convexity results on arrangements of straight lines, duals of statements perhaps better known in the setting of configurations of points: Helly’s theorem, Radon’s theorem, Carathéodory’s theorem, Kirchberger’s theorem, the Hahn -Banach theorem, the Krein-Milman theorem, and Tverberg’s generalization of Radon’s theorem (cf. [Chapter 4](#)). We state two of these.

THEOREM 5.1.2 *Helly’s Theorem for Pseudoline Arrangements* [GP82a]

If $A_1, \dots, A_n$ are subsets of an arrangement A of pseudolines, and p is a point not on any pseudoline of A such that, for any i, j, k , A contains a pseudoline in the p -convex hull of each of A_i, A_j, A_k , then there is an extension A' of A containing a pseudoline lying in the p -convex hull of each of $A_1, \dots, A_n$.

THEOREM 5.1.3 *Tverberg’s Theorem for Pseudoline Arrangements* [Rou88b]

If $A = \{L_1, \dots, L_n\}$ is a pseudoline arrangement with $n \geq 3m - 2$, and p is a point not on any member of A , then A can be partitioned into subarrangements $A_1, \dots, A_m$ and extended to an arrangement A' containing a pseudoline lying in the p -convex hull of A_i for every $i = 1, \dots, m$.

Some of these convexity theorems, but not all, extend to higher dimensional arrangements; see [BLS⁺99, Sections 9.2, 10.4], as well as Section 14.3 of this Handbook.

It is not difficult to see that the pseudolines in an arrangement may be drawn as polygonal lines, with bends only at vertices [Grü72]. Related to this is the following representation, which will be discussed further in Section 5.3.

THEOREM 5.1.4 [Goo80]

Every arrangement of pseudolines is isomorphic to a wiring diagram.

Theorem 5.1.4 is used in proving the following duality theorem, which extends to the setting of pseudolines the fundamental duality theorem between lines and points in the projective plane.

THEOREM 5.1.5 [Goo80]

If A is a pseudoline arrangement and S a point set in $\mathbf{P}^2$, and if I is the set of all true statements of the form “ $p \in S$ is incident to $L \in A$,” then there is a pseudoline arrangement $\hat{S}$ and a point set $\hat{A}$ such that the set of all incidences holding between members of $\hat{A}$ and members of $\hat{S}$ is precisely the dual $\hat{I}$ of I .

THEOREM 5.1.6 [AS02]

For Euclidean arrangements, the result of Theorem 5.1.5 holds with the additional property that the duality preserves above-below relationships as well.

5.2 RELATED STRUCTURES

GLOSSARY

Circular sequence of permutations: A doubly infinite sequence of permutations of $1, \dots, n$ associated with an arrangement $\mathcal{A}$ of lines $L_1, \dots, L_n$ by sweeping a directed line across $\mathcal{A}$; see Figure 5.2.3 and the corresponding sequence below.

Local equivalence: Two circular sequences of permutations are locally equivalent if, for each index i , the order in which it switches with the remaining indices is either the same or opposite in the two sequences; see Figure 5.2.4 and Theorem 5.2.2 below.

Local sequence of unordered switches: In a wiring diagram, the permutation α_i given by the order in which the remaining pseudolines cross the i th pseudoline of the arrangement. In Figure 5.1.2, for example, α_2 is $(1, 5, \{3, 4\})$.

Configuration of points: A (labeled) family $\mathcal{S} = \{p_1, \dots, p_n\}$ of points, not all collinear, in $\mathbf{P}^2$.

Order type of a configuration $\mathcal{S}$: The mapping that assigns to each ordered triple i, j, k in $\{1, \dots, n\}$ the orientation of the triple (p_i, p_j, p_k) .

Combinatorial equivalence: Configurations $\mathcal{S}$ and $\mathcal{S}'$ are combinatorially equivalent if the set of permutations of $1, \dots, n$ obtained by projecting $\mathcal{S}$ onto every line in general position agrees with the corresponding set for $\mathcal{S}'$.

Generalized configuration: A finite set of points in $\mathbf{P}^2$, together with a pseudoline joining each pair, the pseudolines forming an arrangement. (Several connecting pseudolines may coincide.) This is sometimes called a *pseudoconfiguration*. An example is shown in Figure 5.2.1.

FIGURE 5.2.1

A generalized configuration of 5 points.

Allowable sequence of permutations: A doubly infinite sequence of permutations of $1, \dots, n$ satisfying the three conditions of Theorem 5.2.1. It follows from those conditions that the sequence is periodic of length $\leq n(n-1)$, and that its period has length $n(n-1)$ if and only if the sequence is *simple*, i.e., each move consists of the switch of a single pair of indices.

ARRANGEMENTS OF STRAIGHT LINES

Much of the work on pseudoline arrangements has been motivated by problems involving straight-line arrangements. In some cases the question has been whether known results in the case of lines really depended on the *straightness* of the lines; for many (but not all) combinatorial results the answer has turned out to be negative. In other cases, generalization to pseudolines (or, equivalently, reformulations in terms of allowable sequences of permutations—see below) has permitted the solution of a more general problem where none was known previously in the straight case. Finally, pseudolines have turned out to be more useful than lines for certain algorithmic applications; this will be discussed in Section 5.7.

For arrangements of straight lines, there is a rich history of combinatorial results, some of which will be summarized in Section 5.4. Much of this is discussed in [Grü72].

Line arrangements are often classified by isomorphism type. For (unlabeled) arrangements of five lines, for example, Figure 5.2.2 illustrates the four possible isomorphism types, only one of which is simple.

FIGURE 5.2.2
The 4 isomorphism types
of arrangements of 5 lines.

There is a second classification of (numbered) line arrangements, which has proven quite useful for certain problems. If a distinguished point not on any line of the arrangement is chosen to play the part of the “vertical point at infinity,” we can think of the arrangement $\mathcal{A}$ as an arrangement of nonvertical lines in the Euclidean plane, and of P_∞ as the “upward direction.” Rotating a directed line through P_∞ then amounts to sweeping a directed vertical line through $\mathcal{A}$ from left to right (say). We can then note the order in which this directed line cuts the lines of $\mathcal{A}$, and we arrive at a periodic sequence of permutations of $1, \dots, n$, known as the *circular sequence of permutations* belonging to $\mathcal{A}$ (depending on the choice of P_∞ and the direction of rotation). This sequence is actually doubly infinite, since the rotation of the directed line through P_∞ can be continued in both directions. For the arrangement in Figure 5.2.3, for example, the circular sequence is

$$\mathcal{A}: \quad \dots 12345 \xrightarrow{12,45} 21354 \xrightarrow{135} 25314 \xrightarrow{25,14} 52341 \xrightarrow{234} 54321 \dots$$

Notice how the “moves” between permutations are indicated.

THEOREM 5.2.1 [GP84]

A circular sequence of permutations arising from a line arrangement has the following properties:

FIGURE 5.2.3
An arrangement of 5 lines.

- (i) The move from each permutation to the next consists of the reversal of one or more nonoverlapping adjacent substrings;
- (ii) After a move in which i and j switch, they do not switch again until every other pair has switched;
- (iii) $1, \dots, n$ do not all switch simultaneously with each other.

If two line arrangements are isomorphic, they may have different circular sequences, depending on the choice of P_∞ (and the direction of rotation). We do have, however:

THEOREM 5.2.2 [GP84]

If A and A' are arrangements of lines in $\mathbf{P}^2$, and Σ and Σ' are any circular sequences of permutations corresponding to A and A' , then A and A' are isomorphic if and only if Σ and Σ' are locally equivalent.

FIGURE 5.2.4
Another arrangement of 5 lines.

Theorem 5.2.2 is illustrated in Figure 5.2.4. Here, the circular sequence of the arrangement A' , which (as an arrangement in $\mathbf{P}^2$) is isomorphic to arrangement A of Figure 5.2.3, is

$$A' : \quad \dots 35124 \xrightarrow{12} 35214 \xrightarrow{52,14} 32541 \xrightarrow{54} 32451 \xrightarrow{324} 42351 \xrightarrow{351} 42153 \dots$$

Reading off the local sequences of unordered switches of each, we get:

	1:	2:	3:	4:	5:
A :	$\dots; 2; 3, 5; 4; \dots$	$\dots; 1; 5; 3, 4; \dots$	$\dots; 1, 5; 2, 4; \dots$	$\dots; 5; 1; 2, 3; \dots$	$\dots; 4; 1, 3; 2; \dots$
A' :	$\dots; 2; 4; 3, 5; \dots$	$\dots; 1; 5; 3, 4; \dots$	$\dots; 2, 4; 1, 5; \dots$	$\dots; 1; 5; 2, 3; \dots$	$\dots; 2; 4; 1, 3; \dots$

We see that the 2-, 3-, and 5-sequences agree, while the 1- and 4-sequences are reversed.

CONFIGURATIONS OF POINTS

Under projective duality, arrangements of lines in $\mathbf{P}^2$ correspond to configurations of points. Some questions seem more natural in this setting of points, however, such as the Sylvester-Erdős problem about the existence of an ordinary line in a noncollinear configuration of points, and Scott's conjecture that the minimum number of directions determined by n noncollinear points is $2\lfloor n/2 \rfloor$.

Corresponding to the classification of line arrangements by isomorphism type, it turns out that the “dual” classification of point configurations is by order type.

THEOREM 5.2.3 [GP84]

If A and A' are arrangements of lines in $\mathbf{P}^2$ and S and S' the point sets dual to them, then A and A' are isomorphic if and only if S and S' have the same (or opposite) order types.

From a configuration of points one also derives a circular sequence of permutations in a natural way, by projecting the points onto a rotating line; this gives a finer classification than order type. The sequence for the arrangement in Figure 5.2.3 comes from the configuration in Figure 5.2.5 in this way.

FIGURE 5.2.5
A configuration of 5 points.

In fact, it follows from projective duality that:

THEOREM 5.2.4 [GP82b]

A sequence of permutations is realizable by points if and only if it is realizable by lines.

The circular sequence of a point configuration can be reconstructed from the set of permutations obtained by projecting it onto all lines in general position.

THEOREM 5.2.5 [GP84]

Two configurations have the same circular sequences if and only if they are combinatorially equivalent.

This becomes useful in higher dimensions (where the circular sequence generalizes to a somewhat unwieldy cell decomposition of a sphere with a permutation associated with every cell), since it means that all one really needs to know is the set of permutations; how they fit together can then be determined.

See Chapter 1 of this Handbook for some recent results and some unsolved problems on point configurations.

GENERALIZED CONFIGURATIONS

Just as pseudoline arrangements generalize arrangements of straight lines, generalized configurations provide the corresponding generalization of configurations of points.

The two classifications described above for point configurations, by order type and by circular sequence of permutations, extend in a natural way to generalized configurations. For example, a circular sequence for the generalized configuration in [Figure 5.2.1](#), which is determined by the cyclic order in which the connecting pseudolines meet a distinguished pseudoline (in this case the “pseudoline at infinity”), is

... 12345³⁴12435¹²21435¹⁴24135³⁵24153¹⁵24513²⁴42513²⁵45213¹³45231²³45321⁴⁵54321 ...

ALLOWABLE SEQUENCES

An allowable sequence of permutations is a combinatorial abstraction of the circular sequence of permutations associated with an arrangement of lines or a configuration of points. We can define, in a natural way, a number of geometric concepts for allowable sequences, such as *collinearity*, *betweenness*, *orientation*, *extreme point*, *convex hull*, *semispace*, *convex n -gon*, *parallel*, etc [GP80a]. Not all allowable sequences are realizable, however, the smallest example being the sequence corresponding to [Figure 5.2.1](#). A realization of this sequence would have to be a drawing of the **bad pentagon** of [Figure 5.2.1](#) with straight lines, and it is not hard to prove that this is impossible.

More generally, we have:

THEOREM 5.2.6 [GP80a]

Suppose Σ is an allowable sequence with extreme points $1, \dots, n$ in counterclockwise order such that, for every i , side $i, i + 1$ extended past vertex $i + 1$ meets diagonal $i - 1, i + 2$ extended past vertex $i + 2$ (the numbering is modulo n). Then Σ is not realizable by a configuration of points.

Allowable sequences provide a means of rephrasing many geometric problems about point configurations or line arrangements in combinatorial terms. For example, Scott’s conjecture on the minimum number of directions determined by n lines has the simple statement: “Every allowable sequence of permutations of $1, \dots, n$ has at least $2\lfloor n/2 \rfloor$ moves in a half-period.” It was proved in this more general form by Ungar [Ung82], and the proof of the original Scott conjecture follows as a corollary; see also [Jam85], [BLS⁺99, Section 1.11], and [AZ99, Chapter 9].

The Erdős-Szekeres problem (see [Chapter 1](#) of this Handbook) looks as follows in this more general combinatorial formulation:

PROBLEM 5.2.7 Generalized Erdős-Szekeres Problem [GP81a]

What is the minimum n such that for every simple allowable sequence Σ on $1, \dots, n$, there are k indices with the property that each occurs before the other $k - 1$ in some term of Σ ?

Allowable sequences arise from pseudoline arrangements by way of wiring diagrams (see [Theorem 5.1.4](#) above), from which they can be read off by sweeping a line across from left to right, just as with an arrangement of straight lines, and they

arise as well from generalized configurations just as from configurations of points. In fact, the following theorem is just a restatement of Theorem 5.1.5.

THEOREM 5.2.8 [GP84]

Every allowable sequence of permutations can be realized both by an arrangement of pseudolines and by a generalized configuration of points.

Allowable sequences have been used to prove the following results, related to the “ k -set” problem (see [Chapter 1](#)):

THEOREM 5.2.9 [Pin03]

Let L be a wiring diagram of size $2n + O(\log \log n)$. Then L has a vertex that is strictly below at least n pseudolines of L and strictly above at least n others.

COROLLARY 5.2.10 [Pin03]

Let L be a wiring diagram of size n . Then L has a vertex P such that the difference between the number of pseudolines strictly above P and the number of those strictly below P is $O(\log \log n)$.

THEOREM 5.2.11 [PP01]

Let L be a simple wiring diagram consisting of n blue and n red pseudolines, and call a vertex P balanced if P is the intersection of a blue and a red pseudoline such that the number of blue pseudolines strictly above P equals the number of red pseudolines strictly above P (and hence the same holds for those strictly below P as well). Then L has at least n balanced vertices, and this result is tight.

WIRING DIAGRAMS

Wiring diagrams provide the simplest “geometric” realizations of allowable sequences. To realize the sequence

$$A: \quad \dots 12345 \overset{12,45}{\rule{0.5em}{0.4pt}} 21354 \overset{135}{\rule{0.5em}{0.4pt}} 25314 \overset{25,14}{\rule{0.5em}{0.4pt}} 52341 \overset{234}{\rule{0.5em}{0.4pt}} 54321 \dots,$$

for example, simply start with horizontal “wires” labeled $1, \dots, n$ in (say) increasing order from bottom to top, and, for each move in the sequence, let the corresponding wires cross. This gives the wiring diagram of [Figure 5.1.2](#), and at the end the wires have all reversed order. (It is then easy to extend the curves in both directions to the “line at infinity,” thereby arriving at a pseudoline arrangement in $\mathbf{P}^2$.)

We have the following isotopy theorem for wiring diagrams.

THEOREM 5.2.12 [GP85a]

If two wiring diagrams numbered $1, \dots, n$ in order are isomorphic as labeled pseudoline arrangements, then one can be deformed continuously to the other (or to its reflection) through wiring diagrams isomorphic as pseudoline arrangements.

LOCAL SEQUENCES AND CLUSTERS OF STARS

The following theorem (proved independently by Streinu and by Felsner and Weil) solves the “cluster of stars” problem posed in [GP84]; we state it here in terms of local sequences of wiring diagrams, as in [FW01].

THEOREM 5.2.13 [Str97, FW01]

A set $(\alpha_i)_{i=1,\dots,n}$ with each α_i a permutation of $\{1, \dots, i-1, i+1, \dots, n\}$, is the set of local sequences of unordered switches of a simple wiring diagram if and only if for all $i < j < k$ the pairs $\{i, j\}$, $\{i, k\}$, $\{j, k\}$ appear all in natural order or all in inverted order in α_k , α_j , α_i (resp.).

HIGHER DIMENSIONS

Just as isomorphism classes of pseudoline arrangements correspond to oriented matroids of rank 3, the corresponding fact holds for higher-dimensional arrangements, known as arrangements of pseudohyperplanes: they correspond to oriented matroids of rank $d+1$ (see Theorem 6.2.4 in Chapter 6 of this Handbook).

It turns out, however, that in dimensions > 2 , generalized configurations of points are (surprisingly) more restrictive than such oriented matroids; thus it is only in the plane that “projective duality” works fully in this generalized setting; see [BLS⁺99, Section 5.3].

5.3 STRETCHABILITY**STRETCHABLE AND NONSTRETCHABLE ARRANGEMENTS**

Stretchability can be described in either combinatorial or topological terms:

THEOREM 5.3.1 [BLS⁺99, Section 6.3]

Given an arrangement $\mathcal{A}$ of pseudolines in $\mathbf{P}^2$, the following are equivalent.

- (i) The cell decomposition induced by $\mathcal{A}$ is combinatorially isomorphic to that induced by some arrangement of straight lines;
- (ii) Some homeomorphism of $\mathbf{P}^2$ to itself maps every $L_i \in \mathcal{A}$ to a straight line.

FIGURE 5.3.1

An arrangement that violates the theorem of Pappus.

Among the first examples observed of a nonstretchable arrangement of pseudolines was the non-Pappus arrangement of 9 pseudolines constructed by Levi: see Figure 5.3.1. Since Pappus's theorem says that points p , q , and r must be collinear if the pseudolines are straight, the arrangement in Figure 5.3.1 is clearly nonstretchable. A second example, involving 10 pseudolines, can be constructed similarly by violating Desargues's theorem.

Ringel showed how to convert the non-Pappus arrangement into a *simple* arrangement that was still nonstretchable. A symmetric drawing of it is shown in Figure 5.3.2.

FIGURE 5.3.2
A simple nonstretchable arrangement
of 9 pseudolines.

Using allowable sequences, Goodman and Pollack proved the conjecture of Grünbaum that the non-Pappus arrangement has the smallest size possible for a nonstretchable arrangement:

THEOREM 5.3.2 [GP80b]

Every arrangement of 8 or fewer pseudolines is stretchable.

In addition, Richter-Gebert proved that the non-Pappus arrangement is unique among simple arrangements of the same size.

THEOREM 5.3.3 [Ric89]

Every simple arrangement of 9 pseudolines is stretchable, with the exception of the simple non-Pappus arrangement.

The “bad pentagon” of Figure 5.2.1, with extra points inserted to “pin down” the intersections of the sides and corresponding diagonals, provides another example of a nonstretchable arrangement; and Theorem 5.2.6, with extra points, provides, after dualizing, an infinite family of nonstretchable arrangements that were proved, by Bokowski and Sturmfels [BS89a], to be “minor-minimal.” This shows that stretchability of simple arrangements cannot be guaranteed by the exclusion of a finite number of “forbidden” subarrangements. A similar example was found by Haiman and Kahn; see [BLS⁺99, Section 8.3].

As for arrangements of more than 8 pseudolines, we have:

THEOREM 5.3.4 [GPWZ94]

Let $\mathcal{A}$ be an arrangement of n pseudolines. If some face of $\mathcal{A}$ is bounded by at least $n - 1$ pseudolines, then $\mathcal{A}$ is stretchable.

Finally, Shor shows in [Sho91] that even if a stretchable pseudoline arrangement has a symmetry, it may be impossible to realize this symmetry in any stretching.

THEOREM 5.3.5 [Sho91]

There exists a stretchable, simple pseudoline arrangement with a combinatorial symmetry such that no isomorphic arrangement of straight lines has the same combinatorial symmetry.

GENERALIZATIONS OF STRETCHABILITY

While not every pseudoline arrangement is isomorphic to an arrangement of straight lines, every pseudoline arrangement is ***d-stretchable***, i.e., realizable by an arrangement of graphs of polynomial functions of sufficiently high degree d . The following result gives the best bounds known on this degree.

THEOREM 5.3.6 [GP85b]

Let d_n be the smallest number d such that every simple arrangement of n pseudolines is d -stretchable. Then, for appropriate $c_1, c_2 > 0$, we have $c_1\sqrt{n} \leq d_n \leq c_2n^2$.

In several papers [PV94, PV96], Pocchiola and Vegter explore another kind of realizability of pseudoline arrangements, by what they call arrangements of pseudotriangles. A ***pseudotriangle*** is a simply connected, bounded subset T of $\mathbb{R}^2$, bounded by 3 convex arcs pairwise tangent at their endpoints, such that T is contained in the triangle formed by these endpoints. The set T^* of directed tangent lines to the boundary of T can be identified by duality with a pseudoline in $\mathbb{P}^2$. Because two disjoint pseudotriangles share exactly one common tangent, if $\mathcal{T} = \{T_1, \dots, T_n\}$ is an arrangement of pairwise disjoint pseudotriangles, the curves $T_1^*, \dots, T_n^*$ form an arrangement of pseudolines which is “realized” by the arrangement $\mathcal{T}$. They prove:

THEOREM 5.3.7 [PV94]

- (i) *Every arrangement of straight lines is isomorphic to one realizable by an arrangement of disjoint pseudotriangles.*
- (ii) *Every arrangement of pseudolines is isomorphic to one realizable by an arrangement of pseudotriangles.*

CONJECTURE 5.3.8 [PV94]

Every arrangement of pseudolines is isomorphic to one realizable by disjoint pseudotriangles.

5.4 COMBINATORIAL RESULTS

Although there are exceptions (see below), most combinatorial results known for line arrangements hold for pseudoline arrangements as well. We survey these in this section, including a number of results that update Grünbaum’s comprehensive 1972 survey [Grü72]. For a discussion of *levels in arrangements* (dually, *k-sets*), see [Chapters 24](#) and [1](#), respectively.

GLOSSARY

Simplicial arrangement: An arrangement of lines or pseudolines in which every cell is a triangle.

Near-pencil: An arrangement with all but one line (or pseudoline) concurrent.

Projectively unique: A line arrangement $\mathcal{A}$ with the property that every isomorphic line arrangement is the image of $\mathcal{A}$ under a projective transformation.

x-monotone path: In an arrangement of lines in $\mathbb{R}^2$, or in a wiring diagram, a path monotonic in the first coordinate, each step following a line (or wire) from one vertex to another. The *length* of an *x-monotone* path is one more than the number of turns from one (pseudo)line to another.

SYLVESTER-TYPE RESULTS

CONJECTURE 5.4.1 [Grü69]

Every arrangement of n pseudolines has at least $\lfloor n/2 \rfloor$ ordinary vertices.

The strongest result to date on Conjecture 5.4.1 is the following theorem of Csima and Sawyer (cf. [Chapter 1](#)), which uses previous work of Hansen and improves a long-standing result of Kelly and Moser.

THEOREM 5.4.2 [CS93]

Every arrangement of n pseudolines, with the exception of the one shown in [Figure 1.1.1\(b\)](#), has at least $6n/13$ ordinary vertices.

The arrangement shown in [Figure 1.1.1\(a\)](#) shows that this result is sharp (see [Chapter 1](#) of this Handbook for more details).

Using (complex) algebro-geometric methods, Hirzebruch was able to prove the following result about the number t_i of vertices of multiplicity exactly i in an arrangement of *straight* lines.

THEOREM 5.4.3 [Hir83]

If an arrangement of n lines is not a near-pencil, then

$$t_2 + \frac{3}{4}t_3 \geq n + t_5 + 2t_6 + 3t_7 + \dots$$

RELATIONS AMONG NUMBERS OF VERTICES, EDGES, AND FACES

THEOREM 5.4.4 *Euler*

If $f_i(\mathcal{A})$ is the number of faces of dimension i in the cell decomposition of $\mathbf{P}^2$ induced by an arrangement $\mathcal{A}$, then $f_0(\mathcal{A}) - f_1(\mathcal{A}) + f_2(\mathcal{A}) = 1$.

In addition to ***Euler's formula***, the following inequalities are satisfied for arbitrary pseudoline arrangements (here, $n(\mathcal{A})$ is the number of pseudolines in the arrangement $\mathcal{A}$).

THEOREM 5.4.5 [Grü72, SE88]

- (i) $1 + f_0(\mathcal{A}) \leq f_2(\mathcal{A}) \leq 2f_0(\mathcal{A}) - 2$, with equality on the left for precisely the simple arrangements, and on the right for precisely the simplicial arrangements;
- (ii) $n(\mathcal{A}) \leq f_0(\mathcal{A}) \leq \binom{n(\mathcal{A})}{2}$, with equality on the left for precisely the near-pencils, and on the right for precisely the simple arrangements;
- (iii) For $n \gg 0$, every f_0 satisfying $n^{3/2} \leq f_0 \leq \binom{n}{2}$, with the exceptions of $\binom{n}{2} - 3$ and $\binom{n}{2} - 1$, is the number of vertices of some arrangement of n pseudolines (in fact, of straight lines);

- (iv) $2n(\mathcal{A}) - 2 \leq f_2(\mathcal{A}) \leq \binom{n(\mathcal{A})}{2} + 1$, with equality on the left for precisely the near-pencils, and on the right for precisely the simple arrangements;
- (v) $f_2(\mathcal{A}) \geq 3n(\mathcal{A}) - 6$ if $\mathcal{A}$ is not a near-pencil.

There are gaps in the possible values for $f_2(\mathcal{A})$, as shown by Theorem 5.4.6, which proves a conjecture posed by Grünbaum and generalized by Purdy, refining Theorem 5.4.5(iv).

THEOREM 5.4.6 [Mar93]

There exists an arrangement $\mathcal{A}$ of n pseudolines with $f_2(\mathcal{A}) = f$ if and only if, for some integer k with $1 \leq k \leq n-2$, we have $(n-k)(k+1) + \binom{k}{2} - \min(n-k, \binom{k}{2}) \leq f \leq (n-k)(k+1) + \binom{k}{2}$. Moreover, if $\mathcal{A}$ exists, it can be chosen to consist of straight lines.

Finally, the following result (proved in the more general setting of geometric lattices) gives a complete set of inequalities for the flag vectors $(n(\mathcal{A}), f_0(\mathcal{A}), i(\mathcal{A}))$ of pseudoline arrangements; here $i(\mathcal{A})$ is the number of vertex-pseudoline incidences determined by the arrangement $\mathcal{A}$.

THEOREM 5.4.7 [Nym01]

The closed convex set generated by all the flag vectors of pseudoline arrangements is determined by the inequalities $i \leq 3f_0 - 3$, $i \geq 2f_0$, $f_0 \geq n$, $n \geq 3$, and, for all $k \in \mathbb{Z}_+$, $(k-1)i - kn - (2k-3)f_0 + \binom{k+1}{2} \geq 0$. This set is minimal for $k \geq 3$.

THE NUMBER OF CELLS OF DIFFERENT SIZES

It is easy to see by induction that a *simple* arrangement of more than 3 pseudolines must have at least one nontriangular cell. This observation leads to many questions about numbers of cells of different types in both simple and nonsimple arrangements, some of which have not yet been answered satisfactorily.

The best result on the maximum number of triangles is the following.

THEOREM 5.4.8 [Grü72, Har85, Rou96, FR98]

The maximum number of triangles in an arrangement of $n \geq 9$ pseudolines is bounded above by $\lfloor n(n-1)/3 \rfloor$, with this bound achieved for infinitely many values of n , even for simple straight line arrangements.

For an algorithm to generate all pseudoline arrangements with a maximal number of triangles, and for connections with other combinatorial structures, as well as a generalization of pseudoline arrangements in $\mathbb{R}^2$ to closed curve arrangements on other surfaces, see [BRS97] and [BP].

PROBLEM 5.4.9 [Grü72]

What is the maximum number of k -sided cells in an arrangement of n pseudolines, for $k > 3$?

On the minimum number of triangles, we have:

THEOREM 5.4.10 [Lev26]

In any arrangement of pseudolines, every pseudoline borders at least 3 triangles. Hence every arrangement of n pseudolines determines at least n triangles.

This minimum is achieved by the “cyclic arrangements” of lines generated by regular polygons, as in Figure 5.4.1.

FIGURE 5.4.1

A cyclic arrangement of 9 lines.

For arrangements in the Euclidean plane $\mathbb{R}^2$, on the other hand, we have:

THEOREM 5.4.11 [FK99]

- (i) *Every simple arrangement of n pseudolines in $\mathbb{R}^2$ contains at least $n - 2$ triangles, with equality achieved for all $n \geq 3$.*
- (ii) *Every arrangement of n pseudolines in $\mathbb{R}^2$ contains at least $2n/3$ triangles, with equality achieved for all $n \equiv 0 \pmod{3}$.*
- (iii) *Every arrangement of n pseudolines in $\mathbb{R}^2$ contains at most $n(n-2)/3$ triangles, with equality achieved for infinitely many values of n .*

The following result distinguishes line from pseudoline arrangements.

THEOREM 5.4.12 [Rou88a]

An arrangement of n lines with only n triangles is simple. However, there exist nonsimple arrangements of n pseudolines with only n triangles.

An example of the second assertion of Theorem 5.4.12 is obtained by “collapsing” the central triangle in Figure 5.3.2.

A similar result for quadrilaterals is the following.

THEOREM 5.4.13 [Grü72, Rou87, FR01]

- (i) *Every arrangement of $n \geq 5$ pseudolines contains at most $n(n-3)/2$ quadrilaterals. For straight-line arrangements, this bound is achieved by a unique simple arrangement for each n .*
- (ii) *A pseudoline arrangement containing $n(n-3)/2$ quadrilaterals must be simple.*

There are infinitely many simple pseudoline arrangements with no quadrilaterals, contrary to what was once believed. The following result implies, however, that there must be many quadrilaterals or pentagons in *every* simple arrangement.

THEOREM 5.4.14 [Rou87]

Every pseudoline in a simple arrangement of $n > 3$ pseudolines borders at least 3 quadrilaterals or pentagons. Hence, if p_4 is the number of quadrilaterals and p_5 the number of pentagons in a simple arrangement, we must have $4p_4 + 5p_5 \geq 3n$.

The following result was proved after the opposite had been conjectured.

THEOREM 5.4.15 [LRS89]

There is a simple arrangement of straight lines containing no two adjacent triangles.

The proof involved finding a pseudoline arrangement with this property, then showing (algebraically, using Bokowski's "inequality reduction method"—see [Section 5.6](#)) that the arrangement, which consists of 12 pseudolines, is stretchable.

SIMPLICIAL ARRANGEMENTS

In addition to 91 “sporadic” examples of simplicial arrangements of straight lines, the following infinite families are known.

THEOREM 5.4.16 [Grü72]

Each of the following arrangements is simplicial:

- (i) *the near-pencil of n lines;*
- (ii) *the sides of a regular n -gon, together with its n axes of symmetry;*
- (iii) *the arrangement in (ii), together with the line at infinity, for n even.*

On the other hand, additional infinite families of (nonstretchable) simplicial arrangements of pseudolines are known, which are constructible from regular polygons by extending sides, diagonals, and axes of symmetry and modifying the resulting arrangement appropriately. For example, Figure 5.4.2 shows a member of such a family having 31 pseudolines, constructed from a decagon in this way.

FIGURE 5.4.2

A simplicial arrangement of 31 pseudolines. (The line at infinity, where “parallel” lines meet, is shown as a circle.)

One of the most important problems on arrangements is the following.

PROBLEM 5.4.17 [Grü72]

Classify all simplicial arrangements of pseudolines. Which of these are stretchable? In particular, are there any infinite families of simplicial line arrangements besides the three of Theorem 5.4.16?

It has apparently not been disproved that every (pseudo)line arrangement is a subarrangement of a simplicial (pseudo)line arrangement.

CONJECTURE 5.4.18 [Grü72]

Except for near-pencils, every simplicial arrangement of straight lines is projectively unique.

Finally, putting together results of Strommer and of Csimá and Sawyer, we get the following theorem; part (ii) is only a slight improvement over the corresponding result for nonsimplicial arrangements.

THEOREM 5.4.19 [Str77, CS93]

- (i) *For every even n , there is a simplicial arrangement of n lines with a total of $(n^2 + 10n - 8)/8$ cells;*
- (ii) *Except for the arrangement of [Figure 1.1.1\(b\)](#), the number of cells in a simplicial arrangement of n pseudolines is $\leq n(n - 1)/3 + 4 - 4n/13$.*

PATHS IN PSEUDOLINE ARRANGEMENTS

The following result is most easily stated in terms of wiring diagrams.

THEOREM 5.4.20 [Mat91, RT03]

The maximum length of an x -monotone path in a wiring diagram of size n is $\Omega(n^2 / \log n)$, and in an arrangement of n lines is $\Omega(n^{7/4})$.

The only upper bound known for the lengths of such paths is the trivial one, $O(n^2)$ (refined to $5n^2/12$ in [RT03]).

For related results on k -levels in arrangements, see [Chapter 24](#).

COMPLEXITY OF SETS OF CELLS IN AN ARRANGEMENT

For cells that “line up” in an arrangement, the best result is:

THEOREM 5.4.21 *Zone Theorem* [BEPY91]

The sum of the numbers of sides in all the cells of an arrangement of $n + 1$ pseudolines that are supported by one of the pseudolines is $\leq 19n/2 - 1$; this bound is tight.

For general sets of faces, on the other hand, Canham proved:

THEOREM 5.4.22 [Can69]

If $F_1, \dots, F_k$ are any k distinct faces of an arrangement of n pseudolines, then $\sum_{i=1}^k p(F_i) \leq n + 2k(k - 1)$, where $p(F)$ is the number of sides of a face F . This is tight for $2k(k - 1) \leq n$.

For $2k(k - 1) > n$, this was improved by Clarkson et al. to the following result, with simpler proofs later found by Székely and by Dey and Pach; the tightness follows from a result of Szemerédi and Trotter, proved independently by Edelsbrunner and Welzl.

THEOREM 5.4.23 [ST83, EW86, CEG⁺90, Szé97, DP98]

The total number of sides in any k distinct cells of an arrangement of n pseudolines is $O(k^{2/3}n^{2/3} + n)$. This bound is (asymptotically) tight in the worst case.

There are a number of results of this kind for arrangements of objects in the plane and in higher dimensions; see [Chapter 24](#), as well as [CEG⁺90].

SEPARATING POINTS BY LINES AND PSEUDOLINES

Da Silva and Fukuda [DF98] say that a set L of (pseudo)lines **isolates** a set P consisting of n points in the plane if each point of P lies in a distinct cell of L . They give an algorithm to determine the smallest possible size of an isolating set, and prove:

THEOREM 5.4.24 [DF98]

Let $r(P)$ be the largest number of collinear points of P , and $l(P)$ (resp. $l'(P)$) the smallest possible size of an isolating set of lines (resp. pseudolines) for P . If $r(P) > \lceil n/2 \rceil$, then $l(P) = r(P) - 1$. If $r(P) \leq \lceil n/2 \rceil$, then $\max\{\lceil (-1 + \sqrt{8n-7})/2 \rceil, r(P) - 1\} \leq l(P) \leq \lceil n/2 \rceil$. Moreover, $l'(P) = \lceil (-1 + \sqrt{8n-7})/2 \rceil$.

5.5 TOPOLOGICAL PROPERTIES

GLOSSARY

Spread: Given the projective plane $\mathbf{P}^2$ with a distinguished line L_∞ , a spread of pseudolines is a family $\mathcal{L} = \{L_x\}_{x \in L_\infty}$ of pseudolines varying continuously with $x = L_x \cap L_\infty$, any two of which meet at a single point (at finite distance).

Topological projective plane: $\mathbf{P}^2$, with a distinguished family $\mathcal{L}$ of pseudolines (its “lines”), is a topological projective plane if, for each $p, q \in \mathbf{P}^2$, exactly one $L_{p,q} \in \mathcal{L}$ passes through p and q , with $L_{p,q}$ varying continuously with p and q .

(There are other notions of both “spread” and “projective plane” [Grü72], but the ones defined here have the closest connection with pseudoline arrangements.)

Isomorphism of topological projective planes: A homeomorphism that maps “lines” to “lines.”

Universal topological projective plane: One containing an isomorphic copy of every pseudoline arrangement.

Topological sweep: If $\mathcal{A}$ is a pseudoline arrangement in the Euclidean plane and $L \in \mathcal{A}$, a topological sweep of $\mathcal{A}$ “starting at L ” is a continuous family of pseudolines including L , each compatible with $\mathcal{A}$, which forms a partition of the plane.

Basic semialgebraic set: The set of solutions to a finite number of polynomial equations and strict polynomial inequalities in $\mathbb{R}^d$. (This term is sometimes used even if the inequalities are not necessarily strict.)

Stable equivalence: A relation on semialgebraic sets that preserves homotopy type. A precise definition appears in [RZ95] and in [Ric96a].

GRAPH-THEORETIC PROPERTIES

THEOREM 5.5.1 [FHNS00]

The graph of a simple projective arrangement of $n \geq 4$ pseudolines is 4-connected.

Using wiring diagrams, the same authors prove:

THEOREM 5.5.2 [FHNS00]

Every projective arrangement with an odd number of pseudolines can be decomposed into two edge-disjoint Hamiltonian paths (plus two unused edges), and the decomposition can be found efficiently.

CONJECTURE 5.5.3 [FHNS00]

All projective arrangements admit decompositions into two Hamiltonian cycles.

EMBEDDING IN LARGER STRUCTURES

In [Grü72], Grünbaum asked a number of questions about extending pseudoline arrangements to more elaborate structures, in particular to spreads and topological planes. The strongest result known about such extendibility is the following, which extends results of Goodman, Pollack, Wenger, and Zamfirescu [GPWZ94].

THEOREM 5.5.4 [GPW96]

There exist uncountably many pairwise nonisomorphic universal topological projective planes.

In particular, this implies the following statements, together with the corresponding statements about spreads, all of which had been conjectured in [Grü72].

- (i) Every pseudoline arrangement can be extended to a topological projective plane.
- (ii) There exists a universal topological projective plane.
- (iii) There are nonisomorphic topological projective planes such that every arrangement in each is isomorphic to some arrangement in the other.

Theorem 5.5.4 also implies the following result, established earlier by Snoeyink and Hershberger (and implicitly by Edmonds, Fukuda, and Mandel—see [BLS⁺99, Section 10.5]).

THEOREM 5.5.5 *Sweeping Theorem* [SH91]

A pseudoline arrangement $\mathcal{A}$ in the Euclidean plane can be swept by a pseudoline, starting at any $L \in \mathcal{A}$.

PROBLEM 5.5.6 [Grü72]

Which arrangements are present (up to isomorphism) in every topological projective plane?

MOVING FROM ONE ARRANGEMENT TO ANOTHER

In [Rin56], Ringel asked whether an arrangement $\mathcal{A}$ of straight lines could always be moved continuously to a given isomorphic arrangement $\mathcal{A}'$ (or to its reflection) so that all intermediate arrangements remained isomorphic. This question, which became known as the “isotopy problem” for arrangements, was eventually solved by Mnëv, and (independently, since news of Mnëv’s results had not yet reached the West) by White in the nonsimple case, then by Jaggi and Mani-Levitska in the simple case [BLS⁺99]. Mnëv’s results are, however, far stronger.

THEOREM 5.5.7 *Mnëv’s Universality Theorem* [Mnë85]

If V is any basic semialgebraic set defined over $\mathbb{Q}$, there is a configuration $\mathcal{S}$ of points in the plane such that the space of all configurations of the same order type as $\mathcal{S}$ is stably equivalent to V . If V is open in some $\mathbb{R}^n$, then there is a simple configuration $\mathcal{S}$ with this property.

From this it follows that the space of line arrangements isomorphic to a given one may have the homotopy type of *any* semialgebraic variety, and in particular may be disconnected, which gives a (very strongly) negative answer to the isotopy question. For a further generalization of Theorem 5.5.7, see [Ric96a].

The line arrangement of smallest size known for which the isotopy conjecture fails consists of 14 lines in general position and was found by Suvorov [Suv88]; see also [Ric96b].

Special cases where the isotopy conjecture *does* hold include:

- (i) every arrangement of 9 or fewer lines in general position [Ric89], and
- (ii) an arrangement of n lines containing a cell bounded by at least $n - 1$ of them.

There are also results of a more combinatorial nature about the possibility of transforming one pseudoline arrangement to another. In [Rin56, Rin57], Ringel proved

THEOREM 5.5.8 *Ringel’s Homotopy Theorem*

If $\mathcal{A}$ and $\mathcal{A}'$ are simple arrangements of pseudolines, then $\mathcal{A}$ can be transformed to $\mathcal{A}'$ by a finite sequence of steps each consisting of moving one pseudoline continuously across the intersection of two others. If $\mathcal{A}$ and $\mathcal{A}'$ are simple arrangements of lines, this can be done within the space of line arrangements.

The second part of Theorem 5.5.8 has been generalized by Roudneff and Sturm-fels [RS88] to arrangements of planes; the first half is still open in higher dimensions.

Ringel also observed that the isotopy property does hold for pseudoline arrangements.

THEOREM 5.5.9 [Rin56]

If $\mathcal{A}$ and $\mathcal{A}'$ are isomorphic arrangements of pseudolines, then $\mathcal{A}$ can be deformed continuously to $\mathcal{A}'$ through isomorphic arrangements.

Ringel did not provide a proof of this observation, but one method of proving it is via Theorem 5.2.12, together with the following isotopy result.

THEOREM 5.5.10 [GP84]

Every arrangement of pseudolines can be continuously deformed (through isomorphic arrangements) to a wiring diagram.

5.6 COMPLEXITY ISSUES

GLOSSARY

λ -matrix: The matrix with entries λ_{ij} = the number of points of the (generalized) configuration $\{p_1, \dots, p_n\}$ to the left of the directed (pseudo)line $\overrightarrow{p_i p_j}$. (λ_{ii} is undefined.)

THE NUMBER OF ARRANGEMENTS

Various exact values, as well as bounds, are known for the number of equivalence classes of the structures discussed in this chapter. For low values of n , some of these are given in Table 5.6.1 [Grü72, GP80a, Ric89, Knu92, Fel97, BLS⁺99, AAK01, BKLR, Fin].

TABLE 5.6.1 Exact numbers known for low n .

EQUIVALENCE CLASS	3	4	5	6	7	8	9	10	11	12	13	14	15
Isom classes of arr's of n lines	1	2	4	17	143	4890

" " " " " gen'd config's	1	2	3	16	135	3315	158830	14320182	2343203071				
Comb'l equiv classes of allow seq's	1	2	20										
" " " " " realizable " "	1	2	19										
Simple allow seq's cont'ing 123... n	2	16	768	...	[see Theorem 5.6.1]								
Simple allow seq's	2	32	4608	...	[see Corollary 5.6.2]								

The only exact formula known for arbitrary n follows from Stanley's formula:

THEOREM 5.6.1 [Sta84]

The number of simple allowable sequences on $1, \dots, n$ containing the permutation 123... n is

$$\frac{\binom{n}{2}!}{1^{n-1}3^{n-2}5^{n-3}\dots(2n-3)^1}.$$

COROLLARY 5.6.2

The total number of simple allowable sequences on $1, \dots, n$ is

$$\frac{(n-2)! \binom{n}{2}!}{1^{n-1} 3^{n-2} 5^{n-3} \dots (2n-3)^1}.$$

For n arbitrary, Table 5.6.2 indicates the known asymptotic bounds [BLS⁺99, Fel97, GP91, GP93, Knu92].

TABLE 5.6.2 Asymptotic bounds for large n (all logarithms are base 2).

EQUIVALENCE CLASS	LOWER BOUND	UPPER BOUND
Isom classes of (labeled) arr's of n pseudolines	$2^{n^2/6-5n/2}$	$2^{1.0850n^2}$
" " " " simple " " " "	"	$2^{.6974n^2}$
Order types of (labeled) n pt configs (simple or not)	$2^{4n \log n + \Omega(n)}$	$2^{4n \log n + O(n)}$
Isotopy classes of (labeled) n pt configs	"	"
Comb'l equiv classes of (labeled) n pt configs	$2^{7n \log n}$	$2^{8n \log n}$

CONJECTURE 5.6.3 [Knu92]

The number of isomorphism classes of simple pseudoline arrangements is $\leq 2^{\binom{n}{2}}$.

HOW MUCH SPACE IS NEEDED TO SPECIFY AN ARRANGEMENT?

A configuration or generalized configuration $\mathcal{S}$ is described, up to isomorphism, by the set of points lying to the left (say) of each line or pseudoline joining a pair of points. The following theorem, which extends to higher dimensions, allows one to encode the order type of $\mathcal{S}$ in essentially one order of magnitude less space.

THEOREM 5.6.4 [GP83, Cor83]

If $\mathcal{S}$ is a configuration or generalized configuration in the plane, the order type of $\mathcal{S}$ is determined by its λ -matrix.

COROLLARY 5.6.5

The order type of an arrangement of pseudolines can be encoded in space $O(n^2 \log n)$.

A modification by Felsner of the λ -matrix encoding for planar arrangements improves this, giving an encoding of wiring diagrams in space $O(n^2)$:

THEOREM 5.6.6 [Fel97]

Given a wiring diagram $\mathcal{A} = \{L_1, \dots, L_n\}$, let $t_j^i = 1$ if the j th crossing along L_i is with L_k for $k > i$, 0 otherwise. Then the mapping that associates to each wiring diagram $\mathcal{A}$ the binary $n \times (n-1)$ matrix (t_j^i) is injective.

The number of stretchable pseudoline arrangements is much smaller than the total number, which suggests that it should be possible to encode these more compactly. The following result of Goodman, Pollack, and Sturmfels (stated here for the dual case of point configurations) shows, however, that the “naive” encoding, by coordinates of an integral representative, is doomed to be inefficient.

THEOREM 5.6.7 [GPS89]

For each configuration S of points (x_i, y_i) in the integer grid $\mathbb{Z}^2$, let

$$\nu(S) = \min \max\{|x_1|, \dots, |x_n|, |y_1|, \dots, |y_n|\},$$

the minimum being taken over all configurations S' of the same order type as S , and let $\nu^*(n) = \max \nu(S)$ over all n -point configurations. Then, for some $c_1, c_2 > 0$,

$$2^{2^{c_1 n}} \leq \nu^*(n) \leq 2^{2^{c_2 n}}.$$

REALIZABILITY

Along with the Universality Theorem of Section 5.5, Mnëv proved that the problem of determining whether a given pseudoline arrangement is stretchable is NP-hard, in fact as hard as the problem of solving general systems of polynomial equations and inequalities over $\mathbb{R}$ (cf. [Chapter 33](#) of this Handbook):

THEOREM 5.6.8 [Mnë85, Mnë88]

The stretchability problem for pseudoline arrangements is polynomially equivalent to the “existential theory of the reals” decision problem.

Shor [Sho91] presents a more compact proof of the NP-hardness result, by encoding a so-called “monotone 3-SAT” formula in a family of suitably modified Pappus and Desargues configurations that turn out to be stretchable if and only if the corresponding formula is satisfiable. (See also [Ric96a].)

The following result provides an upper bound for the realizability problem.

THEOREM 5.6.9 [BLS⁺99, Sections 8.4, A.5]

The stretchability problem for pseudoline arrangements can be decided in singly exponential time and polynomial space in the Turing machine model of complexity. The number of arithmetic operations needed is bounded above by $2^{4n \log n + O(n)}$.

The NP-hardness does not mean, however, that it is pointless to look for algorithms to determine stretchability, particularly in special cases. Indeed, a good deal of work has been done on this problem by Bokowski, in collaboration with Guedes de Oliveira, Pock, Richter-Gebert, Scharnbacher, and Sturmfels. Four main algorithmic methods have been developed to test for the realizability (or nonrealizability) of an oriented matroid, i.e., in the rank 3 case, the stretchability (respectively nonstretchability) of a pseudoline arrangement:

- (i) The **inequality reduction method**: this attempts to find a relatively small system of inequalities that still carries all the information about a given oriented matroid;
- (ii) The **solvability sequence method**: this attempts to find an elimination order with special properties for the coordinates in a potential realization of an order type;
- (iii) The **final polynomial method**: this attempts to find a bracket polynomial (cf. [Chapter 59](#)) whose existence will imply the nonrealizability of an order type;
- (iv) Bokowski’s **rubber-band method**: an elementary heuristic that has proven surprisingly effective in finding realizations [Poc91].

Not every realizable order type has a solvability sequence, but it turns out that every nonrealizable one does have a final polynomial, and an algorithm due to Lombardi can be used to find one [Lom90].

All of these methods extend to higher dimensions. For details about the first three, see [BS89b].

CONSTRUCTING ARRANGEMENTS

An $O(n^2)$ algorithm is given in [EOS86, ESS93] to “construct” an arrangement $\mathcal{A}$ of lines (hyperplanes, in general, in time $O(n^d)$), i.e., to construct its face lattice. This algorithm is used as a subroutine in a number of other algorithms in computational geometry (see [Ede87]). From this one can find the λ -matrix of $\mathcal{A}$ in time $O(n^2)$, which is optimal.

SORTING INTERSECTIONS OF LINES OR PSEUDOLINES

Steiger and Streinu consider the problem of x -sorting line or pseudoline intersections, i.e., determining the order of the x -coordinates of the intersections of the lines or pseudolines in a Euclidean arrangement. They prove:

THEOREM 5.6.10 [SS94]

- (i) *There is a decision tree of depth $O(n^2)$ to x -sort the vertices of a simple arrangement of n lines;*
- (ii) *$\Omega(n^2 \log n)$ comparisons are necessary to x -sort the vertices of a simple arrangement of n pseudolines.*

(The second statement is a corollary of Theorem 5.6.1 above.)

Even though this is only a “pseudo-algorithmic” distinction, since it holds in the decision-tree model of computation, nevertheless this result is one of the few known instances where there is a clear computational difference between lines and pseudolines.

5.7 APPLICATIONS

Planar arrangements of lines and pseudolines, as well as point configurations, arise in many problems of computational geometry. Here we describe several such applications involving pseudolines in particular.

GLOSSARY

Tangent visibility graph of a set of pairwise disjoint convex objects: The graph formed by the tangents to pairs of objects, cut off at their points of tangency (provided these segments do not meet any other objects) and by the arcs into which they divide the boundaries of the objects.

Pseudoline graph: Given a Euclidean pseudoline arrangement Γ and a subset E of its vertices, the graph $G = (\Gamma, E)$ whose vertices are the members of Γ , with

two vertices joined by an edge whenever the intersection of the corresponding pseudolines belongs to E .

Extendible set of pseudosegments: A set of Jordan arcs, each chosen from a different pseudoline belonging to a simple Euclidean arrangement.

Diamond: Two pairs $\{l_1, l_2\}, \{l_3, l_4\}$ of pseudolines in a Euclidean arrangement form a diamond if the intersection of one pair lies above each member of the second and the intersection of the other pair below each member of the first.

TOPOLOGICAL SWEEP

The original idea behind what has come to be known as *topologically sweeping an arrangement* was applied, by Edelsbrunner and Guibas, to the case of an arrangement of straight lines. In order to construct the arrangement, rather than using a line to sweep it, they used a pseudoline, and achieved a saving of a factor of $\log n$ in the time required, while keeping the storage linear.

THEOREM 5.7.1 [EG89]

The cell complex of an arrangement of n lines in the plane can be computed in $O(n^2)$ time and $O(n)$ space by sweeping a pseudoline across it.

This result can be applied to a number of problems, and results in an improvement of known bounds on each: minimum area triangle spanned by points, visibility graph of segments, and (in higher dimensions) enumerating faces of a hyperplane arrangement and testing for degeneracies in a point configuration.

The idea of a topological sweep was then generalized, by Snoeyink and Hershberger, to sweeping a pseudoline across an arrangement of *pseudolines*; they prove the possibility of such a sweep (Theorem 5.5.5), and show that it can be performed in the same time and space as in Theorem 5.7.1. They also apply this result to finding a short Boolean formula for a polygon with curved edges.

The topological sweep method was also used by Chazelle and Edelsbrunner [CE92] to report all k -segment intersections in an arrangement of n line segments in (optimal) $O(n \log n + k)$ time, and has been generalized to higher dimensions.

APPLICATIONS OF DUALITY

Theorem 5.1.6, and the algorithm used to compute the dual arrangement, are used by Agarwal and Sharir to compute incidences between points and pseudolines and to compute a subset of faces in a pseudoline arrangement [AS02]. An additional application is due to Sharir and Smorodinsky.

THEOREM 5.7.2 [SS03]

Let Γ be a simple Euclidean pseudoline arrangement, E a subset of vertices of Γ , and $G = (\Gamma, E)$ the corresponding pseudoline graph. Then there is a drawing of G in the plane, with the edges constituting an extendible set of pseudosegments, such that for any two edges e, e' of G , e and e' form a diamond if and only if their corresponding drawings cross.

Conversely, for any graph $G = (V, E)$ drawn in the plane with its edges constituting an extendible set of pseudosegments, there is a simple Euclidean arrangement Γ of pseudolines and a one-to-one mapping ϕ from V onto Γ with each edge $uv \in E$

mapped to the vertex $\phi(u) \cap \phi(v)$ of Γ , such that two edges in E cross if and only if their images are two vertices of Γ forming a diamond.

This can then be used to provide a simple proof of the Tamaki-Tokuyama theorem:

THEOREM 5.7.3 [TT97]

Let Γ and G be as in Theorem 5.7.2. If G is diamond-free, then G is planar, and hence $|E| \leq 3n - 6$.

PSEUDOTRIANGULATIONS

Pocchiola and Vegter introduced the concept of a pseudotriangulation (see [Section 5.3](#) above) in order to compute the visibility graph of a collection of pairwise disjoint convex obstacles. Then they showed that a collection of disjoint pseudotriangles dualizes to a pseudoline arrangement, and that certain pseudoline arrangements could be realized in this way by collections of pseudotriangles. This enables them to generalize certain algorithms for configurations of points to configurations of more general convex objects.

Their results include the following.

THEOREM 5.7.4 [PV94]

Given a collection of n disjoint convex objects in the plane, a pseudotriangulation can be computed in $O(n \log n)$ time, the dual arrangement in $O(n^2)$ time and space, and the tangent visibility graph in $O(n^2)$ time and linear space.

Streinu has modified the notions of pseudotriangle and pseudotriangulation as follows in order to give an algorithmic solution of the **Carpenter's Rule problem** previously settled existentially by Connelly, Demaine, and Rote [CDR03]: A **pseudotriangle** is a planar polygon with precisely three vertices having internal angles less than π , and a **pseudotriangulation** of a point set P in the plane is a partition of the convex hull of P into pseudotriangles whose vertex set is precisely P . She proves:

THEOREM 5.7.5 [Str00]

Every planar polygon can be convexified in $O(n^2)$ motions, each consisting of a one-degree-of-freedom mechanism constructed from a pseudotriangulation with a single convex-hull edge removed, which is moved until two of its adjacent edges align, followed by a local flip of diagonals to restore a pseudotriangulation. A starting pseudotriangulation can be computed in time $O(n^2)$ and subsequently updated in linear time per step.

With the same definitions, Kettner et al. prove:

THEOREM 5.7.6 [KKM⁺03]

Every planar point set in general position has a pseudotriangulation every vertex of which has degree at most 5, and this bound is tight.

If a pseudotriangulation is such that no edge can be removed and leave a pseudotriangulation, it is called *minimal*; in that case it must have exactly $n - 2$ pseudotriangles. Brönnimann et al. have adduced some experimental evidence for:

CONJECTURE 5.7.7 [BKPS01, RRSS01]

For any set S of points in general position in the plane, there are at least as many minimal pseudotriangulations of S as triangulations, with equality if and only if S is in convex position.

PSEUDOVISIBILITY

In a series of papers, O'Rourke and Streinu introduce what they call the “vertex-edge visibility graph” of a polygon, which encodes more information than the standard vertex visibility graph, and use it to study the visibility problem in the polygon. They then generalize this concept to *pseudopolygons*, whose vertices and edges come from generalized configurations of points (see [Section 5.2](#)), and show that the reconstruction problem for vertex-edge visibility graphs can be solved as long as pseudopolygons are permitted. They prove:

THEOREM 5.7.8 [OS96]

There is a polynomial-time algorithm for the problem of deciding whether a graph is the vertex-edge pseudovisibility graph of a pseudopolygon.

COROLLARY 5.7.9 [OS96]

The decision problem for vertex visibility graphs of pseudopolygons is in NP.

(This last result is in contrast to the fact that the same problem with straight-edge visibility is only known to be in PSPACE.)

Finally, Streinu has used Theorem 5.2.6 above to construct examples of non-stretchable pseudopolygons and of nonstretchable pseudovisibility graphs [Str03].

5.8 SOURCES AND RELATED MATERIAL**FURTHER READING**

[BLS⁺99]: A comprehensive account of oriented matroid theory, including a great many references; most references not given explicitly in this chapter can be traced through this book.

[Ede87]: An introduction to computational geometry, focusing on arrangements and their algorithms.

[GP91, GP93]: Two surveys on allowable sequences and order types and their complexity.

[Grü72]: A monograph on planar arrangements and their generalizations, with excellent problems (many still unsolved) and a very complete bibliography up to 1972.

INTRODUCTION

The theory of *oriented matroids* provides a broad setting in which to model, describe, and analyze combinatorial properties of geometric configurations. Mathematical objects of study that appear to be disjoint and independent, such as *point and vector configurations*, *arrangements of hyperplanes*, *convex polytopes*, *directed graphs*, and *linear programs* find a common generalization in the language of oriented matroids.

The oriented matroid of a finite set of points P extracts relative position and orientation information from the configuration; for example, it can be given by a list of signs that encodes the orientations of all the bases of P . In the passage from a concrete point configuration to its oriented matroid, metrical information is lost, but many structural properties of P have their counterparts at the—purely combinatorial—level of the oriented matroid.

We first introduce oriented matroids in the context of several models and motivations (Section 6.1). Then we present some equivalent axiomatizations (Section 6.2). Finally, we discuss concepts that play central roles in the theory of oriented matroids (Section 6.3), among them *duality*, *realizability*, the study of *simplicial cells*, and the treatment of *convexity*.

6.1 MODELS AND MOTIVATIONS

This section discusses geometric examples that are usually treated on the level of concrete coordinates, but where an “oriented matroid point of view” gives deeper insight. We also present these examples as standard models that provide intuition for the behavior of general oriented matroids.

6.1.1 ORIENTED BASES OF VECTOR CONFIGURATIONS

GLOSSARY

Vector configuration: A matrix $X = (x_1, \dots, x_n) \in (\mathbb{R}^d)^n$, usually assumed to have full rank d .

Matroid of X : The pair $M_X = (E, \mathcal{B}_X)$, where $E := \{1, 2, \dots, n\}$ and $\mathcal{B}_X$ is the set of all (column index d -sets) of bases of X .

Matroid: A pair $M = (E, \mathcal{B})$, where E is a finite set, and $\mathcal{B} \subset 2^E$ is a nonempty

collection of subsets of E (the **bases** of M) that satisfies the **Steinitz exchange axiom**: For all $B_1, B_2 \in \mathcal{B}$ and $e \in B_1 \setminus B_2$, there exists an $f \in B_2 \setminus B_1$ such that $(B_1 \setminus e) \cup f \in \mathcal{B}$.

Signs: Elements of the set $\{-, 0, +\}$, used as a shorthand for the corresponding elements of $\{-1, 0, +1\}$.

Chirotope of X : The map

$$\begin{aligned} \chi_X: \quad E^d &\rightarrow \{-, 0, +\} \\ (\lambda_1, \dots, \lambda_d) &\mapsto \text{sign}(\det(x_{\lambda_1}, \dots, x_{\lambda_d})). \end{aligned}$$

Ordinary (unoriented) *matroids*, as introduced in 1935 by Whitney (see Kung [Kun86], Oxley [Ox192]), can be considered as an abstraction of vector configurations in finite dimensional vector spaces over arbitrary fields. All the bases of a matroid M have the same cardinality d , which is called the **rank** of the matroid. Equivalently, we can identify M with the characteristic function of the bases $B_M: E^d \rightarrow \{0, 1\}$, where $B_M(\lambda) = 1$ if and only if $\{\lambda_1, \dots, \lambda_d\} \in \mathcal{B}$.

One can obtain examples of matroids as follows: Take a finite set of vectors

$$X = \{x_1, x_2, \dots, x_n\} \subset K^d$$

of rank d in a finite-dimensional vector space K^d and consider the set of bases of K^d formed by subsets of the points in X . In other words, the pair

$$M_X = (E, \mathcal{B}_X) = \left(\{1, \dots, n\}, \{ \{\lambda_1, \dots, \lambda_d\} \mid \det(x_{\lambda_1}, \dots, x_{\lambda_d}) \neq 0 \} \right)$$

forms a matroid.

The basic information about the incidence structure of the points in X is contained in the underlying matroid M_X . However, the matroid alone presents only a weak model of a geometric configuration; for example, all configurations of n points in **general position** in the plane (i.e., no three points on a line) have the same matroid $M = U_{3,n}$: here no information beyond the dimension and size of the configuration, and the fact that it is in general position, is retained for the matroid.

In contrast to matroids, the theory of **oriented matroids** considers the structure of dependencies in vector spaces over *ordered* fields. Roughly speaking, an oriented matroid is a matroid where in addition every basis is equipped with an orientation. These oriented bases have to satisfy an oriented version of the Steinitz exchange axiom (to be described later). In other words, oriented matroids not only describe the incidence structure between the points of X and the hyperplanes spanned by points of X (this is the matroid information); they also encode the positions of the points relative to the hyperplanes: “Which points lie on the positive side of a hyperplane, which points lie on the negative side, and which lie on the hyperplane?” If $X \in (K^d)^n$ is a configuration of n points in a d -dimensional vector space K^d over an ordered field K , we can describe the corresponding oriented matroid χ_X by the function:

$$\begin{aligned} \chi_X: \quad E^d &\rightarrow \{-, 0, +\} \\ (\lambda_1, \dots, \lambda_d) &\mapsto \text{sign}(\det(x_{\lambda_1}, \dots, x_{\lambda_d})). \end{aligned}$$

This map χ_X is called the **chirotope** of X and is very closely related to the oriented matroid of X . It encodes much more information than the corresponding matroid, including orientation and convexity information about the underlying configuration.

6.1.2 CONFIGURATIONS OF POINTS

GLOSSARY

Affine point configuration: A matrix $P = (p_1, \dots, p_n) \in (\mathbb{R}^{d-1})^n$, usually assumed to have full rank $d - 1$, i.e., to affinely span $\mathbb{R}^{d-1}$.

Associated vector configuration: The matrix $X \in (\mathbb{R}^d)^n$ obtained from a point configuration by adding a row of ones. This corresponds to the embedding of the affine space $\mathbb{R}^{d-1}$ into the linear vector space $\mathbb{R}^d$ via $p \mapsto x = \begin{pmatrix} p \\ 1 \end{pmatrix}$.

Oriented matroid of an affine point configuration: The oriented matroid of the associated vector configuration.

Covector of a vector configuration X : Partition of $X = (x_1, \dots, x_n)$ induced by a linear hyperplane, into points on the hyperplane, on its positive side, and on its negative side.

Oriented matroid of X : The collection $\mathcal{L} \subset \{-, 0, +\}^n$ of all covectors of X .

Let $X := (x_1, \dots, x_n) \in (\mathbb{R}^d)^n$ be an $n \times d$ matrix and let $E := \{1, \dots, n\}$. We interpret the columns of X as n vectors in the d -dimensional real vector space $\mathbb{R}^d$. For a linear functional $y^T \in (\mathbb{R}^d)^*$ we set

$$C_X(y) = (\text{sign}(y^T x_1), \dots, \text{sign}(y^T x_n)).$$

Such a sign vector is called a **covector** of X . We denote the collection of all covectors of X by

$$\mathcal{L}_X := \{C_X(y) \mid y \in \mathbb{R}^d\}.$$

The pair $\mathcal{M}_X = (E, \mathcal{L}_X)$ is called the **oriented matroid** of X . Here each sign vector $C_X(y) \in \mathcal{L}_X$ describes the positions of the vectors $x_1, \dots, x_n$ relative to the linear hyperplane $H_y = \{x \in \mathbb{R}^d \mid y^T x = 0\}$: the sets

$$\begin{aligned} C_X(y)^0 &:= \{e \in E \mid C_X(y)_e = 0\} \\ C_X(y)^+ &:= \{e \in E \mid C_X(y)_e > 0\} \\ C_X(y)^- &:= \{e \in E \mid C_X(y)_e < 0\} \end{aligned}$$

describe how H_y partitions the set of points X . Here $C_X(y)^0$ contains the points on H_y , while $C_X(y)^+$ and $C_X(y)^-$ contain the points on the positive and on the negative side of H_y , respectively. In particular, if $C_X(y)^- = \emptyset$, then all points not on H_y lie on the positive side of H_y . In other words, in this case H_y determines a face of the positive cone

$$\text{pos}(x_1, \dots, x_n) := \left\{ \lambda_1 x_1 + \lambda_2 x_2 + \dots + \lambda_n x_n \mid 0 \leq \lambda_i \in \mathbb{R} \text{ for } 1 \leq i \leq n \right\}$$

of all points of X . The face lattice of the cone $\text{pos}(X)$ can be recovered from $\mathcal{L}_X$. It is simply the set $\mathcal{L}_X \cap \{+, 0\}^E$, partially ordered by the order induced from the relation “ $0 < +$.”

If, in the configuration X , we have $x_{i,d} = 1$ for all $1 \leq i \leq n$, then we can consider X as representing homogeneous coordinates of an *affine* point set X' in $\mathbb{R}^{d-1}$.

Here the affine points correspond to the original points x_i after removal of the d th coordinate. The face lattice of the convex polytope $\text{conv}(X') \subset \mathbb{R}^{d-1}$ is then identical to the face lattice of $\text{pos}(X)$. Hence, $\mathcal{M}_X$ can be used to recover the *convex hull* of X' .

Thus oriented matroids are generalizations of point configurations in linear or affine spaces. For general oriented matroids we weaken the assumption that the hyperplanes spanned by points of the configuration are flat to the assumption that they only satisfy certain topological incidence properties. Nonetheless, this kind of picture is sometimes misleading since not all oriented matroids have this type of representation (compare the “Type II representations” of [BLS⁺93, Section 5.3]).

6.1.3 ARRANGEMENTS OF HYPERPLANES AND OF HYPERSPHERES

GLOSSARY

Hyperplane arrangement $\mathcal{H}$: Collection of (oriented) linear hyperplanes in $\mathbb{R}^d$, given by normal vectors $x_1, \dots, x_n$.

Hypersphere arrangement induced by $\mathcal{H}$: Intersection of $\mathcal{H}$ with the unit sphere S^{d-1} .

Covectors of $\mathcal{H}$: Sign vectors of the cells in $\mathcal{H}$; equivalently, $\mathbf{0}$ together with the sign vectors of the cells in $\mathcal{H} \cap S^{d-1}$.

We obtain a different picture if we polarize the situation and consider *hyperplane arrangements* rather than configurations of points. For a real matrix $X := (x_1, \dots, x_n) \in (\mathbb{R}^d)^n$ consider the system of hyperplanes $\mathcal{H}_X := (H_1, \dots, H_n)$ with

$$H_i := \{y \in \mathbb{R}^d \mid y^T x_i = 0\}.$$

Each vector x_i induces an orientation on H_i by defining

$$H_i^+ := \{y \in \mathbb{R}^d \mid y^T x_i > 0\}$$

to be the **positive side** of H_i . We define H_i^- analogously to be the **negative side** of H_i . To avoid degenerate cases we assume that X contains at least one proper basis (i.e., the matrix X has rank d). The hyperplane arrangement $\mathcal{H}_X$ subdivides $\mathbb{R}^d$ into polyhedral cones. Without loss of information we can intersect with the unit sphere S^{d-1} and consider the sphere system

$$\mathcal{S}_X := (H_1 \cap S^{d-1}, \dots, H_n \cap S^{d-1}) = \mathcal{H}_X \cap S^{d-1}.$$

Our assumption that X contains at least one proper basis translates to the fact that the intersection of all $H_1 \cap \dots \cap H_n \cap S^{d-1}$ is empty. $\mathcal{H}_X$ induces a cell decomposition $\Gamma(\mathcal{S}_X)$ on S^{d-1} . Each face of $\Gamma(\mathcal{S}_X)$ corresponds to a sign vector in $\{-, 0, +\}^E$ that indicates the position of the cell with respect to the $(d-2)$ -spheres $H_i \cap S^{d-1}$ (and therefore with respect to the hyperplanes H_i) of the arrangement. The list of all these sign vectors is exactly the set $\mathcal{L}_X$ of covectors of $\mathcal{H}_X$.

While the visualization of oriented matroids by sets of points in $\mathbb{R}^n$ does not fully generalize to the case of nonrepresentable oriented matroids, the picture of

FIGURE 6.1.1

An arrangement of nine great circles on S^2 . The arrangement corresponds to a Pappus configuration.

hyperplane arrangements has a well-defined extension that also covers all the non-realizable cases. We will see that as a consequence of the topological representation theorem of Folkman and Lawrence (Section 6.2.4) every rank- d oriented matroid can be represented as an arrangement of oriented *pseudospheres* (or pseudohyperplanes) embedded in the S^{d-1} (resp. in $\mathbb{R}^d$). Arrangements of pseudospheres are systems of topological $(d-2)$ -spheres embedded in S^{d-1} that satisfy certain intersection properties that clearly hold in the case of “straight” arrangements.

6.1.4 ARRANGEMENTS OF PSEUDOLINES

GLOSSARY

Pseudoline: Simple closed curve p in the projective plane $\mathbb{RP}^2$ that is topologically equivalent to a line (i.e., there is a self-homeomorphism of $\mathbb{RP}^2$ mapping p to a straight line).

Arrangement of pseudolines: Collection of pseudolines $\mathcal{P} := (p_1, \dots, p_n)$ in the projective plane, any two of them intersecting exactly once.

Simple arrangement: No three pseudolines meet in a common point. (Equivalently, the associated oriented matroid is *uniform*.)

Equivalent arrangements: Arrangements $\mathcal{P}_1$ and $\mathcal{P}_2$ that generate isomorphic cell decompositions of $\mathbb{RP}^2$. (In this case there exists a self-homeomorphism of $\mathbb{RP}^2$ mapping $\mathcal{P}_1$ to $\mathcal{P}_2$.)

Stretchable arrangement of pseudolines: An arrangement that is equivalent to an arrangement of projective lines.

An *arrangement of pseudolines* in the projective plane is a collection of pseudolines such that any two pseudolines intersect in exactly one point, where they

cross. (See Grünbaum [Grü72] and Richter [Ric89].) We will always assume that $\mathcal{P}$ is *essential*, i.e., that the intersection of all the pseudolines p_i is empty.

An arrangement of pseudolines behaves in many respects just like an arrangement of n lines in the projective plane. (In fact, there are only very few combinatorial theorems known that are true for straight arrangements, but not true in general for pseudoarrangements.) Figure 6.1.2 shows a small example of a nonstretchable arrangement of pseudolines. (It is left as a challenging exercise to the reader to prove the nonstretchability.) Up to isomorphism this is the only simple nonstretchable arrangement of 9 pseudolines [Ric89, Knu92]; every arrangement of 8 (or fewer) pseudolines is stretchable [GP80].

FIGURE 6.1.2

A nonstretchable arrangement of nine pseudolines. It was obtained by Ringel [Rin56] as a perturbation of the Pappus configuration.

To associate with a projective arrangement $\mathcal{P}$ an oriented matroid we represent the projective plane (as customary) by the 2-sphere with antipodal points identified. With this, every arrangement of pseudolines gives rise to an arrangement of *great pseudocircles* on S^2 . For each great pseudocircle on S^2 we choose a positive side. Each cell induced by $\mathcal{P}$ on S^2 now corresponds to a unique sign vector. The collection of all these sign vectors again forms a set of covectors $\mathcal{L}_{\mathcal{P}} \setminus \{\mathbf{0}\}$ of an oriented matroid of rank 3. Conversely, as a special case of the topological representation theorem, *every* oriented matroid of rank 3 has a representation by an *oriented* pseudoline arrangement.

Thus we can use pseudoline arrangements as a standard picture to represent rank-3 oriented matroids. The easiest picture is obtained when we restrict ourselves to the upper hemisphere of S^2 and assume w.l.o.g. that each pseudoline crosses the equator exactly once, and that the crossings are distinct (i.e., no intersection of the great pseudocircles lies on the equator). Then we can represent this upper hemisphere by an arrangement of mutually crossing, oriented affine pseudolines in the plane $\mathbb{R}^2$. (We did this implicitly while drawing Figure 6.1.2.) For a recent and reasonably elementary proof of the fact that rank-3 oriented matroids are equivalent to arrangements of pseudolines see Bokowski, Mock, and Streinu [BMS01].

By means of this equivalence, all problems concerning pseudoline arrangements can be translated to the language of oriented matroids. For instance, the problem of stretchability is equivalent to the realizability problem for oriented matroids.

6.2 AXIOMS AND REPRESENTATIONS

In this section we define oriented matroids formally. It is one of the main features of oriented matroid theory that the same object can be viewed under quite dif-

ferent aspects. This results in the fact that there are many different equivalent axiomatizations, and it is sometimes very useful to “jump” from one point of view to another. Statements that are difficult to prove in one language may be easy in another. For this reason we present here several different axiomatizations. We also give a (partial) dictionary that indicates how to translate among them. For a complete version of the basic equivalence proofs—which are highly nontrivial—see [BLS⁺93, Chapters 3 and 5].

We will give axiomatizations of oriented matroids for the following four types of representations:

- Collections of covectors,
- Collections of cocircuits,
- Signed bases,
- Arrangements of pseudospheres.

In the last part of this section these concepts are illustrated by an example.

GLOSSARY

Sign vector: Vector C in $\{-, 0, +\}^E$, where E is a finite index set, usually $\{1, \dots, n\}$. For $e \in E$, the e -component of C is denoted by C_e .

Positive, negative, and zero part of C :

$$\begin{aligned} C^+ &:= \{e \in E \mid C_e = +\}, \\ C^- &:= \{e \in E \mid C_e = -\}, \\ C^0 &:= \{e \in E \mid C_e = 0\}. \end{aligned}$$

Support of C : $\underline{C} := \{e \in E \mid C_e \neq 0\}$.

Zero vector: $\mathbf{0} := (0, \dots, 0) \in \{-, 0, +\}^E$.

Negative of a sign vector: $-C$, defined by $(-C)^+ := C^-$, $(-C)^- := C^+$ and $(-C)^0 = C^0$.

Composition of C and D : $(C \circ D)_e := \begin{cases} C_e & \text{if } C_e \neq 0, \\ D_e & \text{otherwise.} \end{cases}$

Separation set of C and D : $S(C, D) := \{e \in E \mid C_e = -D_e \neq 0\}$.

We partially order the set of sign vectors by “ $0 < +$ ” and “ $0 < -$.” The partial order on sign vectors, denoted by $C \leq D$, is understood componentwise; equivalently, we have

$$C \leq D \iff \left[C^+ \subset D^+ \text{ and } C^- \subset D^- \right].$$

For instance, if $C := (+, +, -, 0, -, +, 0, 0)$ and $D := (0, 0, -, +, +, -, 0, -)$, then we have:

$$C^+ = \{1, 2, 6\}, \quad C^- = \{3, 5\}, \quad C^0 = \{4, 7, 8\}, \quad \underline{C} = \{1, 2, 3, 5, 6\},$$

$$C \circ D = (+, +, -, +, -, +, 0, -), \quad C \circ D \geq C, \quad S(C, D) = \{5, 6\}.$$

Furthermore, for $x \in \mathbb{R}^n$, we denote by $\sigma(x) \in \{-, 0, +\}^E$ the image of x under the componentwise sign function σ that maps $\mathbb{R}^n$ to $\{-, 0, +\}^E$.

6.2.1 COVECTOR AXIOMS

Definition: An *oriented matroid* given in terms of its covectors is a pair $\mathcal{M} := (E, \mathcal{L})$, where $\mathcal{L} \in \{-, 0, +\}^E$ satisfies

$$(CV0) \quad \mathbf{0} \in \mathcal{L}$$

$$(CV1) \quad C \in \mathcal{L} \implies -C \in \mathcal{L}$$

$$(CV2) \quad C, D \in \mathcal{L} \implies C \circ D \in \mathcal{L}$$

$$(CV3) \quad C, D \in \mathcal{L}, e \in S(C, D) \implies \text{there is a } Z \in \mathcal{L} \text{ with } Z_e = 0 \text{ and with } Z_f = (C \circ D)_f \text{ for } f \in E \setminus S(C, D).$$

It is not difficult to check that these covector axioms are satisfied by the sign vector system $\mathcal{L}_X$ of the cells in a hyperplane arrangement $\mathcal{H}_X$, as defined in the last section. The first two axioms are satisfied trivially. For (CV2) assume that x_C and x_D are points in $\mathbb{R}^d$ with $\sigma(x_C^T \cdot X) = C \in \mathcal{L}_X$ and $\sigma(x_D^T \cdot X) = D \in \mathcal{L}_X$. Then (CV2) is implied by the fact that for sufficiently small $\epsilon > 0$ we have $\sigma((x_C + \epsilon x_D)^T \cdot X) = C \circ D$. The geometric content of (CV3) is that if $H_e := \{y \in \mathbb{R}^d \mid y^T x_e = 0\}$ is a hyperplane separating x_C and x_D then there exists a point x_Z on H_e with the property that x_Z is on the same side as x_C and x_D for all hyperplanes not separating x_C and x_D . We can find such a point by intersecting H_e with the line segment that connects x_C and x_D .

As we will see later the partially ordered set $(\mathcal{L}, \leq)$ describes the face lattice of a cell decomposition of the sphere S^{d-1} by pseudohyperspheres. Each sign vector corresponds to a face of the cell decomposition. We define the *rank* d of $\mathcal{M} = (E, \mathcal{L})$ to be the (unique) length of the maximal chains in $(\mathcal{L}, \leq)$ minus one. In the case of realizable arrangements $\mathcal{S}_X$ of hyperspheres, the lattice $(\mathcal{L}_X, \leq)$ equals the face lattice of $\Gamma(\mathcal{S}_X)$.

6.2.2 COCIRCUITS

The covectors of (inclusion-)minimal support in $\mathcal{L} \setminus \{\mathbf{0}\}$ correspond to the 0-faces (= vertices) of the cell decomposition. We call the set $\mathcal{C}^*(\mathcal{M})$ of all such minimal covectors the *cocircuits* of $\mathcal{M}$. An oriented matroid can be described by its set of cocircuits, as shown by the following theorem.

THEOREM 6.2.1 Cocircuit Characterization

A collection $\mathcal{C}^* \in \{-, 0, +\}^E$ is the set of cocircuits of an oriented matroid $\mathcal{M}$ if and only if it satisfies

$$(CC0) \quad \mathbf{0} \notin \mathcal{C}^*$$

$$(CC1) \quad C \in \mathcal{C}^* \implies -C \in \mathcal{C}^*$$

$$(CC2) \quad \text{For all } C, D \in \mathcal{C}^* \text{ we have: } \underline{C} \subset \underline{D} \implies C = D \text{ or } C = -D$$

$$(CC3) \quad C, D \in \mathcal{C}^*, C \neq -D, \text{ and } e \in S(C, D) \implies \text{there is a } Z \in \mathcal{C}^* \text{ with } Z^+ \subset (C^+ \cup D^+) \setminus \{e\} \text{ and } Z^- \subset (C^- \cup D^-) \setminus \{e\}.$$

THEOREM 6.2.2 *Covector/Cocircuit Translation*

For every oriented matroid $\mathcal{M}$, one can uniquely determine the set $\mathcal{C}^*$ of cocircuits from the set $\mathcal{L}$ of covectors of $\mathcal{M}$, and conversely, as follows:

- (i) $\mathcal{C}^*$ is the set of vectors with minimal support in $\mathcal{L} \setminus \{\mathbf{0}\}$:
 $\mathcal{C}^* = \{C \in \mathcal{L} \setminus \{\mathbf{0}\} \mid C' \leq C \implies C' \in \{\mathbf{0}, C\}\}$
- (ii) $\mathcal{L}$ is the set of all sign vectors obtained by successive composition of a finite number of cocircuits from $\mathcal{C}^*$:
 $\mathcal{L} = \{C_1 \circ \dots \circ C_k \mid k \geq 0, C_1, \dots, C_k \in \mathcal{C}^*\}.$

6.2.3 CHIROTOPES

GLOSSARY

Alternating sign map: A map $\chi: E^d \longrightarrow \{-, 0, +\}$ such that any transposition of two components changes the sign: $\chi(\tau_{ij}(\lambda)) = -\chi(\lambda)$.

Chirotope: An alternating sign map χ that encodes the basis orientations of an oriented matroid $\mathcal{M}$ of rank d .

We now present an axiom system for *chirotopes*, which characterizes oriented matroids in terms of basis orientations. Here an algebraic connection to determinant identities becomes obvious. Chirotopes are the main tool for translating problems in oriented matroid theory to an algebraic setting [BS89a]. They also form a description of oriented matroids that is very practical for many algorithmic purposes (for instance in computational geometry; see Knuth [Knu92]).

Definition: Let $E := \{1, \dots, n\}$ and $0 \leq d \leq n$. A **chirotope of rank d** is an alternating sign map $\chi: E^d \rightarrow \{-, 0, +\}$ that satisfies

(CHI1) The map $|\chi|: E^d \rightarrow \{0, 1\}$, $\lambda \mapsto |\chi(\lambda)|$ is a matroid, and

(CHI2) For every $\lambda \in E^{d-2}$ and $a, b, c, d \in E \setminus \lambda$ the set

$$\left\{ \chi(\lambda, a, b) \cdot \chi(\lambda, c, d), -\chi(\lambda, a, c) \cdot \chi(\lambda, b, d), \chi(\lambda, a, d) \cdot \chi(\lambda, b, c) \right\}$$

either contains $\{-1, +1\}$ or equals $\{0\}$.

Where does the motivation of this axiomatization come from? If we again consider a configuration $X := (x_1, \dots, x_n)$ of vectors in $\mathbb{R}^d$, we can observe the following identity among the $d \times d$ submatrices of X :

$$\begin{aligned} & \det(x_{\lambda_1}, \dots, x_{\lambda_{d-2}}, x_a, x_b) \cdot \det(x_{\lambda_1}, \dots, x_{\lambda_{d-2}}, x_c, x_d) \\ & - \det(x_{\lambda_1}, \dots, x_{\lambda_{d-2}}, x_a, x_c) \cdot \det(x_{\lambda_1}, \dots, x_{\lambda_{d-2}}, x_b, x_d) \\ & + \det(x_{\lambda_1}, \dots, x_{\lambda_{d-2}}, x_a, x_d) \cdot \det(x_{\lambda_1}, \dots, x_{\lambda_{d-2}}, x_b, x_c) = 0 \end{aligned}$$

for all $\lambda \in E^{d-2}$ and $a, b, c, d \in E \setminus \lambda$. Such a relation is called a **three-term Grassmann-Plücker identity**. If we compare this identity to our axiomatization, we see that (CHI2) implies that

$$\begin{aligned} \chi_X: \quad E^d & \rightarrow \{-, 0, +\} \\ (\lambda_1, \dots, \lambda_d) & \mapsto \text{sign}(\det(x_{\lambda_1}, \dots, x_{\lambda_d})) \end{aligned}$$

is consistent with these identities. More precisely, if we consider χ_X as defined above for a vector configuration X , the above Grassmann-Plücker identities imply that (CHI2) is satisfied. (CHI1) is also satisfied since for the vectors of X the Steinitz exchange axiom holds. (In fact the exchange axiom is a consequence of higher order Grassmann-Plücker identities.)

Consequently, χ_X is a chirotope for every $X \in (\mathbb{R}^d)^n$. Thus chirotopes can be considered as a combinatorial model of the determinant values on vector configurations. The following is not easy to prove, but essential.

THEOREM 6.2.3 *Chirotope/Cocircuit Translation*

For each chirotope χ of rank d on $E := \{1, \dots, n\}$ the set

$$\mathcal{C}^*(\chi) = \left\{ (\chi(\lambda, 1), \chi(\lambda, 2), \dots, \chi(\lambda, n)) \mid \lambda \in E^{d-1} \right\}$$

forms the set of cocircuits of an oriented matroid. Conversely, for every oriented matroid $\mathcal{M}$ with cocircuits $\mathcal{C}^*$ there exists a unique pair of chirotopes $\{\chi, -\chi\}$ such that $\mathcal{C}^*(\chi) = \mathcal{C}^*(-\chi) = \mathcal{C}^*$.

The retranslation of cocircuits into signs of bases is straightforward but needs extra notation. It is omitted here.

6.2.4 ARRANGEMENTS OF PSEUDOSPHERES

GLOSSARY

The $(d-1)$ -sphere: The standard unit sphere $S^{d-1} := \{x \in \mathbb{R}^d \mid \|x\| = 1\}$, or any homeomorphic image of it.

Pseudosphere: The image $s \subset S^{d-1}$ of the equator $\{x \in S^{d-1} \mid x_d = 0\}$ in the unit sphere under a self homeomorphism $\phi: S^{d-1} \rightarrow S^{d-1}$. (This definition describes topologically *tame* embeddings of a $(d-2)$ -sphere in S^{d-1} . Pseudospheres behave “nicely” in the sense that they divide S^{d-1} into two sides homeomorphic to open $(d-1)$ -balls.)

Oriented pseudosphere: A pseudosphere together with a choice of a positive side s^+ and a negative side s^- .

Arrangement of pseudospheres: A set of n pseudospheres in S^{d-1} with the extra condition that any subset of $d+2$ or fewer pseudospheres is **realizable**: it defines a cell decomposition of S^{d-1} that is isomorphic to a decomposition by an arrangement of $d+2$ linear hyperplanes.

Essential arrangement: An arrangement such that the intersection of all the pseudospheres is empty.

Rank: The codimension in S^{d-1} of the intersection of all the pseudospheres. For an essential arrangement in S^{d-1} , the rank is d .

Topological representation of $\mathcal{M} = (E, \mathcal{L})$: An essential arrangement of oriented pseudospheres such that $\mathcal{L}$ is the collection of sign vectors associated with the cells of the arrangement.

One of the most important interpretations of oriented matroids is given by the topological representation theorem of Folkman and Lawrence [FL78]; see also

[BLS⁺93, Chapters 4 and 5] and [BKMS01]. It states that oriented matroids are in bijection to (combinatorial equivalence classes of) *arrangements of oriented pseudospheres*. Arrangements of pseudospheres are a topological generalization of hyperplane arrangements, in the same way in which arrangements of pseudolines generalize line arrangements. Thus every rank- d oriented matroid describes a certain cell decomposition of the $(d-1)$ -sphere. Arrangements of pseudospheres are collections of pseudospheres that have intersection properties just like those satisfied by arrangements of proper subspheres.

Definition: A finite collection $\mathcal{P} = (s_1, s_2, \dots, s_n)$ of pseudospheres in S^{d-1} is an *arrangement of pseudospheres* if the following conditions hold (we set $E := \{1, \dots, n\}$):

(PS1) For all $A \subset E$ the set $S_A = \bigcap_{e \in A} s_e$ is a topological sphere.

(PS2) If $S_A \not\subset s_e$, for $A \subset E, e \in E$, then $S_A \cap s_e$ is a pseudosphere in S_A with sides $S_A \cap s_e^+$ and $S_A \cap s_e^-$.

Notice that this definition permits two pseudospheres of the arrangement to be identical. An entirely different, but equivalent, definition is given in the Glossary.

We see that every essential arrangement of pseudospheres $\mathcal{P}$ partitions the $(d-1)$ -sphere into a regular cell complex $\Gamma(\mathcal{P})$. Each cell of $\Gamma(\mathcal{P})$ is uniquely determined by a sign vector in $\{-, 0, +\}^E$ encoding the relative position with respect to each pseudosphere s_i . Conversely, $\Gamma(\mathcal{P})$ characterizes $\mathcal{P}$ up to homeomorphism. $\mathcal{P}$ is **realizable** if there exists an arrangement of proper spheres $\mathcal{S}_X$ with $\Gamma(\mathcal{P}) \cong \Gamma(\mathcal{S}_X)$.

The translation of arrangements of pseudospheres to oriented matroids is given by the topological representation theorem of Folkman and Lawrence [FL78], as follows. (For the definition of “loop,” see Section 6.3.1.)

THEOREM 6.2.4 *The Topological Representation Theorem (pseudosphere-covector translation)*

If $\mathcal{P}$ is an essential arrangement of pseudospheres on S^{d-1} then $\Gamma(\mathcal{P}) \cup \{\mathbf{0}\}$ forms the set of covectors of an oriented matroid of rank d . Conversely, for every oriented matroid $(E, \mathcal{L})$ of rank d (without loops) there exists an essential arrangement of pseudospheres $\mathcal{P}$ on S^{d-1} with $\Gamma(\mathcal{P}) = \mathcal{L} \setminus \{\mathbf{0}\}$.

6.2.5 DUALITY

GLOSSARY

Orthogonality: Two sign vectors $C, D \in \{-, 0, +\}^E$ are *orthogonal* if the set

$$\{C_e \cdot D_e \mid e \in E\}$$

either equals $\{0\}$ or contains $\{+, -\}$. We then write $C \perp D$.

Vector of $\mathcal{M}$: A sign vector that is orthogonal to all covectors of $\mathcal{M}$; a covector of the dual oriented matroid $\mathcal{M}^*$.

Circuit of $\mathcal{M}$: A vector of minimal nonempty support; a cocircuit of the dual oriented matroid $\mathcal{M}^*$.

There is a natural duality structure relating oriented matroids of rank d on n elements to oriented matroids of rank $n-d$ on n elements. It is an amazing fact that the existence of such a duality relation can be used to give another axiomatization of oriented matroids (see [BLS⁺93, Section 3.4]). Here we restrict ourselves to the definition of the dual of an oriented matroid $\mathcal{M}$.

THEOREM 6.2.5 Duality

For every oriented matroid $\mathcal{M} = (E, \mathcal{L})$ of rank d there is a unique oriented matroid $\mathcal{M}^* = (E, \mathcal{L}^*)$ of rank $|E| - d$ given by

$$\mathcal{L}^* = \left\{ D \in \{-, 0, +\}^E \mid C \perp D \text{ for every } C \in \mathcal{L} \right\}.$$

$\mathcal{M}^*$ is called the **dual** of $\mathcal{M}$. In particular, $(\mathcal{M}^*)^* = \mathcal{M}$.

In particular, the cocircuits of the dual oriented matroid $\mathcal{M}^*$, which we call the *circuits* of $\mathcal{M}$, also determine $\mathcal{M}$. Hence the collection $\mathcal{C}(\mathcal{M})$ of all circuits of an oriented matroid $\mathcal{M}$, given by

$$\mathcal{C}(\mathcal{M}) := \mathcal{C}^*(\mathcal{M}^*),$$

is characterized by the *the same* cocircuit axioms. Analogously, the *vectors* of $\mathcal{M}$ are obtained as the covectors of $\mathcal{M}^*$; they are characterized by the covector axioms.

An oriented matroid $\mathcal{M}$ is realizable if and only if its dual $\mathcal{M}^*$ is realizable. The reason for this is that a matrix $(I_d | A)$ represents $\mathcal{M}$ if and only if $(-A^T | I_{n-d})$ represents $\mathcal{M}^*$. (Here I_d denotes a $d \times d$ identity matrix, $A \in \mathbb{R}^{d \times (n-d)}$, and $A^T \in \mathbb{R}^{(n-d) \times d}$ denotes the transpose of A .)

Thus for a realizable oriented matroid $\mathcal{M}_X$ the vectors represent the linear dependencies among the columns of X , while the circuits represent minimal linear dependencies. Similarly, in the pseudoarrangements picture, circuits correspond to minimal systems of closed hemispheres that cover the whole sphere, while vectors correspond to consistent unions of such covers that never require the use of both hemispheres determined by a pseudosphere. This provides a direct geometric interpretation of circuits and vectors.

6.2.6 AN EXAMPLE

We close this section with an example that demonstrates the different representations of an oriented matroid. Consider the planar point configuration X given in Figure 6.2.1(a).

Homogeneous coordinates for X are given by

$$X := \begin{pmatrix} 0 & 3 & 1 \\ -3 & 1 & 1 \\ -2 & -2 & 1 \\ 2 & -2 & 1 \\ 3 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}.$$

FIGURE 6.2.1

An example of an oriented matroid on 6 elements.

The chirotope χ_X of $\mathcal{M}$ is given by the orientations:

$$\begin{aligned}
 \chi(1, 2, 3) &= + & \chi(1, 2, 4) &= + & \chi(1, 2, 5) &= + & \chi(1, 2, 6) &= + & \chi(1, 3, 4) &= + \\
 \chi(1, 3, 5) &= + & \chi(1, 3, 6) &= + & \chi(1, 4, 5) &= + & \chi(1, 4, 6) &= - & \chi(1, 5, 6) &= - \\
 \chi(2, 3, 4) &= + & \chi(2, 3, 5) &= + & \chi(2, 3, 6) &= + & \chi(2, 4, 5) &= + & \chi(2, 4, 6) &= + \\
 \chi(2, 5, 6) &= - & \chi(3, 4, 5) &= + & \chi(3, 4, 6) &= + & \chi(3, 5, 6) &= + & \chi(4, 5, 6) &= +
 \end{aligned}$$

Half of the cocircuits of $\mathcal{M}$ are given in the table below (the other half is obtained by negating the data):

$$\begin{array}{lll}
 (0, 0, +, +, +, +) & (0, -, 0, +, +, +) & (0, -, -, 0, +, -) \\
 (0, -, -, -, 0, -) & (0, -, -, +, +, 0) & (+, 0, 0, +, +, +) \\
 (+, 0, -, 0, +, +) & (+, 0, -, -, 0, -) & (+, 0, -, -, +, 0) \\
 (+, +, 0, 0, +, +) & (+, +, 0, -, 0, +) & (+, +, 0, -, -, 0) \\
 (+, +, +, 0, 0, +) & (-, +, +, 0, -, 0) & (-, -, +, +, 0, 0)
 \end{array}$$

Observe that the cocircuits correspond to the point partitions produced by hyperplanes spanned by points. Half of the circuits of $\mathcal{M}$ are given in the next table. The circuits correspond to sign patterns induced by minimal linear dependencies on the rows of the matrix X . It is easy to check that every pair consisting of a circuit and a cocircuit fulfills the orthogonality condition.

$$\begin{array}{lll}
 (+, -, +, -, 0, 0) & (+, -, +, 0, -, 0) & (+, -, +, 0, 0, -) \\
 (+, -, 0, +, -, 0) & (+, +, 0, +, 0, -) & (+, -, 0, 0, -, +) \\
 (+, 0, -, +, -, 0) & (+, 0, +, +, 0, -) & (+, 0, +, 0, +, -) \\
 (+, 0, 0, +, -, -) & (0, +, -, +, -, 0) & (0, +, -, +, 0, -) \\
 (0, +, +, 0, +, -) & (0, +, 0, +, +, -) & (0, 0, +, -, +, -)
 \end{array}$$

An affine picture of a realization of the dual oriented matroid is given in Figure 6.2.1(b). The minus-sign at point 6 indicates that a reorientation at point 6 has taken place. It is easy to check that the circuits and the cocircuits interchange their roles when dualizing the oriented matroid.

Figure 6.2.1(c) shows the corresponding arrangement of pseudolines. The circle bounding the configuration represents the projective line at infinity representing line 6.

6.3 IMPORTANT CONCEPTS

In this section we briefly introduce some very basic concepts in the theory of oriented matroids. The list of topics treated here is tailored toward some areas of oriented matroid theory that are particularly relevant for applications. Thus many other topics of great importance are left out. In particular, see [BLS⁺93, Section 3.3] for minors of oriented matroids, and [BLS⁺93, Chapter 7] for basic constructions.

6.3.1 SOME BASIC CONCEPTS

In the following glossary, we list some fundamental concepts of oriented matroid theory. Each of them can be expressed in terms of any one of the representations of oriented matroids that we have introduced (covectors, cocircuits, chirotopes, pseudoarrangements), but for each of these concepts some representations are much more convenient than others. Also, each of these concepts has some interesting properties with respect to the duality operator—which may be more or less obvious, depending on the representation that one uses.

GLOSSARY

Direct sum: An oriented matroid $\mathcal{M} = (E, \mathcal{L})$ has a **direct sum decomposition**, denoted by $\mathcal{M} = \mathcal{M}(E_1) \oplus \mathcal{M}(E_2)$, if E has a partition into nonempty subsets E_1 and E_2 such that $\mathcal{L} = \mathcal{L}_1 \times \mathcal{L}_2$ for two oriented matroids $\mathcal{M}_1 = (E_1, \mathcal{L}_1)$ and $\mathcal{M}_2 = (E_2, \mathcal{L}_2)$. If $\mathcal{M}$ has no direct sum decomposition, then it is **irreducible**.

Loops and coloops: A loop of $\mathcal{M} = (E, \mathcal{L})$ is an element $e \in E$ that satisfies $C_e = 0$ for all $C \in \mathcal{L}$. A coloop satisfies $\mathcal{L} \cong \mathcal{L}' \times \{-, 0, +\}$, where $\mathcal{L}'$ is obtained by deleting the e -components from the vectors in $\mathcal{L}$. If $\mathcal{M}$ has a direct sum decomposition with $E_2 = \{e\}$, then e is either a loop or a coloop.

Acyclic oriented matroid: An oriented matroid $\mathcal{M} = (E, \mathcal{L})$ for which $(+, \dots, +)$ is a covector in $\mathcal{L}$; equivalently, the union of the supports of all nonnegative cocircuits is E .

Totally cyclic oriented matroid: An oriented matroid without nonnegative cocircuits; equivalently, $\mathcal{L} \cap \{0, +\}^E = \{\mathbf{0}\}$.

Uniform: An oriented matroid $\mathcal{M}$ of rank d on E is **uniform** if all of its cocircuits have size $|E| - d + 1$. Equivalently, $\mathcal{M}$ is uniform if it has a chirotope with values in $\{+, -\}$.

$\mathcal{M}$ is realizable: There is a vector configuration X with $\mathcal{M}_X = \mathcal{M}$.

Realization of $\mathcal{M}$: A vector configuration X with $\mathcal{M}_X = \mathcal{M}$.

THEOREM 6.3.1 Duality II

Let $\mathcal{M}$ be an oriented matroid on the ground set E , and $\mathcal{M}^*$ its dual.

- $\mathcal{M}$ is acyclic if and only if $\mathcal{M}^*$ is totally cyclic. (However, “most” oriented matroids are neither acyclic nor totally cyclic!)

- $e \in E$ is a loop of $\mathcal{M}$ if and only if it is a coloop of $\mathcal{M}^*$.
- $\mathcal{M}$ is uniform if and only if $\mathcal{M}^*$ is uniform.
- $\mathcal{M}$ is a direct sum $\mathcal{M}(E) = \mathcal{M}(E_1) \oplus \mathcal{M}(E_2)$ if and only if $\mathcal{M}^*$ is a direct sum $\mathcal{M}^*(E) = \mathcal{M}^*(E_1) \oplus \mathcal{M}^*(E_2)$.

Duality of oriented matroids captures, among other things, the concepts of linear programming duality [BK92] [BLS⁺93, Chapter 10] and the concept of Gale diagrams for polytopes [Grü67, Section 5.4] [Zie95, Lecture 6]. For the latter, we note here that the vertex set of a d -dimensional convex polytope P with $d+k$ vertices yields a configuration of $d+k$ vectors in $\mathbb{R}^{d+1}$, and thus an oriented matroid of rank $d+1$ on $d+k$ points. Its dual is a realizable oriented matroid of rank $k-1$, the **Gale diagram** of P . It can be modeled by an affine point configuration of dimension $k-2$, called an **affine Gale diagram** of P . Hence, for “small” k , we can represent a (possibly high-dimensional) polytope with “few vertices” by a low-dimensional point configuration. In particular, this is beneficial in the case $k=4$, where polytopes with “universal” behavior can be analyzed in terms of their 2-dimensional affine Gale diagrams. For further details, see Chapter 16 of this Handbook.

6.3.2 REALIZABILITY AND REALIZATION SPACES

GLOSSARY

Realization space: Let $\chi: E^d \rightarrow \{-, 0, +\}$ be a chirotope with $\chi(1, \dots, d) = +$. The *realization space* $\mathcal{R}(\chi)$ is the set of all matrices $X \in \mathbb{R}^{d \times n}$ with $\chi_X = \chi$ and $x_i = e_i$ for $i = 1, \dots, d$, where e_i is the i th unit vector. If $\mathcal{M}$ is the corresponding oriented matroid, we write $\mathcal{R}(\mathcal{M}) = \mathcal{R}(\chi)$.

Rational realization: A realization $X \in \mathbb{Q}^{d \times n}$; that is, a point in $\mathcal{R}(\chi) \cap \mathbb{Q}^{d \times n}$.

Basic primary semialgebraic set: The (real) solution set of an arbitrary finite system of polynomial equations and strict inequalities with integer coefficients.

Existential theory of the reals: The problem of solving arbitrary systems of polynomial equations and inequalities with integer coefficients.

Stable equivalence: A strong type of arithmetic and homotopy equivalence. Two semialgebraic sets are stably equivalent if they can be connected by a sequence of rational coordinate changes, together with certain projections with contractible fibers. (See [RZ95], and [Ric96a] for details.) In particular, two stably equivalent semialgebraic sets have the same number of components, they are homotopy-equivalent, and either both or neither of them have rational points.

One of the main problems in oriented matroid theory is to design algorithms that find a realization of a given oriented matroid if it exists. However, for oriented matroids with large numbers of points, one cannot be too optimistic, since the realizability problem for oriented matroids is NP-hard. This is one of the consequences of Mnëv’s universality theorem below. An upper bound for the worst-case complexity of the realizability problem is given by the following theorem. It follows

from general complexity bounds for algorithmic problems about semialgebraic sets by Basu, Pollack, and Roy [BPR96] (see also [Chapter 33](#) of this Handbook).

THEOREM 6.3.2 *Complexity of the Best General Algorithm Known*

The realizability of a rank- d oriented matroid on n points can be decided by solving a system of $S = \binom{n}{d}$ real polynomial equations and strict inequalities of degree at most $D = d - 1$ in $K = (n - d - 1)(d - 1)$ variables. Thus, with the algorithms of [BPR96], the number of bit operations needed to decide realizability is (in the Turing machine model of complexity) bounded by $(S/K)^K \cdot S \cdot D^{O(K)}$.

THE UNIVERSALITY THEOREM

A basic observation is that all oriented matroids of rank 2 are realizable. In particular, up to change of orientations and permuting the elements in E there is only one uniform oriented matroid of rank 2. The realization space of an oriented matroid of rank 2 is always stably equivalent to $\{0\}$; in particular, if $\mathcal{M}$ is uniform of rank 2 on n elements, then $\mathcal{R}(\mathcal{M})$ is isomorphic to an open subset of $\mathbb{R}^{2n-4}$.

In contrast to the rank-2 case, Mnëv's universality theorem states that for oriented matroids of rank 3, the realization space can be "arbitrarily complicated." Here is the first glimpse of this:

- The realization spaces of all realizable uniform oriented matroids of rank 3 and at most 9 elements are contractible (Richter [Ric89]).
- There is a realizable rank-3 oriented matroid on 9 elements that has no realization with rational coordinates (Perles [Grü67, p. 93]).
- There is a realizable rank-3 oriented matroid on 14 elements with disconnected realization space (Suvorov [Suv88]; see also Richter-Gebert [Ric96b]).

The universality theorem is a fundamental statement with various implications for the configuration spaces of various types of combinatorial objects.

THEOREM 6.3.3 *Mnëv's Universality Theorem* [Mnë88]

For every basic primary semialgebraic set V defined over $\mathbb{Z}$ there is a chirotope χ of rank 3 such that V and $\mathcal{R}(\chi)$ are stably equivalent.

Although some of the facts in the following list were proved earlier than Mnëv's universality theorem, they all can be considered as consequences of the construction techniques used by Mnëv.

CONSEQUENCES OF THE UNIVERSALITY THEOREM

1. The full field of algebraic numbers is needed to realize all oriented matroids of rank 3.
2. The realizability problem for oriented matroids is NP-hard (Mnëv [Mnë88], Shor [Sho91]).
3. The realizability problem for oriented matroids is (polynomial-time-)equivalent to the "Existential Theory of the Reals" (Mnëv [Mnë88]).

4. For every finite simplicial complex Δ , there is an oriented matroid whose realization space is homotopy-equivalent to Δ .
5. Realizability of rank-3 oriented matroids cannot be characterized by excluding a finite set of “forbidden minors” (Bokowski and Sturmfels [BS89b]).
6. In order to realize all combinatorial types of integral rank-3 oriented matroids on n elements, even uniform ones, in the integer grid $\{1, 2, \dots, f(n)\}^3$, the “coordinate size” function $f(n)$ has to grow doubly exponentially in n (Goodman, Pollack, and Sturmfels [GPS90]).
7. The **isotopy problem** for oriented matroids (Can one given realization of $\mathcal{M}$ be continuously deformed, through realizations, to another given one?) has a negative solution in general, even for uniform oriented matroids of rank 3 [JMSW89].

6.3.3 TRIANGLES AND SIMPLICIAL CELLS

There is a long tradition of studying *triangles* in arrangements of pseudolines. In his 1926 paper [Lev26], Levi already considered them to be important structures. There are good reasons for this. On the one hand, they form the simplest possible cells of full dimension, and are therefore of basic interest. On the other hand, if the arrangement is simple, triangles locate the regions where a “smallest” local change of the combinatorial type of the arrangement is possible. Such a change can be performed by taking one side of the triangle and “pushing” it over the vertex formed by the other two sides. It was observed by Ringel [Rin56] that any two simple arrangements of pseudolines can be deformed into one another by performing a sequence of such “triangle flips.”

Moreover, the realizability of a pseudoline arrangement may depend on the situation at the triangles. For instance, if any one of the triangles in the nonrealizable example of Figure 6.1.2 other than the central one is flipped, the whole configuration becomes realizable.

TRIANGLES IN ARRANGEMENTS OF PSEUDOLINES

Let $\mathcal{P}$ be any arrangement of n pseudolines.

1. For any pseudoline ℓ in $\mathcal{P}$ there are at least 3 triangles adjacent to ℓ .
Either the $n - 1$ pseudolines different from ℓ intersect in one point (i.e., $\mathcal{P}$ is a **near-pencil**), or there are at least $n - 3$ triangles that are not adjacent to ℓ . Thus $\mathcal{P}$ contains at least n triangles (Levi [Lev26]).
2. $\mathcal{P}$ is **simplicial** if all its regions are bounded by exactly 3 (pseudo)lines.
Except for the near-pencils, there are two infinite classes of simplicial line arrangements and 91 additional “sporadic” simplicial line arrangements (and many more simplicial pseudoarrangements) known (Grünbaum [Grü71]).
3. If $\mathcal{P}$ is simple, then it contains at most $\frac{n(n-1)}{3}$ triangles.
For infinitely many values of n , there exists a simple arrangement with $\frac{n(n-1)}{3}$ triangles (Roudneff, Harborth).
4. Any two simple arrangements $\mathcal{P}_1$ and $\mathcal{P}_2$ can be deformed into one another by a sequence of simplicial flips (Ringel [Rin56]).

FIGURE 6.3.1

*A simple arrangement of 28 pseudolines
with a maximal number of 252 triangles.*

Every arrangement of pseudospheres in S^{d-1} has a centrally symmetric representation. Thus we can always derive an arrangement of projective pseudohyperplanes (pseudo $(d-2)$ -planes in $\mathbb{RP}^{d-1}$) by identifying antipodal points. The proper analogue for the triangles in rank 3 are the $(d-1)$ -simplices in projective arrangements of pseudohyperplanes in rank d , i.e., the regions bounded by the minimal number, d , of pseudohyperplanes. We call an arrangement **simple** if no more than $d-1$ planes meet in a point.

It was conjectured by Las Vergnas in 1980 [Las80] that (as in the rank-3 case) any two simple arrangements can be transformed into each other by a sequence of flips of simplicial regions. In particular this requires that every simple arrangement contain *at least one* simplicial region (which was also conjectured by Las Vergnas). If we consider the case of realizable arrangements only, it is not difficult to prove that any two members in this subclass can be connected by a sequence of flips of simplicial regions and that each realizable arrangement contains at least one simplicial cell. In fact, Shannon [Sha79] proved that every arrangement (even the nonsimple ones) of n projective hyperplanes in rank d contains at least n simplicial regions. More precisely, for every hyperplane h there are at least d simplices adjacent to h and at least $n-d$ simplices not adjacent to h . The contrast between the Las Vergnas conjecture and the results known for the nonrealizable case is dramatic:

SIMPLICIAL CELLS IN PSEUDOARRANGEMENTS

1. There is an arrangement of 8 pseudoplanes in rank 4 having only 7 simplicial regions (Altshuler and Bokowski [ABS80], Roudneff and Sturmfels [RS88]).
2. Every rank-4 arrangement with $n < 13$ pseudoplanes has at least one simplicial region (Bokowski and Rohlf's [BR01]).
3. For every $k > 2$ there is a rank-4 arrangement of $4k$ pseudoplanes having only $3k+1$ simplicial regions. (This result of Richter-Gebert [Ric93] was improved

by Bokowski and Rohlfs [BR01] to arrangements of $5k$ pseudoplanes with $7k - c$ simplicial regions.)

4. There is a rank-4 arrangement consisting of 20 pseudoplanes for which one plane is not adjacent to any simplicial region (Richter-Gebert [Ric93]; improved to 17 pseudoplanes by Bokowski and Rohlfs [BR01]).

OPEN PROBLEMS

The topic of simplicial cells is interesting and rich in structure even in rank 3. The case of higher dimensions is full of unsolved problems and challenging conjectures. These problems are relevant for various problems of great geometric and topological interest, such as the structure of spaces of triangulations. Three key problems are:

1. Classify simplicial arrangements. Is it true, at least, that there are only finitely many types of simplicial arrangements of straight lines outside the three known infinite families?
2. Does every arrangement of pseudohyperplanes contain at least one simplicial region?
3. Is it true that any two simple arrangements of pseudospheres can be transformed into one another by a sequence of triangle flips?

6.3.4 MATROID POLYTOPES

The convexity properties of a point configuration X are modeled superbly by the oriented matroid $\mathcal{M}_X$. The combinatorial versions of many theorems concerning convexity also hold on the level of general (including nonrealizable) oriented matroids. For instance, there are purely combinatorial versions of Carathéodory's, Radon's, and Helly's theorems [BLS⁺93, Section 9.2].

In particular, oriented matroid theory provides us with an entirely combinatorial model of convex polytopes, known as “matroid polytopes.” The following definition provides this context in terms of face lattices.

Definition: The face lattice of an acyclic oriented matroid $\mathcal{M} = (E, \mathcal{L})$ is the set

$$\text{FL}(\mathcal{M}) := \{C^0 \mid C \in \mathcal{L} \cap \{0, +\}^E\},$$

partially ordered by inclusion. The elements of $\text{FL}(\mathcal{M})$ are the **faces** of $\mathcal{M}$. $\mathcal{M}$ is a **matroid polytope** if $\{e\}$ is a face for every $e \in E$.

Every polytope gives rise to a matroid polytope: if $P \subset \mathbb{R}^d$ is a d -polytope with n vertices, then the canonical embedding $x \mapsto \binom{x}{1}$ creates a vector configuration X_P of rank $d + 1$ from the vertex set of P . The oriented matroid of X_P is a matroid polytope $\mathcal{M}_P$, whose face lattice $\text{FL}(\mathcal{M})$ is canonically isomorphic to the face lattice of P .

Matroid polytopes provide a very precise model of (the combinatorial structure of) convex polytopes. In particular, the topological representation theorem implies that *every* matroid polytope of rank d is the face lattice of a regular piecewise linear (PL) cell decomposition of a $(d-2)$ -sphere. Thus matroid polytopes form an

excellent combinatorial model for convex polytopes: in fact, much better than the model of PL spheres (which does not have an entirely combinatorial definition).

However, the construction of a polar fails in general for matroid polytopes. The cellular spheres that represent matroid polytopes have dual cell decompositions (because they are piecewise linear), but this dual cell decomposition is not in general a matroid polytope, even in rank 4 (Billera and Munson [BM84]; Bokowski and Schuchert [BS95]). In other words, the order dual of the face lattice of a matroid polytope (as an abstract lattice) is *not in general* the face lattice of a matroid polytope. (Matroid polytopes form an important tool for polytope theory, not only because of the parts of polytope theory that work for them, but also because of those that fail.)

For every matroid polytope one has the dual oriented matroid (which is totally cyclic, hence not a matroid polytope). In particular, the setup for Gale diagrams generalizes to the framework of matroid polytopes; this makes it possible to also include nonpolytopal spheres in a discussion of the realizability properties of polytopes. This amounts to perhaps the most powerful single tool ever developed for polytope theory. It leads to, among other things, the classification of d -dimensional polytopes with at most $d + 3$ vertices, the proof that all matroid polytopes of rank $d + 1$ with at most $d + 3$ vertices are realizable, the construction of nonrational polytopes as well as of nonpolytopal spheres with $d + 4$ vertices, etc.

ALGORITHMIC APPROACH TO POLYTOPE CLASSIFICATION

A powerful approach, via matroid polytopes, to the problem of classifying all convex polytopes with given parameters is largely due to Bokowski and Sturmfels [BS89a]. Here we restrict our attention to the simplicial case—there are additional technical problems to deal with in the nonsimplicial case, and very little work has been done there as yet. However, the program has been successfully completed for the classification of all simplicial 3-spheres with 9 vertices (Altshuler, Bokowski, and Steinberg [ABS80]) and of all neighborly 5-spheres with 10 vertices (Bokowski and Shemer [BS87]) into polytopes and nonpolytopes. At the core of the matroidal approach lies the following hierarchy:

$$\left(\begin{array}{c} \text{simplicial} \\ \text{spheres} \end{array} \right) \supset \left(\begin{array}{c} \text{uniform} \\ \text{matroid polytopes} \end{array} \right) \supset \left(\begin{array}{c} \text{convex} \\ \text{polytopes} \end{array} \right).$$

The plan of attack is the following. First, one enumerates all isomorphism types of simplicial spheres with given parameters. Then, for each sphere, one computes *all* (uniform) matroid polytopes that have the given sphere as their face lattices. Finally, for each matroid polytope, one tries to decide realizability.

At both of the steps of this hierarchy there are considerable subtleties involved that lead to important insights. For a given simplicial sphere, there may be

- *no* matroid polytope that supports it. In this case the sphere is called **non-matroidal**. The Barnette sphere [BLS⁺93, Proposition 9.5.3] is an example.
- *exactly one* matroid polytope. In this (important) case the sphere is called **rigid**. That is, a matroid polytope $\mathcal{M}$ is rigid if $\text{FL}(\mathcal{M}') = \text{FL}(\mathcal{M})$ already implies $\mathcal{M}' = \mathcal{M}$. For rigid matroid polytopes the face lattice uniquely defines the oriented matroid, and thus every statement about the matroid polytope yields a statement about the sphere. In particular, the matroid polytope and the sphere have the same realization space.

Rigid matroid polytopes are a priori rare; however, the *Lawrence construction* [BLS⁺93, Section 9.3] [Zie95, Section 6.6] associates with every oriented matroid $\mathcal{M}$ on n elements in rank d a rigid matroid polytope $\Lambda(\mathcal{M})$ with $2n$ vertices of rank $n + d$. The realizations of $\Lambda(\mathcal{M})$ can be retranslated into realizations of $\mathcal{M}$.

- or *many* matroid polytopes.

The situation is similarly complex for the second step, from matroid polytopes to convex polytopes. In fact, for each matroid polytope there may be

- *no* convex polytope—this is the case for a nonrealizable matroid polytope. These exist already with relatively few vertices; namely in rank 5 with 9 vertices [BS95], and in rank 4 with 10 vertices [BLS⁺93, Proposition 9.4.5].
- essentially *only one*—this is the rare case where the matroid polytope is “projectively unique.”
- or *many* convex polytopes—the space of all polytopes for a given matroid polytope is the realization space of the oriented matroid, and this may be arbitrarily complicated. In fact, a combination of Mnëv’s universality theorem, the Lawrence construction, and a scattering technique [BS89a, Theorem 6.2] (in order to handle the simplicial case) yields the following amazing universality theorem.

THEOREM 6.3.4 *Mnëv’s Universality Theorem for Polytopes* [Mnë88]

For every [open] basic primary semialgebraic set V defined over $\mathbb{Z}$ there is an integer d and a [simplicial] d -dimensional polytope P on $d + 4$ vertices such that V and the realization space of P are stably equivalent.

7 LATTICE POINTS AND LATTICE POLYTOPES

Alexander Barvinok

INTRODUCTION

Lattice polytopes arise naturally in number theory, algebraic geometry, optimization, combinatorics, probability, and analysis. They possess a very rich structure arising from the interaction of algebraic, convex, analytic, and combinatorial properties. In this chapter, we concentrate on the theory of lattice polytopes and only sketch their numerous applications. We briefly discuss their role in optimization and polyhedral combinatorics (Section 7.1). In Section 7.2 we discuss the *decision problem*, the problem of finding whether a given polytope contains a lattice point. In Section 7.3 we address the *counting problem*, the problem of counting all lattice points in a given polytope. The *asymptotic problem* (Section 7.4) explores the behavior of the number of lattice points in a varying polytope (for example, if a dilatation is applied to the polytope). Finally, in Section 7.5 we discuss *problems with quantifiers*. These problems are natural generalizations of the decision and counting problems. Whenever appropriate we address algorithmic issues. For general references in the area of computational complexity/algorithms see [AHU74]. We summarize the computational complexity status of our problems in Table 7.0.1.

TABLE 7.0.1 Computational complexity of basic problems.

PROBLEM NAME	BOUNDED DIMENSION	UNBOUNDED DIMENSION
Decision problem	polynomial	NP-hard
Counting problem	polynomial	#P-hard
Asymptotic problem	polynomial	#P-hard*
Problems with quantifiers	unknown; polynomial for $\forall\exists$	NP-hard

* in bounded codimension this reduces polynomially to volume computation

7.1 INTEGRAL POLYTOPES IN POLYHEDRAL COMBINATORICS

We describe some combinatorial and computational properties of integral polytopes. General references are [GLS88], [GW93], [Sch86], [Lag95], [DL97], and [Zie00].

GLOSSARY

$\mathbb{R}^d$: Euclidean d -dimensional space with scalar product $\langle x, y \rangle = x_1y_1 + \dots + x_dy_d$, where $x = (x_1, \dots, x_d)$ and $y = (y_1, \dots, y_d)$.

$\mathbb{Z}^d$: The subset of $\mathbb{R}^d$ consisting of the points with integral coordinates.

Polytope: The convex hull of finitely many points in $\mathbb{R}^d$.

Face of a polytope P : The intersection of P and the boundary hyperplane of a halfspace containing P .

Facet: A face of codimension 1.

Vertex: A face of dimension 0; the set of vertices of P is denoted by $\text{Vert } P$.

$\mathcal{H}$ -description of a polytope ($\mathcal{H}$ -polytope): A representation of the polytope as the set of solutions of finitely many linear inequalities.

$\mathcal{V}$ -description of a polytope ($\mathcal{V}$ -polytope): The representation of the polytope by the set of its vertices.

Integral polytope: A polytope with all of its vertices in $\mathbb{Z}^d$.

$(0, 1)$ -polytope: A polytope P such that each coordinate of every vertex of P is either 0 or 1.

An integral polytope $P \subset \mathbb{R}^d$ can be given either by its $\mathcal{H}$ -description or by its $\mathcal{V}$ -description or (somewhat implicitly) as the convex hull of integral points in some other polytope Q : $P = \text{conv}\{Q \cap \mathbb{Z}^d\}$. In most cases it is difficult to translate one description into another. The following examples illustrate some typical kinds of behavior.

INTEGRALITY OF $\mathcal{H}$ -POLYTOPES

It is an NP-hard problem to decide whether an $\mathcal{H}$ -polytope $P \subset \mathbb{R}^d$ is integral. However, if the dimension d is fixed then the straightforward procedure of generating all the vertices of P and checking their integrality has polynomial time complexity. A rare case where an $\mathcal{H}$ -polytope P is a priori integral is known under the general name of “total unimodularity.” Let A be an $n \times d$ integral matrix such that every minor of A is either 0 or 1 or -1 . Such a matrix A is called **totally unimodular**. If $b \in \mathbb{Z}^n$ is an integral vector then the set of solutions to the system of linear inequalities $Ax \leq b$ is an integral polytope in $\mathbb{R}^d$, provided this set is bounded. Examples of totally unimodular matrices include matrices of vertex-edge incidences of oriented graphs and of bipartite graphs. A complete characterization of totally unimodular matrices and a polynomial time algorithm for recognizing a totally unimodular matrix is provided by a theorem of P. Seymour (see [Sch86]). A family of integral polytopes, called **transportation polytopes**, were intensively studied in the literature (see [EKK84]). An example of a transportation polytope is provided by the set of $m \times n$ nonnegative matrices $x = (x_{ij})$ whose row and column sums are given positive integers. Integral points in this polytope are called **contingency tables**; they play an important role in statistics. A particular transportation polytope, called the **Birkhoff polytope**, is the set B_n of $n \times n$ nonnegative matrices with all row and column sums equal to 1. Alternatively, it may be described as the convex hull of the $n!$ permutation matrices $\pi(\sigma)_{ij} = \delta_{j\sigma(j)}$ for all permutations σ of the set $\{1, \dots, n\}$.

The notion of total unimodularity has been generalized in various directions, thus leading to new classes of integral polytopes (see [Cor01]).

$\mathcal{V}$ -POLYTOPES WITH MANY VERTICES

There are several important situations where the explicit $\mathcal{V}$ -description of an integral polytope is too long and a shorter description is desirable although not always

available. For example, a $(0, 1)$ -polytope may be given as the convex hull of the characteristic vectors

$$\chi_S(i) = \begin{cases} 1 & \text{if } i \in S, \\ 0 & \text{otherwise} \end{cases}$$

for some combinatorially interesting family $\mathcal{S}$ of subsets $S \subset \{1, \dots, d\}$ (see [GLS88] for various examples). The most famous example is the **traveling salesman polytope**, the convex hull TSP_n of the $(n-1)!$ permutation matrices $\pi(\sigma)$ where σ is a permutation of the set $\{1, \dots, n\}$ consisting of precisely one cycle (cf. the Birkhoff polytope B_n above). The problem of the $\mathcal{H}$ -description of the traveling salesman polytope has attracted a lot of attention (see [GW93] and [EKK84] for some references) because of its relevance to combinatorial optimization. C.H. Papadimitriou proved that it is a co-NP-complete problem to establish whether two given vertices of TSP_n are adjacent, i.e., connected by an edge. L. Billera and A. Sarangarajan proved that every $(0, 1)$ -polytope can be realized as a face of TSP_n for sufficiently large n (see [BS96]). Thus the combinatorics of TSP_n contrasts with the combinatorics of the Birkhoff polytope B_n .

Another important polytope arising in this way is the **cut polytope**, the famous counterexample to the Borsuk conjecture (see [DL97]). It is defined as the convex hull of the set of $n \times n$ matrices x_S , where

$$x_S(i, j) = \begin{cases} 1 & \text{if } |\{i, j\} \cap S| = 1 \text{ and } i \neq j, \\ 0 & \text{otherwise,} \end{cases}$$

where S ranges over all subsets of the set $\{1, \dots, n\}$.

CONVEX HULL OF INTEGRAL POINTS

Let $P \subset \mathbb{R}^d$ be a polytope. Then the convex hull P_I of the set $P \cap \mathbb{Z}^d$, if nonempty, is an integral polytope. Generally, the number of facets or vertices of P_I depends not only on the number of facets or vertices of P but also on the actual numerical size of the description of P (see [CHKM92]). Furthermore, it is an NP-complete problem to check whether a given point belongs to P_I , where P is given by its $\mathcal{H}$ -description. If, however, the dimension d is fixed then the complexity of the facial description of the polytope P_I is polynomial in the complexity of the description of P . In particular, the number of vertices of P_I is bounded by a polynomial of degree $d-1$ in the input size of P (see [CHKM92]).

Integrality imposes some restrictions on the combinatorial structure of a polytope. It is known that the combinatorial type of any 2- or 3-dimensional polytope can be realized by an integral polytope. J. Richter-Gebert constructed a 4-dimensional polytope with a nonintegral (and, therefore, nonrational) combinatorial type [Ric96]. Earlier, N. Mnëv had shown that for sufficiently large d there exist nonrational d -polytopes with $d+4$ vertices. The number $N_d(V)$ of classes of integral d -polytopes having volume V and nonisomorphic with respect to affine transformations of $\mathbb{R}^d$ preserving the integral lattice $\mathbb{Z}^d$ has logarithmic order

$$c_1(d)V^{\frac{d-1}{d+1}} \leq \log N_d(V) \leq c_2(d)V^{\frac{d-1}{d+1}}$$

for some nonzero constants $c_1(d), c_2(d)$ [BV92].

7.2 DECISION PROBLEM

We consider the following general decision problem: Given a polytope $P \subset \mathbb{R}^d$ and a lattice $\Lambda \subset \mathbb{R}^d$, decide whether $P \cap \Lambda = \emptyset$ and, if the intersection is nonempty, find a point in $P \cap \Lambda$. We describe the main structural and algorithmic results for this problem. General references are [GL87], [GLS88], [GW93], [Sch86], and [Lag95].

GLOSSARY

Lattice: A discrete additive subgroup Λ of $\mathbb{R}^d$, i.e., $x - y \in \Lambda$ for any $x, y \in \Lambda$ and Λ does not contain limit points.

Basis of a lattice: A set of linearly independent vectors $u_1, \dots, u_k$ such that every vector $y \in \Lambda$ can be (uniquely) represented in the form $y = m_1 u_1 + \dots + m_k u_k$ for some integers $m_1, \dots, m_k$.

Rank of a lattice: The cardinality of any basis of the lattice. If $\Lambda \subset \mathbb{R}^d$ has rank d , Λ is said to be of **full rank**.

Determinant of a lattice: For a lattice of rank k the k -volume of the parallelepiped spanned by any basis of the lattice.

Reciprocal lattice: For a full rank lattice $\Lambda \subset \mathbb{R}^d$, the lattice $\Lambda^* = \{x \in \mathbb{R}^d \mid \langle x, y \rangle \in \mathbb{Z} \text{ for all } y \in \Lambda\}$.

Polyhedron: An intersection of finitely many halfspaces in $\mathbb{R}^d$.

Convex body: A compact convex set in $\mathbb{R}^d$ with nonempty interior.

Lattice Polytope: For a given lattice Λ , a polytope with all of its vertices in Λ .

Applying a suitable linear transformation one can reduce the decision problem to the case in which $\Lambda = \mathbb{Z}^k$ and $P \subset \mathbb{R}^k$ is a full-dimensional polytope, $k = \text{rank } \Lambda$.

The decision problem is known to be NP-complete for $\mathcal{H}$ -polytopes as well as for $\mathcal{V}$ -polytopes, although some special cases admit a polynomial time algorithm. In particular, if one fixes the dimension d then the decision problem becomes polynomially solvable. The main tool is provided by the so-called “flatness results.”

FLATNESS THEOREMS

Let $P \subset \mathbb{R}^d$ be a convex body and let $l \in \mathbb{R}^d$ be a nonzero vector. The number

$$\max\{\langle l, x \rangle \mid x \in P\} - \min\{\langle l, x \rangle \mid x \in P\}$$

is called the **width** of P with respect to l . For a full rank lattice $\Lambda \subset \mathbb{R}^d$, the minimum width of P with respect to a nonzero vector $l \in \Lambda^*$ is called the **lattice width** of P .

The following general result is known under the unifying name of “flatness theorem”.

THEOREM 7.2.1

There is a function $f : \mathbb{N} \rightarrow \mathbb{R}$ such that for any full rank lattice $\Lambda \subset \mathbb{R}^d$ and any convex body $P \subset \mathbb{R}^d$ with $P \cap \Lambda = \emptyset$, the lattice width of P does not exceed $f(d)$.

There are two types of results relating to the flatness theorem.

First, one may be interested in making $f(d)$ as small as possible. One can observe that $f(d) \geq d$: for some small $\epsilon > 0$, consider $\Lambda = \mathbb{Z}^d$ and the polytope P defined by the inequalities $x_1 + \dots + x_d \leq d - \epsilon$, $x_i \geq \epsilon$ for $i = 1, \dots, d$. It is known that one can choose $f(d) = O(d^{3/2})$ and it is conjectured that one can choose $f(d)$ as small as $O(d)$. W. Banaszczyk proved that if P is centrally symmetric, then one can choose $f(d) = O(d \log d)$, which is optimal up to a logarithmic factor. For these and related results, see [BLPS99]. There are results regarding the lattice width of some interesting classes of convex sets. Thus, if $P \subset \mathbb{R}^d$ is an ellipsoid which does not contain lattice points, then the lattice width of P is $O(d)$ [BLPS99]. J.-M. Kantor [Kan99] showed that for any $\alpha < 1/e$ one can find a sufficiently large d and a lattice simplex P such that P has no lattice points other than its vertices and such that the lattice width of P is at least αd . If P is a 3-dimensional lattice polytope which does not contain any lattice point other than its vertices, then the lattice width of P is 1 (see [Sca85]).

Second, one may be interested in the best width bound for which the corresponding vector $l \in \Lambda^*$ can be computed in polynomial time. The best bound known is $2^{O(d)}$, where l is polynomially computable even if the dimension d varies; see [GLS88]. J. Håstad proved that there is a polynomial time certificate certifying the distance from a given point $x \in \mathbb{R}^d$ to a given lattice $\Lambda \subset \mathbb{R}^d$ within a factor of $O(d^2)$. Namely, if Λ is a full-dimensional lattice, there exists a vector $l \in \Lambda^*$ with

$$\min_{u \in \Lambda} \|x - u\| \geq \frac{\{\{ \langle l, x \rangle \}\}}{\|l\|} \geq \frac{1}{6d^2 + 1} \min_{u \in \Lambda} \|x - u\|,$$

where $\{\{\cdot\}\}$ is the distance to the nearest integer.

ALGORITHMS FOR THE DECISION PROBLEMS

Flatness theorems allow one to reduce the dimension in the decision problem: Assuming that $\Lambda = \mathbb{Z}^d$ and that the body P does not contain an integral point, one constructs a vector $l \in \mathbb{Z}^d$ for which P has a small width and reduces the d -dimensional decision problem to a family of $(d-1)$ -dimensional decision problems $P_i = \{x \in P \mid \langle l, x \rangle = i\}$, where i ranges between $\min\{\langle l, x \rangle \mid x \in P\}$ and $\max\{\langle l, x \rangle \mid x \in P\}$. This reduction is the main idea of polynomial time algorithms in fixed dimension. The best complexity known for the decision problem in terms of the dimension d is $d^{O(d)}$.

Constructing l efficiently relies on two major components (see [GLS88]). First, a linear transformation T is computed, such that the image $T(P)$ is “almost round,” meaning that $T(P)$ is sandwiched between a pair of concentric balls with the ratio of their radii bounded by some small constant depending only on the dimension d . At this stage, a linear programming algorithm is used. Second, a reasonably short nonzero vector u is constructed in the lattice Λ^* reciprocal to $\Lambda = T(\mathbb{Z}^d)$. A basis reduction algorithm is used at this stage. Then we let $l = (T^*)^{-1}u$.

One can streamline the process by using the generalized lattice reduction [LS92] tailored to a given polytope. A polynomial time algorithm based on counting lattice points in the polytope and not using the flatness argument is sketched in [BP99].

MINKOWSKI'S CONVEX BODY THEOREM

The following classical result, known as “Minkowski’s convex body theorem,” provides a very useful criterion.

THEOREM 7.2.2

Suppose that $B \subset \mathbb{R}^d$ is a convex body, centrally symmetric about the origin 0, and $\Lambda \subset \mathbb{R}^d$ is a lattice of full rank. If $\text{vol } B \geq 2^d \det \Lambda$ then B contains a nonzero point of Λ .

For the proof and various generalizations see, for example, [GL87]. An important generalization (Minkowski's Second Theorem) concerns the existence of i linearly independent lattice points in a convex body. Namely, if $\lambda_i = \inf \left\{ \lambda > 0 \mid \lambda B \cap \Lambda \text{ contains } i \text{ linearly independent points} \right\}$ is the “ i th successive minimum,” then $\lambda_1 \dots \lambda_d \leq (2^d \det \Lambda) / (\text{vol } B)$.

If B is a convex body such that $\text{vol } B = 2^d \det \Lambda$ but B does not contain a nonzero lattice point in its interior, then B is called **extremal**. Every extremal body is necessarily a polytope. Moreover, this polytope contains at most $2(2^d - 1)$ facets, and therefore, for every dimension d , there exist only finitely many combinatorially different extremal polytopes. The contracted polytope $P = \{x/2 \mid x \in B\}$ has the property that its lattice translates $P + x \mid x \in \Lambda$ tile the space $\mathbb{R}^d$. Such a tiling polytope is called a **parallelohedron**. Similarly, for every dimension d there exist only finitely many combinatorially different parallelohedra. Parallelohedra can be characterized intrinsically: a polytope is a parallelohedron if and only if it is centrally symmetric, every facet of it is centrally symmetric, and every class of parallel ridges ($(d-2)$ -dimensional faces) consists of four or six ridges. If $q : \mathbb{R}^d \rightarrow \mathbb{R}$ is a positive definite quadratic form, then the **Dirichlet-Voronoi cell** $P_q = \{x \mid q(x) \leq q(x - \lambda) \text{ for any } \lambda \in \Lambda\}$ is a parallelohedron. The problem of finding whether a centrally symmetric polyhedron P contains a nonzero point from a given lattice Λ is known to be NP-complete even in the case of the standard cube $P = \{(x_1, \dots, x_d) \mid -1 \leq x_i \leq 1\}$. For fixed dimension d there exists a polynomial time algorithm since the problem obviously reduces to the decision problem (one can add the extra inequality $x_1 + \dots + x_d \geq 1$).

VOLUME BOUNDS

An integral simplex in $\mathbb{R}^d$ containing no integral points other than its vertices has volume $1/2$ if $d = 2$ but already for $d = 3$ can have an arbitrarily large volume (the smallest possible volume of such a simplex is $1/d!$). On the other hand, if an integral polytope P contains precisely $k > 0$ integral points then its volume is bounded by a function of k and d . The best bound known, $\text{vol } P \leq k(7(k+1))^{2^{d+1}}$, is due to J. Lagarias and G.M. Ziegler (see [Lag95]).

7.3 COUNTING PROBLEM

We consider the following problem: Given a polytope $P \subset \mathbb{R}^d$, compute exactly or approximately the number of integral points $|P \cap \mathbb{Z}^d|$ in P .

For counting in general convex bodies see [CHKM92]. For some applications in the combinatorics of generating functions and representation theory see, for example, [BZ88] and [Sta86]. For applications in statistical physics (computing permanents) and statistics (counting contingency tables), see [JS97]. For general information see the surveys [GW93] and [BP99].

GLOSSARY

Rational polyhedron: The set

$$P = \{x \in \mathbb{R}^d \mid \langle a_i, x \rangle \leq \beta_i, \ i = 1, \dots, m\},$$

where $a_i \in \mathbb{Z}^d$ and $\beta_i \in \mathbb{Z}$ for $i = 1, \dots, m$.

Polyhedral cone: A set $K \subset \mathbb{R}^d$ of the form $K = \{\sum_{i=1}^k \lambda_i u_i \mid \lambda_i \geq 0, \ i = 1, \dots, k\}$ for some vectors $u_1, \dots, u_k \in \mathbb{R}^d$. The vectors $u_1, \dots, u_k$ are called **generators** of K .

Rational cone: A polyhedral cone having a set of generators belonging to $\mathbb{Z}^d$. A rational cone is a rational polyhedron.

Simple cone: A polyhedral cone generated by linearly independent vectors.

Cone of feasible directions at a point: The cone

$$K_v = \{x \mid v + \epsilon x \in P \text{ for all sufficiently small } \epsilon > 0\}$$

for a point v of a polytope P . If v is a vertex, then the cone K_v is generated by the vectors $u_i = v_i - v$, where $[v_i, v]$ is an edge of P .

Fundamental parallelepiped of a simple cone: The set

$$\Pi = \{\lambda_1 u_1 + \dots + \lambda_k u_k \mid 0 \leq \lambda_i < 1, \ i = 1, \dots, k\},$$

where $u_1, \dots, u_k$ are linearly independent generators of the cone.

Unimodular cone: A rational simple cone $K \subset \mathbb{R}^d$ whose fundamental parallelepiped does not contain points of $\mathbb{Z}^d$ other than 0.

Simple polytope: A polytope P such that the cone K_v of feasible directions is simple for every vertex v of P .

Totally unimodular polytope: An integral polytope P such that the cone K_v of feasible directions is unimodular for every vertex v of P .

GENERAL INFORMATION

The counting problem is known to be $\#P$ -hard even for an integral $\mathcal{H}$ - or $\mathcal{V}$ -polytope.

However, if the dimension d is fixed, one can solve the counting problem in polynomial time (see [BP99]).

SOME EXPLICIT FORMULAS IN LOW DIMENSIONS

The classical Pick formula expresses the number of integral points in a convex integral polygon $P \subset \mathbb{R}^2$ in terms of its area and the number of integral points on the boundary ∂P :

$$|P \cap \mathbb{Z}^2| = \text{area}(P) + \frac{1}{2} \cdot |\partial P \cap \mathbb{Z}^2| + 1$$

(see, for example, [Mor93b], [GW93]). This formula almost immediately gives rise to a polynomial time algorithm for counting integral points in integral polygons.

An important explicit formula for the number of integral points in a lattice tetrahedron of a special kind was proven by L. Mordell. Let a, b, c be pairwise coprime positive integers and $\Delta(a, b, c) \subset \mathbb{R}^3$ be the tetrahedron with vertices $(0, 0, 0)$, $(a, 0, 0)$, $(0, b, 0)$, and $(0, 0, c)$. Then

$$|\Delta(a, b, c) \cap \mathbb{Z}^3| = \frac{abc}{6} + \frac{ab + ac + bc + a + b + c}{4} + \frac{1}{12} \left(\frac{ac}{b} + \frac{bc}{a} + \frac{ab}{c} + \frac{1}{abc} \right) - s(bc, a) - s(ac, b) - s(ab, c) + 2. \quad (7.3.1)$$

Here

$$s(p, q) = \sum_{i=1}^q \left(\left(\frac{i}{q} \right) \right) \left(\left(\frac{pi}{q} \right) \right), \quad \text{where} \quad ((x)) = x - 0.5(\lfloor x \rfloor + \lceil x \rceil),$$

is the Dedekind sum. A similar formula was found in dimension 4. The famous reciprocity relation $s(p, q) + s(q, p) = (p/q + q/p + 1/pq - 3)/12$ allows one to compute the Dedekind sum $s(p, q)$ in polynomial time. A version of formula (7.3.1) was used by M. Dyer to construct polynomial time algorithms for the counting problem in dimensions 3 and 4. Formula (7.3.1) was generalized to an arbitrary tetrahedron by J. Pommersheim (see [BP99]). A generalization to higher dimensions was suggested in [CS94].

Computationally efficient formulas for the number of lattice points are known for some particular polytopes, most notably zonotopes. Given integral points $v_1, \dots, v_n$ in $\mathbb{R}^d$, a **zonotope** spanned by $v_1, \dots, v_n$ is the polytope

$$P = \left\{ \lambda_1 v_1 + \dots + \lambda_n v_n \mid 0 \leq \lambda_i \leq 1 \quad \text{for } i = 1, \dots, n \right\}.$$

For each subset $S \subset \{v_1, \dots, v_n\}$ of linearly independent points, let a_S be the index of the sublattice generated by S in the lattice $\mathbb{Z}^d \cap \text{span}(S)$, where $a_\emptyset = 1$. Then $|P \cap \mathbb{Z}^d| = \sum_S a_S$ (see Chapter 4, Problem 31 of [Sta86]).

EXPONENTIAL SUMS

A powerful tool for solving the counting problem exactly is provided by **exponential sums**, which may be regarded as generating functions for sets of integral points.

Let $P \subset \mathbb{R}^d$ be a polytope and $c \in \mathbb{R}^d$ be a vector. We consider the exponential sum $\sum_{x \in P \cap \mathbb{Z}^d} \exp\{\langle c, x \rangle\}$. If $c = 0$ we get the number of integral points in P . The reason for introducing the parameter c is that for a “generic” c the exponential sums reveal some nontrivial algebraic properties that become less visible when $c = 0$. To describe these properties we need to consider exponential sums over rational polyhedra and, in particular, over cones.

EXPONENTIAL SUMS OVER RATIONAL POLYHEDRA

Let $K \subset \mathbb{R}^d$ be a rational cone without straight lines generated by vectors $u_1, \dots, u_k$ in $\mathbb{Z}^d$. Then the series $\sum_{x \in K \cap \mathbb{Z}^d} \exp\{\langle c, x \rangle\}$ converges for any c such that $\langle c, u_i \rangle < 0$

for all $i = 1, \dots, k$ and defines a meromorphic function of c which we denote by $f_K(c)$. For a simple rational cone $K \subset \mathbb{R}^d$ with linearly independent generators $u_1, \dots, u_k$ we have

$$f_K(c) = \left(\sum_{x \in \Pi \cap \mathbb{Z}^d} \exp\{\langle c, x \rangle\} \right) \cdot \prod_{i=1}^k \frac{1}{1 - \exp\{\langle c, u_i \rangle\}},$$

where Π is the fundamental parallelepiped of K . In particular, if K is unimodular then

$$f_K(c) = \prod_{i=1}^k \frac{1}{1 - \exp\{\langle c, u_i \rangle\}},$$

since the corresponding sum is just the multiple geometric series. Generally speaking, the farther a given cone is from being unimodular, the more complicated the formula for $f_K(c)$ will be.

These results are known in many different forms (see, for example, Section 4.6 of [Sta86]). Furthermore, the function $f_K(c)$ can be extended to a finitely additive measure, defined on rational polyhedra in $\mathbb{R}^d$ and taking its values in the space of meromorphic functions in d variables, so that the measure of a rational polyhedron with a straight line is equal to 0. To state the result precisely, let us associate with every set $A \in \mathbb{R}^d$ its **indicator function** $[A] : \mathbb{R}^d \rightarrow \mathbb{R}$, given by

$$[A](x) = \begin{cases} 1 & \text{if } x \in A, \\ 0 & \text{otherwise.} \end{cases}$$

The following result was proved by A.G. Khovanskii and A. Pukhlikov [KP92] and, independently, by J. Lawrence [Law91].

THEOREM 7.3.1 *Lawrence-Khovanskii-Pukhlikov Theorem*

There exists a map that associates, to every rational polyhedron $P \subset \mathbb{R}^d$, a meromorphic function $f_P(c)$, $c \in \mathbb{C}^d$, such that:

The correspondence $P \mapsto f_P$ preserves linear dependencies among indicator functions of rational polyhedra:

$$\sum_{i=1}^m \alpha_i [P_i] = 0 \quad \text{implies} \quad \sum_{i=1}^m \alpha_i f_{P_i}(c) = 0$$

for rational polyhedra P_i and integers α_i ;

If P does not contain straight lines, then

$$f_P(c) = \sum_{x \in P \cap \mathbb{Z}^d} \exp\{\langle c, x \rangle\}$$

for all c such that the series converges absolutely;

If P contains a straight line then $f_P(c) \equiv 0$.

If $P + m$ is a translation of P by an integral vector m then

$$f_{P+m}(c) = \exp\{\langle c, v \rangle\} f_P(c).$$

For example, suppose that $d = 1$ and let us choose $P_+ = [0, +\infty)$, $P_- = (-\infty, 0]$, $P_0 = \{0\}$, and $P = (-\infty, +\infty)$. Then

$$f_{P_+}(c) = \sum_{x=0}^{+\infty} \exp\{cx\} = \frac{1}{1 - \exp\{c\}} \quad \text{and} \quad f_{P_-}(c) = \sum_{x=0}^{-\infty} \exp\{cx\} = \frac{1}{1 - \exp\{-c\}}.$$

Moreover, $f_{P_0} = 1$ and $f_P = 0$ since P contains a straight line. We see that $[P] = [P_+] + [P_-] - [P_0]$ and that $f_P = f_{P_+} + f_{P_-} - f_{P_0}$.

Let $P \subset \mathbb{R}^d$ be a rational polytope and let $v \in P$ be its vertex. Let us consider the translation $v + K_v$ of the cone K_v of feasible directions at v . The following crucial result was proved by M. Brion [Bri98].

THEOREM 7.3.2 *Brion's Theorem*

Let $P \subset \mathbb{R}^d$ be a rational polytope. Then

$$\sum_{x \in P \cap \mathbb{Z}^d} \exp\{\langle c, x \rangle\} = \sum_{v \in \text{Vert } P} f_{v+K_v}(c).$$

If the polytope is integral, we have $f_{v+K_v}(c) = \exp\{\langle c, v \rangle\} f_{K_v}(c)$. We note that if K is a unimodular cone and v is a rational vector then $f_{K+v} = \exp\{\langle c, w \rangle\} f_K(c)$, where $w \in \mathbb{Z}^d$ is a certain “rounding” of v with respect to K . Namely, assume that K is the conic hull of some integral vectors $u_1, \dots, u_d$ that constitute a basis of $\mathbb{Z}^d$. Let $u_1^*, \dots, u_d^*$ be the biorthogonal basis such that $\langle u_i^*, u_j \rangle = \delta_{ij}$. Then $w = \sum_{i=1}^d \lceil \langle v, u_i^* \rangle \rceil u_i$.

Essentially, Theorem 7.3.2 can be deduced from Theorem 7.3.1 by noticing that the indicator function of every (rational) polyhedron P can be written as the sum of the indicator functions $[v + K_v]$ modulo indicator functions of (rational) polyhedra with straight lines; see [BP99].

Brion's formula allows one to reduce the counting of integral points in polytopes to the counting of points in polyhedral cones, a much easier problem. Below we discuss two instances where the application of exponential sums and Brion's identities leads to an efficient computational solution of the counting problem.

COUNTING IN FIXED DIMENSION

The following result was obtained by A. Barvinok (see [BP99]).

THEOREM 7.3.3

Let us fix the dimension d . Then there exists a polynomial time algorithm that, for any given rational polytope $P \subset \mathbb{R}^d$, computes the number $|P \cap \mathbb{Z}^d|$ of integral points in P .

THE IDEA OF THE ALGORITHM

We assume that the polytope is given by its $\mathcal{V}$ -description. Let us choose a “generic” $c \in \mathbb{Q}^d$. We can compute the number $|P \cap \mathbb{Z}^d|$ as the limit of the exponential sum

$$\lim_{t \rightarrow 0} \sum_{x \in P \cap \mathbb{Z}^d} \exp\{\langle tc, x \rangle\},$$

where t is a real parameter. Using Brion's Theorem 7.3.2, we reduce the problem to the computation of the constant term in the Laurent expansion of the meromorphic function $f_v(t) = f_{v+K_v}(tc)$, where v is a vertex of P and K_v is the cone of feasible directions at v . If K_v is a unimodular cone, we have an explicit formula for $f_{v+K_v}(c)$

(see above) and thus can easily compute the desired term. However, for $d > 1$ the cone K_v does not have to be unimodular. It turns out, nevertheless, that for any given rational cone K one can construct in polynomial time a decomposition $K = \sum_{i \in I} \epsilon_i K_i$, $\epsilon_i \in \{-1, 1\}$, of the “inclusion-exclusion” type, where the cones K_i are unimodular (see below). Thus one can get an explicit expression $f_{v+K_v}(c) = \sum_{i \in I} \epsilon_i \cdot f_{v+K_i}(c)$ and then compute the constant term of the Laurent expansion of $f_v(t)$. The complexity of the algorithm in terms of the dimension d is $d^{O(d)}$.

COUNTING IN TOTALLY UNIMODULAR POLYTOPES

One can efficiently count the number of integral points in a totally unimodular polytope given by its vertex description even in varying dimension.

THEOREM 7.3.4 [BP99]

There exists an algorithm that, for any d and any given integral vertices $v_1, \dots, v_m \in \mathbb{Z}^d$ such that the polytope $P = \text{conv}\{v_1, \dots, v_m\}$ is totally unimodular, computes the number of integral points of P in time linear in the number m of vertices.

Moreover, the same result holds for rational polytopes with unimodular cones of feasible directions at the vertices. The algorithm uses Brion’s formulas (Theorem 7.3.2) and the explicit formula above for the exponential sum over a unimodular cone.

EXAMPLE: COUNTING CONTINGENCY TABLES

Suppose A is an $n \times d$ totally unimodular matrix (see Section 7.1). Let us choose $b \in \mathbb{Z}^n$ such that the set P_b of solutions to the system $Ax \leq b$ of linear inequalities is a simple polytope. Then P_b is totally unimodular.

For example, if we know all the vertices of a simple transportation polytope P , we can compute the number of integral points of P in time linear in the number of vertices of P .

One can construct an efficient algorithm for counting integral points in a polytope that is somewhat “close” to totally unimodular and for which the explicit formulas for $f_{K_v}(c)$ are therefore not too long.

One particular application is counting contingency tables (see Section 7.1). Implementation of the algorithm based on Brion’s formula, codes, and numerical results, as well as other algebraic approaches, are discussed in [DLS03].

CONNECTIONS WITH TORIC VARIETIES

It was first observed by A.G. Khovanskii in the 1970s, and has since then become widely known, that the number of integral points in an integral polytope is related to some algebro-geometric invariants of the associated toric variety (see [Oda88]). Naturally, for smooth toric varieties (they correspond to totally unimodular polytopes) computation is much easier. Various formulas for the number of integral points in polytopes were first obtained for totally unimodular polytopes and then,

by the use of resolution of singularities, generalized to arbitrary integral polytopes (see, for example, [BP99]). Resolution of singularities of toric varieties reduces to dissection of a polyhedral cone into unimodular cones. However, as one can see, it is impossible to subdivide a rational cone into polynomially (in the input) many unimodular cones even in dimension $d = 2$. For example (see Figure 7.3.1), the plane cone K generated by the points $(1, 0)$ and $(1, n)$ cannot be subdivided into fewer than $2n - 1$ unimodular cones, whereas a polynomial time subdivision would give a polynomial in $\log n$ cones. On the other hand, if we allow a signed linear combination of the inclusion-exclusion type, then one can easily represent this cone as a combination of 3 unimodular cones: $[K] = [K_1] - [K_2] + [K_3]$, where K_1 is generated by the basis $(1, 0)$ and $(0, 1)$, K_2 is generated by $(0, 1)$ and $(1, n)$, and K_3 is generated by $(1, n)$. Moreover, modulo rational cones with straight lines (cf. Theorem 7.3.1), we need to use only two unimodular cones: $[K] = [K_3] + [K_4]$ modulo rational cones with straight lines, where K_3 is the cone generated by $(1, n)$ and $(0, -1)$ and K_4 is the cone generated by $(0, 1)$ and $(1, 0)$. Consequently, from Theorem 7.3.1, $f_K(c) = (1 - \exp\{c_1 + nc_2\})^{-1} (1 - \exp\{-c_2\})^{-1} + (1 - \exp\{c_1\})^{-1} (1 - \exp\{c_2\})^{-1}$ for $c = (c_1, c_2)$. As we have mentioned above, once we allow “signed” combinations, any rational polyhedral cone can be decomposed into unimodular cones in polynomial time, provided the dimension is fixed. Moreover, if we allow decompositions modulo rational cones with straight lines, the algorithm can be sped up further: roughly from $2^{O(d^2)}$ to $2^{O(d)}$ (see [BP99]).

FIGURE 7.3.1
Decomposition of a cone
into unimodular cones.

CONNECTIONS WITH VALUATIONS

The number of integral points $\nu(P) = |P \cap \mathbb{Z}^d|$ in an integral polytope $P \subset \mathbb{R}^d$ is a **valuation**, that is, it preserves linear relations among indicator functions of polytopes; and it is lattice-translation-invariant, i.e., $\nu(P + l) = \nu(P)$ for any $l \in \mathbb{Z}^d$. General properties of valuations and the related notion of the “polytope algebra” have been intensively studied (see, for example, [McM93] and [Mor93a]). Various identities discovered in this area might prove useful in dealing with particular counting problems (see [BP99]). For example, if the transportation polytope P_b is not simple, one can apply the following recipe. First, triangulating the normal cone at the vertex, we represent it as a combination of unimodular cones (we discard lower-dimensional cones). Then, passing to the dual cones, we get the desired representation of the cone of feasible directions (we discard cones with straight lines).

ANALYTICAL METHODS

The number $|P \cap \Lambda|$ of lattice points of Λ in the polytope P can be interpreted as the integral over P of the periodic delta-function

$$\sum_{y \in \Lambda} \delta_y(x) = (\det \Lambda)^{-1} \sum_{l \in \Lambda^*} \exp\{2\pi i \langle l, x \rangle\}.$$

Depending on the interpretation of this integral one can get various formulas. For example, if the above series is approximated as $t \rightarrow \infty$ by the theta-series

$$\theta_t(x) = t^{d/2} \sum_{y \in \Lambda} \exp\{-t\pi \|x - y\|^2\} = (\det \Lambda)^{-1} \sum_{l \in \Lambda^*} \exp\{-\pi \|l\|^2/t\} \exp\{2\pi i \langle l, x \rangle\},$$

then as the limit $\lim_{t \rightarrow \infty} \int_P \theta_t(x) dx$ one gets the number of lattice points in P , each lattice point y counted with weight equal to the spherical measure $\gamma(K_y)$ of the cone K_y of feasible directions at y normalized in such a way that the spherical measure of $\mathbb{R}^d$ is equal to 1 (see [GL87] and [BP99] for some information about this weighted counting).

Applying Parseval's theorem one can get the famous Siegel identity (see [GL87])

$$2^d \det \Lambda - \text{vol } B = \frac{1}{\text{vol } B} \sum_{l \in \Lambda^* \setminus 0} \left| \int_B \exp\{-\pi i \langle l, x \rangle\} dx \right|^2,$$

where B is a 0-symmetric convex body not containing nonzero lattice points (cf. Theorem 7.2.2).

R. Diaz and S. Robins [DR97] have obtained nice “cotangent” formulas for the number of integral points in an integral simplex by integrating an appropriately “smoothed out” sum $f(x) = \sum_{l \in \mathbb{Z}^d} \exp\{2\pi i \langle l, x \rangle\}$. Suppose that $P \subset \mathbb{R}^d$ is an integral simplex, that is, the convex hull of $d+1$ affinely independent integral vectors $v_1, \dots, v_{d+1}$. Embedding $\mathbb{R}^d \rightarrow \mathbb{R}^d$ as the affine hyperplane $x_{d+1} = 1$, Diaz and Robins express the number of integral points in P in terms of a certain sum over finite abelian groups that are factors of $\mathbb{Z}^{d+1} \cap \text{span}(v_{i_1}, \dots, v_{i_k})$ modulo the sublattice generated by $v_{i_1}, \dots, v_{i_k}$. Relations of this construction to higher Dedekind sums are discussed in [BP99].

The following simple observation often leads to practically efficient (although theoretically exponential time) algorithms. Suppose we want to count integral points $x = (x_1, \dots, x_d)$ in a polyhedron $P \subset \mathbb{R}^d$ defined by the equations

$$\sum_{j=1}^d a_{ij} x_j = b_i, \quad i = 1, \dots, m$$

and inequalities

$$x_j \geq 0, \quad j = 1, \dots, d,$$

where $A = (a_{ij})$ is a given $m \times d$ integer matrix. Let $z_1, \dots, z_m$ be (complex) variables and let

$$f_A(z_1, \dots, z_m) = \prod_{j=1}^d \sum_{x=0}^{+\infty} z_1^{a_{1j}x} z_2^{a_{2j}x} \dots z_m^{a_{mj}x} = \prod_{j=1}^d \frac{1}{1 - z_1^{a_{1j}} z_2^{a_{2j}} \dots z_m^{a_{mj}}}.$$

Thus the number $|P \cap \mathbb{Z}^d|$ is equal to the coefficient of $z_1^{b_1} \cdots z_m^{b_m}$ in $f_A(z_1, \dots, z_m)$ in a neighborhood of $z_1 = \dots = z_m = 0$. This coefficient may be extracted by numerical differentiation, or by (repeated) application of the residue formula, or by numerical integration using the Cauchy or Martinelli-Bochner integral representation for the Taylor coefficients. M. Beck and D. Pixton [BP02] report results on numerical computation for the problem of counting contingency tables using repeated application of the residue formula.

As discussed in [BV97b], various identities relating functions f_A mirror corresponding identities among indicator functions of rational polyhedra. In particular, decompositions of f_A into “simple fractions” correspond to decompositions of P into simple cones.

Quite a few useful inequalities for the number of lattice points can be found in [GW93], [Lag95], and [GL87]. Blichfeldt’s inequality states that

$$|B \cap \Lambda| \leq \frac{d!}{\det \Lambda} \text{vol } B + d,$$

where B is a convex body containing at least $d + 1$ affinely independent lattice points. Davenport’s inequality implies that

$$|B \cap \mathbb{Z}^d| \leq \sum_{i=0}^d \binom{d}{i} V_i(B),$$

where the V_i are the intrinsic volumes. A conjectured stronger inequality, $|B \cap \mathbb{Z}^d| \leq V_0(K) + \dots + V_d(K)$, was shown to be false in dimensions $d \geq 207$, although it is correct for $d = 2, 3$. Furthermore, H. Hadwiger proved that $|B \cap \mathbb{Z}^d| \geq \sum_{i=0}^d (-1)^{d-i} V_i(B)$, provided $B \subset \mathbb{R}^d$ is a convex body having a nonempty interior (see [Lag95]).

PROBABILISTIC METHODS

Often, we need the number of integral points only approximately. Probabilistic methods based on Monte-Carlo methods have turned out to be quite successful. The main idea can be described as follows (see [JS97]). Suppose we want to approximate the cardinality of a finite set X (for example, X may be the set of lattice points in a polytope). Suppose, further, that we can present a “filtration” $X_0 \subset X_1 \subset \dots \subset X_n = X$, where $|X_0| = 1$ (in general, we require $|X_0|$ to be small) and $|X_{i+1}|/|X_i| \leq 2$ (in general, we require the ratio $|X_{i+1}|/|X_i|$ to be reasonably small). Finally, suppose that we have an efficient procedure for sampling an element $x \in X_i$ uniformly at random (in practice, we settle for “almost uniform” sampling). Given an $\epsilon > 0$ and a $\delta > 0$, with probability at least $1 - \delta$ one can estimate the ratio $|X_{i+1}|/|X_i|$, within a relative error ϵ/n , by sampling $O(n\epsilon^{-1} \ln \delta^{-1})$ points at random from X_{i+1} and counting how many times the points end up in X_i . Then, by “telescoping,” with probability at least $(1 - \delta)^n$, we estimate

$$|X| = |X_n| = \frac{|X_n|}{|X_{n-1}|} \cdots \frac{|X_{i+1}|}{|X_i|} \cdots \frac{|X_2|}{|X_1|}$$

within relative error ϵ .

The bottleneck of the method is the ability to sample a point $x \in X_i$ uniformly at random. To achieve that, a Markov chain on X_i is designed, which converges fast (“mixes rapidly”) to the uniform distribution. Usually, there are some natural candidates for such Markov chains and the main difficulty is to establish whether they indeed mix rapidly.

Counting various combinatorial structures can be interpreted as counting vertices in a certain $(0, 1)$ -polytope. For example, computing the number of perfect matchings in a given bipartite graph on $n + n$ vertices, or, equivalently, computing the permanent of a given $n \times n$ matrix of 0’s and 1’s, can be viewed as counting the number of vertices in a particular face of the Birkhoff polytope B_n . M. Jerrum, A. Sinclair, and E. Vigoda [JSV01] have constructed a polynomial-time probabilistic algorithm to approximate the permanent of any given nonnegative matrix. B. Morris and A. Sinclair [MS99] have presented a polynomial-time probabilistic algorithm to compute the number of $(0, 1)$ -vectors $(x_1, \dots, x_n)$ satisfying the inequality $a_1x_1 + \dots + a_nx_n \leq b_n$, where a_i and b are given positive integers.

In the problem of counting contingency tables, the following simple Markov chain was proposed by P. Diaconis to obtain a random contingency table with prescribed row and column sums. Given a contingency table A , we select at random a pair of rows (i, i') and a pair of columns (j, j') and obtain a new table with the same row and column sums by incrementing a_{ij} and $a_{i'j'}$ by one and decrementing $a_{ij'}$ and $a_{i'j}$ by one, provided this leaves all entries nonnegative. This Markov chain is observed to be rapidly mixing in practice (see [JS97]).

One can obtain some crude and quick bounds on the number of vertices of a $(0, 1)$ -polytope by computing the Hamming distance from a random $(0, 1)$ -vector to the nearest vertex of the polytope [BS01]. Often, this distance can be efficiently computed by solving an appropriate combinatorial optimization problem. This way one can determine, for example, whether the number of vertices is exponentially large in the dimension n in some rigorously defined sense.

7.4 ASYMPTOTIC PROBLEMS

If $P \subset \mathbb{R}^d$ is an integral polytope then the number of integral points in the dilated polytope $nP = \{nx \mid x \in P\}$ for a natural number n is a polynomial in n , known as the Ehrhart polynomial. We review several results concerning the Ehrhart polynomial and its generalizations.

GLOSSARY

Todd polynomial: The homogeneous polynomial $\text{td}_k(x_1, \dots, x_m)$ of degree k defined as the coefficient of t^k in the expansion

$$\prod_{i=1}^m \frac{tx_i}{1 - \exp\{-tx_i\}} = \sum_{k=0}^{\infty} t^k \cdot \text{td}_k(x_1, \dots, x_m).$$

Tangent cone at a face of a polytope: The cone K_F of feasible directions at any point in the relative interior of the face $F \subset P$.

Apex of a cone: The largest linear subspace contained in the cone.

Dual cone: The cone $K^* = \{x \in \mathbb{R}^d \mid \langle x, y \rangle \leq 0 \text{ for all } y \in K\}$, where $K \subset \mathbb{R}^d$ is a given cone.

vol_k: The normalized k -volume of a k -dimensional rational polytope $P \subset \mathbb{R}^d$ computed as follows. Let $L \subset \mathbb{R}^d$ be the k -dimensional linear subspace parallel to the affine span of P . Then $\text{vol}_k(P)$ is the Euclidean k -dimensional volume of P in the affine span of P divided by the determinant of the lattice $\Lambda = \mathbb{Z}^d \cap L$.

EHRHART POLYNOMIALS

The following fundamental result was suggested by Ehrhart (see, for example, [Sta86] and [Sta83]).

THEOREM 7.4.1

Let $P \subset \mathbb{R}^d$ be an integral polytope. For a natural number n we denote by $nP = \{nx \mid x \in P\}$ the n -fold dilatation of P . Then the number of integral points in nP is a polynomial in n :

$$|nP \cap \mathbb{Z}^d| = E_P(n) \quad \text{for some polynomial} \quad E_P(x) = \sum_{i=0}^d e_i(P) \cdot x^i.$$

Moreover, for positive integers n the value of $(-1)^{\deg E_P} E_P(-n)$ is equal to the number of integral points in the relative interior of the polytope nP (the “reciprocity law”).

The polynomial E_P is called the **Ehrhart polynomial** and its coefficients $e_i(P)$ are called **Ehrhart coefficients**. For various proofs of Theorem 7.4.1 see, for example, [Sta86], [Sta83] and [BP99]. The existence of the Ehrhart polynomials and the reciprocity law can be derived from the single fact that the number of integral points in a polytope is a lattice-translation-invariant valuation (see [McM93] and Section 7.3 above).

If P is a rational polytope, we define $e_k(P) = n^{-k} e_k(P_1)$, where n is a positive integer such that $P_1 = nP$ is an integral polytope. For an integral polytope $P \subset \mathbb{R}^d$, one has $|P \cap \mathbb{Z}^d| = e_0(P) + e_1(P) + \dots + e_d(P)$. (This formula is no longer true, however, if P is a general rational polytope.) The Ehrhart coefficients constitute a basis of all additive functions (valuations) ν on rational polytopes that are invariant under unimodular transformations (see [McM93] and [GW93]).

GENERAL PROPERTIES

It is known that $e_0(P) = 1$, $e_d(P) = \text{vol}_d(P)$, and $e_{d-1}(P) = \frac{1}{2} \sum_F \text{vol}_{d-1} F$, where the sum is taken over all the facets of P . Thus, computation of the two highest coefficients reduces to computation of the volume. In fact, the computation of any fixed number of the highest Ehrhart coefficients of an $\mathcal{H}$ -polytope reduces in polynomial time to the computation of the volumes of faces; see [BP99] and also below.

EXISTENCE OF LOCAL FORMULAS

The Ehrhart coefficients can be decomposed into a sum of “local” summands. The following theorem was proven by P. McMullen (see [McM93], [Mor93a], and [BP99]).

THEOREM 7.4.2

For any natural numbers k and d there exists a real valued function $\mu_{k,d}$, defined on the set of all rational polyhedral cones $K \subset \mathbb{R}^d$, such that for every rational full-dimensional polytope $P \subset \mathbb{R}^d$ we have

$$e_k(P) = \sum_F \mu_{k,d}(K_F) \cdot \text{vol}_k F,$$

where the sum is taken over all k -dimensional faces F of P and K_F is the tangent cone at the face F . Moreover, one can choose $\mu_{k,d}$ to be an additive measure on polyhedral cones.

The function $\mu_{k,d}$ that satisfies the conditions of Theorem 7.4.2 is not unique and it is a difficult problem to choose a computationally efficient $\mu_{k,d}$ (see also Morelli’s formulas, below). However, for some specific values of k and d a “canonical” choice of $\mu_{k,d}$ has long been known.

EXAMPLE

For a cone $K \subset \mathbb{R}^d$, let $\gamma(K)$ be the spherical measure of K normalized in such a way that $\gamma(\mathbb{R}^d) = 1$. Thus $\gamma(K) = 0.5$ if K is a halfspace. One can choose $\mu_{d,d} = \mu_{d-1,d} = \gamma$ because of the formulas for $e_d(P)$ and $e_{d-1}(P)$ (see above).

On the other hand, one can choose $\mu_{0,d}(K) = \gamma(K^*)$, where K^* is the dual cone, since it is known that $e_0(P) = 1$. We note that if $\mu(K)$ is an additive measure on polyhedral cones then $\nu(K) = \mu(K^*)$ is also an additive measure on polyhedral cones. Moreover, for integral zonotopes (see Section 7.3), one can always choose $\mu_{k,d}(K_F) = \gamma(K_F^*)$ [BP99]. If F is a k -dimensional face of P then K_F^* is a $(d-k)$ -dimensional cone and $\gamma(K_F^*)$ is understood as the spherical measure in the span of K_F^* .

EULER-MACLAURIN FORMULAS

Let $P \subset \mathbb{R}^d$ be a full-dimensional totally unimodular polytope. Let $\{l_i \mid i = 1, \dots, m\}$ be the set of integral outer normals to the facets of P . We assume that the l_i are *primitive*, i.e., $\alpha l_i \notin \mathbb{Z}^d$ for any i and any $0 < \alpha < 1$. Say $P = \{x \in \mathbb{R}^d \mid \langle l_i, x \rangle \leq b_i \text{ for } i = 1, \dots, m\}$ for some $b_1, \dots, b_m \in \mathbb{Z}$. Let $h = (h_1, \dots, h_m) \in \mathbb{R}^m$ be a vector. If $\|h\|$ is small enough, then the “perturbed” polytope $P_h = \{x \in \mathbb{R}^d \mid \langle l_i, x \rangle \leq b_i + h_i\}$ has the same “shape” as P and the volume of P_h is a polynomial function of h .

The following expression for the Ehrhart coefficient $e_k(P)$ was found in [KP92]:

$$e_{d-k}(P) = \text{td}_k \left(\frac{\partial}{\partial h_1}, \dots, \frac{\partial}{\partial h_m} \right) \text{vol}_d(P_h) \Big|_{h=0}.$$

Thus $\text{td}_0 = 1$, $\text{td}_1(x_1, \dots, x_m) = (x_1 + \dots + x_m)/2$, etc. The formula can be considered as a far-reaching extension of the classical Euler-Maclaurin formula.

If the polytope is simple, one can formally define

$$b_{d-k}(P) = \text{td}_k \left(\frac{\partial}{\partial h_1}, \dots, \frac{\partial}{\partial h_m} \right) \text{vol}_d(P_h) \Big|_{h=0}.$$

However, $b_{d-k}(P)$ are no longer Ehrhart coefficients if P is not totally unimodular. To get $e_{d-k}(P)$, one should introduce a correction term for each face of codimension $k-1$ of P . When $k=2$, such correction terms have been found by A.G. Khovanskii and J.-M. Kantor. These terms involve Dedekind sums (see [Section 7.3](#)) and they are computable in polynomial time (see [BP99]).

The correction terms for an arbitrary k have been suggested by M. Brion and M. Vergne [BV97a].

MORELLI'S FORMULAS

General formulas for $e_k(P)$ were obtained in [Mor93b]. R. Morelli constructed an explicit measure $\mu_{k,d}(K)$ as in Theorem 7.4.2, which, however, is not a real number but a real-valued rational function on the Grassmannian $\mathbf{G}_{k+1}(\mathbb{R}^d)$ of all $(k+1)$ -dimensional subspaces in $\mathbb{R}^d$. Let K be a full-dimensional cone whose apex is a k -dimensional subspace (if K is not such a cone then $\mu_{k,d}(K) = 0$). There is an explicit formula for $\mu_{k,d}(K) : \mathbf{G}_{k+1}(\mathbb{R}^d) \rightarrow \mathbb{R}$ when the dual k -dimensional cone $K^* \subset \mathbb{R}^d$ is unimodular. If K^* is not unimodular, then we define $\mu_{k,d}(K)$ using the additivity of $\mu_{k,d}$ (cf. the discussion in Section 7.3 about decomposing a polyhedral cone into unimodular cones). The cone K contains $d-k$ $(k+1)$ -dimensional halfspaces (“edges”) whose intersection is the k -dimensional apex V of K . Let E_s , $s = 1, \dots, d-k$, be the linear spans of these edges. For every s we choose an oriented basis $(b_1^s, \dots, b_{k+1}^s)$ of the $(k+1)$ -dimensional lattice $(E_s \cap \mathbb{Z}^d)$, so that all these orientations are coherent with some fixed orientation of the apex V . Let $A \in \mathbf{G}_{k+1}(\mathbb{R}^d)$ be a $(k+1)$ -dimensional subspace. We define the value of $\mu_{k,d}(K)$ on A as follows: Choose any basis $u_1, \dots, u_{k+1}$ of A . Define a $(k+1) \times (k+1)$ matrix M^s by the formula $M_{ij}^s = \langle b_i^s, u_j \rangle$. Let $f_s = \det M^s$ and define $\mu_{k,d}(K)$ on A to be equal to

$$\frac{\text{td}_{d-k}(f_1, \dots, f_{d-k})}{f_1 \cdots f_{d-k}}.$$

If $d-k$ is fixed then the function $\mu_{k,d}(K) : \mathbf{G}_{k+1}(\mathbb{R}^d) \rightarrow \mathbb{R}$ is polynomially computable. Therefore, computation of any fixed number of the highest Ehrhart coefficients reduces in polynomial time to computation of the volumes of faces for an $\mathcal{H}$ -polytope (see [BP99]).

THE h^* -VECTOR

General properties of generating functions (see [Sta86]) imply that for every integral d -dimensional polytope P there exist integers $h_0^*(P), \dots, h_d^*(P)$ such that

$$\sum_{n=0}^{\infty} E_P(n) x^n = \frac{h_0^*(P) + h_1^*(P)x + \dots + h_d^*(P)x^d}{(1-x)^{d+1}}.$$

The $(d+1)$ -vector $h^*(P) = (h_0^*(P), \dots, h_d^*(P))$ is called the **h^* -vector** of P . It is clear that $h^*(P)$ is a (vector-valued) valuation on the set of integral polytopes and

that $h^*(P)$ is invariant under a unimodular transformation of $\mathbb{Z}^d$. Moreover, the functions $h_k^*(P)$ constitute a basis of all valuations on integral polytopes that are invariant under unimodular transformations. Unlike the Ehrhart coefficients $e_k(P)$, the numbers $h_k^*(P)$ are not homogeneous. However, $h_k^*(P)$ are monotone (and, therefore, nonnegative): if $Q \subset P$ are two integral polytopes then $h_k^*(P) \geq h_k^*(Q)$ [Sta93]. This property follows from the fact that polytopes admit triangulations that are Cohen-Macaulay complexes (see Chapter 18). If these complexes are Gorenstein then one gets the **Dehn-Sommerville equations** $h_k^*(P) = h_{d-k}^*(P)$. For example, the h^* -vector of the Birkhoff polytope B_n (see Section 7.1) satisfies the Dehn-Sommerville equations (see [Sta83]).

In principle, there is a combinatorial way to calculate $h^*(P)$. Namely, let Δ be a triangulation of P such that every d -dimensional simplex of Δ is integral and has volume $1/d!$ (see Section 7.2). Let $f_k(\Delta)$ be the number of k -dimensional faces of the triangulation Δ . Then

$$h_k^*(P) = \sum_{i=0}^k (-1)^{k-i} \binom{d-i}{d-k} f_{i-1}(\Delta),$$

where we let $f_{-1}(\Delta) = 1$. Such a triangulation may not exist for the polytope P but it exists for mP , where m is a sufficiently large integer (see [KKMS73]). Generally, this triangulation Δ would be too big, but for some special polytopes with nice structure (for example, for the so-called *poset polytopes*) it may provide a very good way to compute $h^*(P)$ and hence the Ehrhart polynomial E_P .

Since the number of integral points in a polytope is a valuation, we get the following result proved by P. McMullen (see [McM93]).

THEOREM 7.4.3

Let $P_1, \dots, P_m$ be integral polytopes in $\mathbb{R}^d$. For an m -tuple of natural numbers $\mathbf{n} = (n_1, \dots, n_m)$, let us define the polytope

$$P(\mathbf{n}) = \{n_1x_1 + \dots + n_mx_m \mid x_1 \in P_1, \dots, x_m \in P_m\}$$

(using “+” for Minkowski addition one can also write $P(\mathbf{n}) = n_1P_1 + \dots + n_mP_m$). Then there exists a polynomial $p(x_1, \dots, x_m)$ of degree at most d such that

$$|P(\mathbf{n}) \cap \mathbb{Z}^d| = p(n_1, \dots, n_m).$$

An interpretation of the values $p(n_1, \dots, n_m)$ for nonpositive integer values of $n_1, \dots, n_m$ can be obtained by using the polytope algebra identities (see [McM93]).

More generally, the existence of local formulas for the Ehrhart coefficients implies that the number of integral points in an integral polytope $P_h = \{x \in \mathbb{R}^d \mid Ax \leq b + h\}$ is a polynomial in h provided P_h is an integral polytope combinatorially isomorphic to the integral polytope P_0 . In other words, if we move the facets of an integral polytope so that it remains integral and has the same facial structure, then the number of integral points varies polynomially.

INTEGRAL POINTS IN RATIONAL POLYTOPES

If P is a rational (not necessarily integral) polytope then $|nP \cap \mathbb{Z}^d|$ is not a polynomial but a **quasipolynomial** (a function of n whose value cycles through the values

of a finite list of polynomials). The following result was independently proven by P. McMullen and R. Stanley (see [McM93] and [Sta86]).

THEOREM 7.4.4

Let $P \subset \mathbb{R}^d$ be a rational polytope. For every r , $0 \leq r \leq d$, let ind_r be the smallest natural number k such that all r -dimensional faces of kP are integral polytopes. Then, for every $n \in \mathbb{N}$,

$$|nP \cap \mathbb{Z}^d| = \sum_{r=0}^d e_r(P, n(\bmod \text{ind}_r)) \cdot n^r$$

for suitable rational numbers $e_r(P, k)$, $0 \leq k < \text{ind}_r$.

P. McMullen also obtained a generalization of the “reciprocity law” (see [Sta86] and [McM93]).

Let us fix an $n \times d$ integer matrix A such that the set $P_b = \{x \mid Ax \leq b\}$, $b \in \mathbb{Z}^n$, if nonempty, is a rational polytope. Let $B \subset \mathbb{Z}^n$ be a set of right-hand-side vectors b such that the combinatorial structure of P_b is the same for all $b \in B$. In [BP99] it is shown that as long as the dimension d is fixed, one can find a polynomially computable formula $F(b)$ for the number $|P_b \cap \mathbb{Z}^d|$, where F is a polynomial of degree d in integer parts of linear functions of b . It is based on Brion’s Theorem (Theorem 7.3.2) and the “rounding” of rational translations of unimodular cones.

Interestingly, for a “typical” (and, therefore, nonrational) polytope P the difference $|tP \cap \mathbb{Z}^d| - t^d \text{vol } P$ has order $O((\ln t)^{d-1+\epsilon})$ as $t \rightarrow +\infty$ [Skr98].

7.5 PROBLEMS WITH QUANTIFIERS

A natural generalization of the decision problem (see [Section 7.2](#)) is a problem with quantifiers. We describe some known results and formulate open questions for this class of problems.

FROBENIUS PROBLEM

The most famous problem from this class is the **Frobenius problem**:

Given k positive integers $a_1, \dots, a_k$ with greatest common divisor 1, find the largest integer m that cannot be represented as an integer combination $a_1 n_1 + \dots + a_k n_k$, $n_i \geq 0$.

The problem is known to be NP-hard in general, but a polynomial time algorithm is known for fixed k [Kan92].

PROBLEM WITH QUANTIFIERS

A general **problem with quantifiers** can be formulated as follows. Suppose that P is a Boolean combination of convex polyhedra: we start with some polyhedra $P_1, \dots, P_k \subset \mathbb{R}^d$ given by their facet descriptions and construct P by using the set-theoretical operations of union, intersection, and complement. We want to find

out if the formula

$$\exists x_1 \forall x_2 \exists x_3 \dots \forall x_m : (x_1, \dots, x_m) \in P \quad (7.5.1)$$

is true. Here x_i is an integral vector from $\mathbb{Z}^{d_i}$, and, naturally, $d_1 + \dots + d_m = d$, $d_i \geq 0$. The parameters that characterize the size of (7.5.1) can be divided into two classes. The first class consists of the parameters characterizing the *combinatorial size* of the formula. These are the dimension d , the number $m - 1$ of quantifier alternations, the number of linear inequalities and Boolean operations that define the polyhedral set P . The parameters from the other class characterize the *numerical size* of the formula. Those are the bit sizes of the numbers involved in the inequalities that define P .

The following fundamental question remains open.

PROBLEM 7.5.1

Let us fix all the combinatorial parameters of the formula (7.5.1). Does there exist a polynomial time algorithm that checks whether this formula is true?

Naturally, “polynomial time” means that the running time of the algorithm is bounded by a polynomial in the numerical size of the formula. The answer to this question is unknown although it is widely believed that such an algorithm indeed exists. A polynomial time algorithm is known if the formula contains not more than 1 quantifier alternation, i.e., if $m \leq 2$ [Kan90]. A related problem is to compute the number of solutions for quantifier-free variables in a formula with quantifiers.

Sets of lattice points described by formulas with existential quantifiers only are studied in [BW03]. Geometrically, such a set S can be viewed as a projection of the set of lattice points in a polyhedron P . Examples include lattice semigroups, (minimal) Hilbert bases of rational cones, and test sets in integer programming. It is shown that if P is bounded and the dimension of P is fixed then the exponential sum over S admits a short (polynomially computable) formula. As a corollary, various counting problems for lattice semigroups, Hilbert bases, and test sets admit polynomial time algorithms in fixed dimension. For a structural theory of lattice semigroups see [K95].

8 LOW-DISTORTION EMBEDDINGS OF FINITE METRIC SPACES¹⁷⁷

Piotr Indyk and Jiří Matoušek

INTRODUCTION

An n -point metric space (X, D) can be represented by an $n \times n$ table specifying the distances. Such tables arise in many diverse areas. For example, consider the following scenario in microbiology: X is a collection of bacterial strains, and for every two strains, one is given their *dissimilarity* (computed, say, by comparing their DNA). It is difficult to see any structure in a large table of numbers, and so we would like to represent a given metric space in a more comprehensible way.

For example, it would be very nice if we could assign to each $x \in X$ a point $f(x)$ in the plane in such a way that $D(x, y)$ equals the Euclidean distance of $f(x)$ and $f(y)$. Such a representation would allow us to see the structure of the metric space: tight clusters, isolated points, and so on. Another advantage would be that the metric would now be represented by only $2n$ real numbers, the coordinates of the n points in the plane, instead of $\binom{n}{2}$ numbers as before. Moreover, many quantities concerning a point set in the plane can be computed by efficient geometric algorithms, which are not available for an arbitrary metric space.

This sounds too good to be generally true: indeed, there are even finite metric spaces that cannot be exactly represented either in the plane or in *any* Euclidean space; for instance, the four vertices of the graph $K_{1,3}$ (a star with 3 leaves) with the shortest-path metric (see Figure 8.0.1a). However, it *is* possible to embed the latter metric in a Euclidean space, if we allow the distances to be distorted somewhat. For example, if we place the center of the star at the origin in $\mathbb{R}^3$ and the leaves at $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, then all distances are preserved *approximately*, up to a factor of $\sqrt{2}$ (Figure 8.0.1b).

FIGURE 8.0.1
A nonembeddable metric space.

Approximate embeddings have proven extremely helpful for approximate solutions of problems dealing with distances. For many important algorithmic problems, they yield the only known good approximation algorithms.

The normed spaces usually considered for embeddings of finite metrics are the spaces ℓ_p^d , $1 \leq p \leq \infty$, and the cases $p = 1, 2, \infty$ play the most prominent roles.

GLOSSARY

Metric space: A pair (X, D) , where X is a set of *points* and $D: X \times X \rightarrow [0, \infty)$ is a *distance function* satisfying the following conditions for all $x, y, z \in X$:

- (i) $D(x, y) = 0$ if and only if $x = y$,
- (ii) $D(x, y) = D(y, x)$ (symmetry), and
- (iii) $D(x, y) + D(y, z) \geq D(x, z)$ (triangle inequality).

Separable metric space: A metric space (X, D) containing a countable dense set; that is, a countable set Y such that for every $x \in X$ and every $\varepsilon > 0$ there exists $y \in Y$ with $D(x, y) < \varepsilon$.

Pseudometric: Like metric except that (i) is not required.

Isometry: A mapping $f: X \rightarrow X'$, where (X, D) and (X', D') are metric spaces, with $D'(f(x), f(y)) = D(x, y)$ for all x, y .

(Real) normed space: A real vector space Z with a mapping $\|\cdot\|_Z: Z \rightarrow [0, \infty]$, the *norm*, satisfying $\|x\|_Z = 0$ iff $x = 0$, $\|\alpha x\|_Z = |\alpha| \cdot \|x\|_Z$ ($\alpha \in \mathbb{R}$), and $\|x + y\|_Z \leq \|x\|_Z + \|y\|_Z$. The metric on Z is given by $(x, y) \mapsto \|x - y\|_Z$.

ℓ_p^d : The space $\mathbb{R}^d$ with the ℓ_p -norm $\|x\|_p = (\sum_{i=1}^d |x_i|^p)^{1/p}$, $1 \leq p \leq \infty$ (where $\|x\|_\infty = \max_i |x_i|$).

Finite ℓ_p metric: A finite metric space isometric to a subspace of ℓ_p^d for some d .

ℓ_p : For a sequence $(x_1, x_2, \dots)$ of real numbers we set $\|x\|_p = (\sum_{i=1}^\infty |x_i|^p)^{1/p}$. Then ℓ_p is the space consisting of all x with $\|x\|_p < \infty$, equipped with the norm $\|\cdot\|_p$. It contains every finite ℓ_p metric as a (metric) subspace.

Distortion: A mapping $f: X \rightarrow X'$, where (X, D) and (X', D') are metric spaces, is said to have distortion at most c , or to be a *c-embedding*, where $c \geq 1$, if there is an $r \in (0, \infty)$ such that for all $x, y \in X$,

$$r \cdot D(x, y) \leq D'(f(x), f(y)) \leq cr \cdot D(x, y).$$

If X' is a normed space, we usually require $r = \frac{1}{c}$ or $r = 1$.

Order of congruence: A metric space (X, D) has order of congruence at most m if every finite metric space that is not isometrically embeddable in (X, D) has a subspace with at most m points that is not embeddable in (X, D) .

8.1 THE SPACES ℓ_p

8.1.1 THE EUCLIDEAN SPACES ℓ_2^d

Among normed spaces, the Euclidean spaces are the most familiar, the most symmetric, the simplest in many respects, and the most restricted. Every finite ℓ_2 metric embeds isometrically in ℓ_p for all p . More generally, we have the following Ramsey-type result on the “universality” of ℓ_2 ; see, e.g., [MS86]:

THEOREM 8.1.1 *Dvoretzky's theorem (a finite quantitative version)*

For every d and every $\varepsilon > 0$ there exists $n = n(d, \varepsilon) \leq 2^{O(d/\varepsilon^2)}$ such that ℓ_2^d can be $(1+\varepsilon)$ -embedded in every n -dimensional normed space.

Isometric embeddability in ℓ_2 has been well understood since the classical works of Menger, von Neumann, Schoenberg, and others (see, e.g., [Sch38]). Here is a brief summary:

THEOREM 8.1.2

- (i) (*Compactness*) A separable metric space (X, D) is isometrically embeddable in ℓ_2 iff each finite subspace is so embeddable.
- (ii) (*Order of congruence*) A finite (or separable) metric space embeds isometrically in ℓ_2^d iff every subspace of at most $d + 3$ points so embeds.
- (iii) For a finite $X = \{x_0, x_1, \dots, x_n\}$, (X, D) embeds in ℓ_2 iff the $n \times n$ matrix $(D(x_0, x_i)^2 + D(x_0, x_j)^2 - D(x_i, x_j)^2)_{i,j=1}^n$ is positive semidefinite; moreover, its rank is the smallest dimension for such an embedding.
- (iv) (*Schoenberg's criterion*) A separable (X, D) isometrically embeds in ℓ_2 iff the matrix $(e^{-\lambda D(x_i, x_j)^2})_{i,j=1}^n$ is positive semidefinite for all $n \geq 1$, for any points $x_1, x_2, \dots, x_n \in X$, and for any $\lambda > 0$. (This is expressed by saying that the functions $x \mapsto e^{-\lambda x^2}$, for all $\lambda > 0$, are positive definite on ℓ_2 .)

Using similar ideas, the problem of finding the smallest c such that a given finite (X, D) can be c -embedded in ℓ_2 can be formulated as a semidefinite programming problem and thus solved in polynomial time [LLR95] (but no similar result is known for embedding in ℓ_2^d with d given!).

8.1.2 THE SPACES ℓ_1^d

GLOSSARY

Cut metric: A pseudometric D on a set X such that, for some partition $X = A \dot{\cup} B$, we have $D(x, y) = 0$ if both $x, y \in A$ or both $x, y \in B$, and $D(x, y) = 1$ otherwise.

Hypermetric inequality: A metric space (X, D) satisfies the $(2k+1)$ -point hypermetric inequality (also called the $(2k+1)$ -gonal inequality) if for every multiset A of k points and every multiset B of $k+1$ points in X , $\sum_{a,a' \in A} D(a, a') + \sum_{b,b' \in B} D(b, b') \leq \sum_{a \in A, b \in B} D(a, b)$. (We get the triangle inequality for $k = 1$.)

Hypermetric space: A space that satisfies the hypermetric inequality for all k .

Cocktail-party graph: The complement of a perfect matching in a complete graph K_{2m} ; also called a **hyperoctahedron graph**.

Half-cube graph: The vertex set consists of all vectors in $\{0, 1\}^n$ with an even number of 0's, and edges connect vectors with Hamming distance 2.

Cartesian product of graphs G and H : The vertex set is $V(G) \times V(H)$, and the edge set is $\{\{(u, v), (u, v')\} \mid u \in V(G), \{v, v'\} \in E(H)\} \cup \{\{(u, v), (u', v)\} \mid \{u, u'\} \in E(G), v \in V(H)\}$. The cubes are Cartesian powers of K_2 .

Girth of a graph: The length of the shortest cycle.

The ℓ_1 spaces are important for many reasons, but considerably more complicated than Euclidean spaces; a general reference here is [DL97]. Many important and challenging open problems are related to embeddings in ℓ_1 or in ℓ_1^d .

Unlike the situation in ℓ_2^n , not every n -point ℓ_1 -metric lives in ℓ_1^n ; dimension of order n^2 is sometimes necessary and always sufficient to embed n -point ℓ_1 -metrics isometrically (similarly for the other ℓ_p -metrics with $p \neq 2$).

The ℓ_1 metrics on an n -point set X are precisely the elements of the **cut cone**; that is, linear combinations with nonnegative coefficients of cut metrics on X . Another characterization is this: A metric D on $\{1, 2, \dots, n\}$ is an ℓ_1 metric iff there exist a measure space (Ω, Σ, μ) and sets $A_1, \dots, A_n \in \Sigma$ such that $D(i, j) = \mu(A_i \Delta A_j)$.

Every ℓ_1 metric is a hypermetric space (since cut metrics satisfy the hypermetric inequalities), but for 7 or more points, this condition is not sufficient. Hypermetric spaces have an interesting characterization in terms of *Delaunay polytopes* of lattices; see [DL97].

ISOMETRIC EMBEDDABILITY

Deciding isometric embeddability in ℓ_1 is NP-hard. On the other hand, the embeddability of *unweighted* graphs, both in ℓ_1 and in a Hamming cube, has been characterized and can be tested in polynomial time. In particular, we have:

THEOREM 8.1.3

- (i) *An unweighted graph G embeds isometrically in some cube $\{0, 1\}^m$ with the ℓ_1 -metric iff it is bipartite and satisfies the pentagonal inequality.*
- (ii) *An unweighted graph G embeds isometrically in ℓ_1 iff it is an isometric subgraph of a Cartesian product of half-cube graphs and cocktail-party graphs.*

A first characterization of cube-embeddable graphs was given by Djokovic [Djo73], and the form in (i) is due to Avis (see [DL97]). Part (ii) is from Shpectorov [Shp93].

ORDER OF CONGRUENCE

The isometric embeddability in ℓ_1^d is characterized by 6-point subspaces (6 is best possible here), and can thus be tested in polynomial time (Bandelt and Chepoi [BC96]). The proof uses a result of Bandelt and Dress [BD92] of independent interest, about certain canonical decompositions of metric spaces (see also [DL97]).

On the other hand, for no $d \geq 3$ it is known whether the order of congruence of ℓ_1^d is finite; there is a lower bound of d^2 (for odd d) or $d^2 - 1$ (for d even).

8.1.3 THE OTHER p

The spaces ℓ_∞^d are the richest (and thus generally the most difficult to deal with); every n -point metric space (X, D) embeds isometrically in ℓ_∞^n . To see this, write $X = \{x_1, x_2, \dots, x_n\}$ and define $f: X \rightarrow \ell_\infty^n$ by $f(x_i)_j = D(x_i, x_j)$.

The other $p \neq 1, 2, \infty$ are encountered less often, but it may be useful to know the cases where all ℓ_p metrics embed with bounded distortion in ℓ_q : This happens iff $p = q$, or $p = 2$, or $q = \infty$, or $1 \leq q \leq p \leq 2$. Isometric embeddings exist in all these cases. Moreover, for $1 \leq q \leq p \leq 2$, the whole of ℓ_p^d can be $(1+\varepsilon)$ embedded

in ℓ_q^{Cd} with a suitable $C = C(p, q, \varepsilon)$ (so the dimension doesn't grow by much); see, e.g., [MS86]. These embeddings are probabilistic. The simplest one is $\ell_2^d \rightarrow \ell_1^{Cd}$, given by $x \mapsto Ax$ for a random ± 1 matrix A of size $Cd \times d$ (surprisingly, no good explicit embedding is known even in this case).

8.2 APPROXIMATE EMBEDDINGS OF GENERAL METRICS IN ℓ_p

8.2.1 BOURGAIN'S EMBEDDING IN ℓ_2

The mother of most embeddings mentioned in the next few sections, from both historical and “technological” points of view, is the following theorem.

THEOREM 8.2.1 *Bourgain* [Bou85]

Any n -point metric space (X, D) can be embedded in ℓ_2 (in fact, in every ℓ_p) with distortion $O(\log n)$.

We describe the embedding, which is constructed probabilistically. We set $m = \lceil \log_2 n \rceil$ and $q = \lceil C \log n \rceil$ (C a suitable constant) and construct an embedding in ℓ_2^{mq} , with the coordinates indexed by $i = 1, 2, \dots, m$ and $j = 1, 2, \dots, q$. For each such i, j , we select a subset $A_{ij} \subseteq X$ by putting each $x \in X$ into A_{ij} with probability 2^{-j} , all the random choices being mutually independent. Then we set $f(x)_{ij} = D(x, A_{ij})$. We thus obtain an embedding in $\ell_2^{O(\log^2 n)}$ (Bourgain's original proof used exponential dimension; the possibility of reducing it was noted later), and it can be shown that the distortion is $O(\log n)$ with high probability.

This yields an $O(n^2 \log n)$ randomized algorithm for computing the desired embedding. The algorithm can be derandomized (preserving the polynomial time and the dimension bound) using the method of conditional probabilities; this result seems to be folklore. Alternatively, it can be derandomized using small sample spaces [LLR95]; this, however, uses dimension $\Theta(n^2)$. Finally, as was remarked above, an embedding of a given space in ℓ_2 with optimal distortion can be computed by semidefinite programming.

The $O(\log n)$ distortion for embedding a general metric in ℓ_2 is tight [LLR95] (and similarly for ℓ_p , $p < \infty$ fixed). Examples of metrics that cannot be embedded any better are the shortest-path metrics of constant-degree expanders. (An n -vertex graph is a **constant-degree expander** if all degrees are bounded by some constant r and each subset of k vertices has at least βk outgoing edges, for $1 \leq k \leq \frac{n}{2}$ and for some constant $\beta > 0$ independent of n .)

Another interesting lower bound is due to Linial et al. [LMN02]: The shortest-path metric of *any* k -regular graph ($k \geq 3$) of girth g requires $\Omega(\sqrt{g})$ distortion for embedding in ℓ_2 .

8.2.2 THE DIMENSION OF EMBEDDINGS IN ℓ_∞

If we want to embed all n -point metrics in ℓ_∞^d , there is a tradeoff between the dimension d and the worst-case distortion. The following result was proved in [Mat96] by adapting Bourgain's technique.

THEOREM 8.2.2

For an integer $b > 0$ set $c = 2b - 1$. Then any n -point metric space can be embedded in ℓ_∞^d with distortion c , where $d = O(bn^{1/b} \log n)$.

An almost matching lower bound can be proved using graphs without short cycles, an idea also going back to [Bou85]. Let $m(g, n)$ be the maximum possible number of edges of an n -vertex graph of girth $g + 1$. For every fixed $c \geq 1$ and integer $g > c$ there exists an n -point metric space such that any c -embedding in ℓ_∞^d has $d = \Omega(m(g, n)/n)$ [Mat96]. The proof goes by counting: Fix a graph G_0 witnessing $m(g, n)$, and let $\mathcal{G}$ be the set of graphs (considered with the shortest-path metric) that can be obtained from G_0 by deleting some edges. It turns out that if $G, G' \in \mathcal{G}$ are distinct, then they cannot have “essentially the same” c -embeddings in ℓ_∞^d , and there are only “few” essentially different embeddings in ℓ_∞^d if d is small.

It is easy to show that $m(g, n) = O(n^{1+1/\lfloor g/2 \rfloor})$ for all g , and this is conjectured to be the right order of magnitude [Erd64]. This has been verified for $g \leq 7$ and for $g = 10, 11$, while only worse lower bounds are known for the other values of g (with exponent roughly $1 + 4/3g$ for g large). Whenever the conjecture holds for some $g = 2b - 1$, the above theorem is tight up to a logarithmic factor for the corresponding b . Unfortunately, although explicit constructions of graphs of a given girth with many edges are known, the method doesn't provide explicit examples of badly embeddable spaces.

DISTANCE ORACLES

An interesting algorithmic result, conceptually resembling the above theorem, was obtained by Thorup and Zwick [TZ01]. They showed that for an integer $b > 0$, every n -point metric space can be stored in a data structure of size $O(n^{1+1/b})$ (with preprocessing time of the same order) so that, within time $O(b)$, the distance between any two points can be approximated within a multiplicative factor of $2b - 1$.

LOW DIMENSION

The other end of the tradeoff between distortion and dimension d , where d is fixed (and then all ℓ_p -norms on $\mathbb{R}^d$ are equivalent up to a constant) was investigated in [Mat90]. For all fixed $d \geq 1$, there are n -point metric spaces requiring distortion $\Omega(n^{1/\lfloor (d+1)/2 \rfloor})$ for embedding in ℓ_2^d (for $d = 2$, an example is the shortest-path metric of K_5 with every edge subdivided $n/10$ times). On the other hand, every n -point space $O(n)$ -embeds in ℓ_2^1 (the real line), and $O(n^{2/d} \log^{3/2} n)$ -embeds in ℓ_2^d , $d \geq 3$.

8.2.3 THE JOHNSON-LINDENSTRAUSS LEMMA: FLATTENING IN ℓ_2

The n -point ℓ_2 metric with all distances equal to 1 requires dimension $n - 1$ for isometric embedding in ℓ_2 . A somewhat surprising and extremely useful result shows that, in particular, this metric can be embedded in dimension only $O(\log n)$ with distortion close to 1.

THEOREM 8.2.3 *Johnson and Lindenstrauss* [JL84]

For every $\varepsilon > 0$, any n -point ℓ_2 metric can be $(1+\varepsilon)$ -embedded in $\ell_2^{O(\log n/\varepsilon^2)}$.

There is an almost matching lower bound for the necessary dimension, due to Alon (see [Mat02a]): $\Omega(\log n/(\varepsilon^2 \log(1/\varepsilon)))$.

All known proofs (see, e.g., [Ach01] for references and an insightful discussion) first place the metric under consideration in ℓ_2^n and then map it into ℓ_2^d by a random linear map $A: \ell_2^n \rightarrow \ell_2^d$. Here A can be a random orthogonal projection (as in [JL84]). It can also be given by a random $n \times d$ matrix with independent $N(0, 1)$ entries [IM98], or even one with independent uniform random ± 1 entries. The proof in the last case, due to [Ach01], is considerably more difficult than the previous ones (which use spherically symmetric distributions), but this version has advantages in applications.

An embedding as in the theorem can be computed deterministically in time $O(n^2 d (\log n + 1/\varepsilon)^{O(1)})$ [EIO02] (also see [Siv02]).

Brinkman and Charikar [BC03] proved that no flattening lemma of comparable strength holds in ℓ_1 . Namely, for every fixed $c > 1$, and every n , they exhibit an n -point ℓ_1 -metric that cannot be c -embedded into ℓ_1^d unless $d = n^{\Omega(1/c^2)}$. A simpler alternative proof was found later by Lee and Naor (manuscript).

In contrast, [Ind00] showed that for every $0 < \varepsilon < 1$ and any ℓ_1 -metric over $X \subset \ell_1^d$, there is a $k \times d$ real matrix $[a_1 \dots a_k]^T$, $k = O(\log |X|/\varepsilon^2)$, such that for any $p, q \in X$, $\|p - q\|_1 \leq \text{median}(|a_1(p - q)|, \dots, |a_k(p - q)|) \leq (1 + \varepsilon)\|p - q\|_1$.

8.2.4 VOLUME-RESPECTING EMBEDDINGS

Feige [Fei00] introduced the notion of *volume-respecting* embeddings in ℓ_2 , with impressive algorithmic applications. While the distortion of a mapping depends only on pairs of points, the volume-respecting condition takes into account the behavior of k -tuples. For an arbitrary k -point metric space (S, D) , we set $\text{Vol}(S) = \sup_{\text{nonexpanding } f: S \rightarrow \ell_2} \text{Evol}(f(S))$, where $\text{Evol}(P)$ is the $(k-1)$ -dimensional volume of the convex hull of P (in ℓ_2). Given a nonexpanding $f: X \rightarrow \ell_2$ for some metric space (X, D) with $|X| \geq k$, we define the k -distortion of f to be

$$\sup_{S \subseteq X, |S|=k} \left(\frac{\text{Vol}(S)}{\text{Evol}(f(S))} \right)^{1/(k-1)}$$

If the k -distortion of f is Δ , we call f (k, Δ) -volume-respecting.

If $f: X \rightarrow \ell_2$ is an embedding scaled so that it is nonexpanding but just so, the 2-distortion coincides with the usual distortion. But note that for $k > 2$, the isometric “straight” embedding of a path in ℓ_2 is not volume-respecting at all. In fact, it is known that for any $k > 2$, no $(k, o(\sqrt{\log n}))$ -volume-respecting embedding of a line exists [DV01].

Extending Bourgain’s technique, Feige proved that for every $k > 2$, every n -point metric space has a $(k, O(\log n + \sqrt{k \log n \log k}))$ -volume-respecting embedding in ℓ_2 .

8.3 APPROXIMATE EMBEDDING OF SPECIAL METRICS IN ℓ_p

GLOSSARY

$\mathcal{G}$ -metric: Let $\mathcal{G}$ be a class of graphs and let $G \in \mathcal{G}$. Each positive weight function $w: E(G) \rightarrow (0, \infty)$ defines a metric D_w on $V(G)$, namely, the shortest-

path metric, where the length of a path is the sum of the weights of its edges. A metric space is a $\mathcal{G}$ -metric if it is isometric to a subspace of $(V(G), D_w)$ for some $G \in \mathcal{G}$ and some w .

Tree metric, planar-graph metric: A $\mathcal{G}$ -metric for $\mathcal{G}$, the class of all trees or all planar graphs, respectively.

Minor: A graph G is a minor of a graph H if it can be obtained from H by repeated deletions of edges and contractions of edges.

8.3.1 TREE METRICS, PLANAR-GRAPH METRICS, AND FORBIDDEN MINORS

A major research direction has been improving Bourgain's embedding in ℓ_2 for restricted families of metric spaces.

TREE METRICS

It is easy to show that any tree metric embeds isometrically in ℓ_1 . Any n -point tree metric can also be embedded isometrically in $\ell_\infty^{O(\log n)}$ [LLR95]. For ℓ_p embeddings, the situation is rather delicate:

THEOREM 8.3.1

Distortion of order $(\log \log n)^{\min(1/2, 1/p)}$ is sufficient for embedding any n -vertex tree metric in ℓ_p ($p \in (1, \infty)$ fixed) [Mat99], and it is also necessary in the worst case (for the complete binary tree; [Bou86]).

Gupta [Gup00] proved that any n -point tree metric $O(n^{1/(d-1)})$ -embeds in ℓ_2^d ($d \geq 1$ fixed), and for $d = 2$ and trees with unit-length edges, Babilon et al. [BMMV02] improved this to $O(\sqrt{n})$.

PLANAR-GRAPH METRICS AND OTHER CLASSES WITH A FORBIDDEN MINOR

The following result was proved by Rao, building on the work of Klein, Plotkin, and Rao.

THEOREM 8.3.2 Rao [Rao99]

Any n -point planar-graph metric can be embedded in ℓ_2 with distortion $O(\sqrt{\log n})$. More generally, let H be an arbitrary fixed graph and let $\mathcal{G}$ be the class of all graphs not containing H as a minor; then any n -point $\mathcal{G}$ -metric can be embedded in ℓ_2 with distortion $O(\sqrt{\log n})$.

This bound is tight even for series-parallel graphs (no K_4 minor) [NR02]; the example is obtained by starting with a 4-cycle and repeatedly replacing each edge by two paths of length 2.

A challenging conjecture, one that would have significant algorithmic consequences, states that under the conditions of Rao's theorem, all $\mathcal{G}$ -metrics can be c -embedded in ℓ_1 for some c depending only on $\mathcal{G}$ (but not on the number of points). Apparently, this conjecture was first published in [GNRS99], where it was verified for the forbidden minors K_4 (series-parallel graphs) and $K_{2,3}$ (outerplanar graphs).

8.3.2 METRICS DERIVED FROM OTHER METRICS

In this section we focus on metrics derived from other metrics, e.g., by defining a distance between two *sets* or *sequences* of points from the underlying metric.

GLOSSARY

Uniform metric: For any set X , the metric (X, D) is uniform if $D(p, q) = 1$ for all $p \neq q, p, q \in X$.

Hausdorff distance: For a metric space (X, D) , the Hausdorff metric H on the set 2^X of all subsets of X is given by $H(A, B) = \min(\vec{H}(A, B), \vec{H}(B, A))$, where $\vec{H}(A, B) = \sup_{a \in A} \inf_{b \in B} D(a, b)$.

Earth-mover distance: For a metric space (X, D) and an integer $d \geq 1$, the earth-mover distance of two d -element sets $A, B \subseteq X$ is the minimum weight of a perfect matching between A and B ; that is, $\min_{\text{bijective } \pi: A \rightarrow B} \sum_{a \in A} D(a, \pi(a))$.

Levenshtein distance (or **edit distance**): For a metric space $M = (\Sigma, D)$, the distance between two strings $w, w' \in \Sigma^*$ is the minimum cost of a sequence of operations that transforms w into w' . The allowed operations are: character insertion (of cost 1), character deletion (of cost 1), or replacement of a symbol a by another symbol b (of cost $D(a, b)$), where $a, b \in \Sigma$. The total cost of the sequence of operations is the sum of all operation costs.

Fréchet distance: For a metric space $M = (X, D)$, the Fréchet distance (also called the **dogkeeper's distance**) between two functions $f, g: [0, 1] \rightarrow X$ is defined as

$$\inf_{\pi: [0, 1] \rightarrow [0, 1]} \sup_{t \in [0, 1]} D(f(t), g(\pi(t)))$$

where π is continuous, monotone increasing, and such that $\pi(0) = 0, \pi(1) = 1$.

HAUSDORFF DISTANCE

The Hausdorff distance is often used in computer vision for comparing geometric shapes, represented as sets of points. However, even computing a single distance $H(A, B)$ is a nontrivial task. As noted in [FCI99], for any n -point metric space (X, D) , the Hausdorff metric on 2^X can be isometrically embedded in ℓ_∞^n .

The dimension of the host norm can be further reduced if we focus on embedding particular Hausdorff metrics. In particular, let H_M^s be the Hausdorff metric over all s -subsets of M . Farach-Colton and Indyk [FCI99] showed that if $M = (\{1, \dots, \Delta\}^k, \ell_p)$, then H_M^s can be embedded in $\ell_\infty^{d'}$ with distortion $1 + \varepsilon$, where $d' = O(s^2(1/\varepsilon)^{O(k)} \log \Delta)$. For a general (finite) metric space $M = (X, D)$ they show that H_M^s can be embedded in $\ell_\infty^{s^{O(1)}|X|^\alpha \log \Delta}$ for any $\alpha > 0$ with constant distortion, where $\Delta = (\min_{p \neq q \in X} D(p, q)) / (\max_{p, q \in X} D(p, q))$.

EARTH-MOVER DISTANCE (EMD)

A very interesting relation between embedding EMD in normed spaces and embeddings in probabilistic trees (discussed below in Section 8.4.1) was discovered in [Cha02]: If a finite metric space can be embedded in a convex combination of

dominating trees with distortion c (see definitions in Section 8.4), then the EMD over it can be embedded in ℓ_1 with distortion $O(c)$. Consequently, the EMD over any n -point metric can be embedded in ℓ_1 with distortion $O(\log n)$.

LEVENSHTEIN DISTANCE AND ITS VARIANTS

The Levenshtein distance is used in text processing and computational biology. The best algorithm computing the Levenshtein distance of two strings w, w' , even approximately, has running time of order $|w| \cdot |w'|$ (for a constant-size Σ). Not much is known about embeddability of this metric in normed spaces, even in the simplest (but nevertheless quite common) case of the uniform metric over $\Sigma = \{0, 1\}$. It is known, however, that the Levenshtein metric, restricted to a certain set of strings, is isomorphic to the shortest path metric over $K_{2,n}$ [ADG⁺03]; this implies that it cannot be embedded in ℓ_1 (or even the square of ℓ_2) with distortion better than $3/2 - O(1/n)$.

However, if we modify the definition of the distance by permitting the movement of an arbitrarily long contiguous block of characters as a single operation, and if the underlying metric is uniform, then the resulting **block-edit** metric can be embedded in ℓ_1 with distortion $O(\log l \cdot \log^* l)$, where l is the length of the embedded strings (see [MS00, CM02] and references therein). The modified metric has applications in computational biology and in string compression. The embedding of a given string can be computed in almost linear time, which yields a very fast approximation algorithm for computing the distance between two strings (the exact distance computation is NP-hard!).

FRÉCHET METRIC

The Fréchet metric is an interesting metric measuring the distances between two *curves*. From the applications perspective, it is interesting to investigate the case where $M = \ell_2^k$ and f, g are continuous, closed polygonal chains, consisting of (say) at most d segments each. Denote the set of such curves by C_d^k . It is not known whether C_d^k , under Fréchet distance, can be embedded in ℓ_∞ with finite dimension (for infinite dimension, an isometric embedding follows from the universality of the ℓ_∞ norm). On the other hand, it is easy to check that for any bounded set $S \subset \ell_\infty^d$, there is an isometry $f: S \rightarrow C_{3d}^1$.

8.3.3 OTHER SPECIAL METRICS

GLOSSARY

(1, 2)-B metric: A metric space (X, D) such that for any $x \in X$ the number of points y with $D(x, y) = 1$ is at most B , and all other distances are equal to 2.

Transposition distance: The (unfortunately named) metric D_T on the set of all permutations of $\{1, 2, \dots, n\}$; $D_T(\pi_1, \pi_2)$ is the minimum number of moves of contiguous subsequences to arbitrary positions needed to transform π_1 into π_2 .

BOUNDED DISTANCE METRICS

Trevisan [Tre01] considered approximate embeddings of $(1, 2)$ - B metrics in ℓ_p^d (in a sense somewhat different from low-distortion embeddings). Guruswami and Indyk [GI03] proved that any $(1, 2)$ - B metric can be isometrically embedded in $\ell_\infty^{O(B \log n)}$.

PERMUTATION METRICS

It was shown in [CMS01] that D_T can be $O(1)$ -embedded in ℓ_1 ; similar results were obtained for other metrics on permutations, including reversal distance and permutation edit distance.

8.4 APPROXIMATE EMBEDDINGS IN RESTRICTED METRICS

GLOSSARY

Dominating metric: Let D, D' be metrics on the same set X . Then D' dominates D if $D(x, y) \geq D'(x, y)$ for all $x, y \in X$.

Convex combination of metrics: Let X be a set, $T_1, T_2, \dots, T_k$ metrics on it, and $\alpha_1, \dots, \alpha_k$ nonnegative reals summing to 1. The convex combination of the T_i (with coefficients α_i) is the metric D given by $D(x, y) = \sum_{i=1}^k \alpha_i T_i(x, y)$, $x, y \in X$.

Hierarchically well-separated tree (k -HST): A 1-HST is exactly an *ultra-metric*; that is, the shortest-path metric on the leaves of a rooted tree T (with weighted edges) such that all leaves have the same distance from the root. For a k -HST with $k > 1$ we require that, moreover, $\Delta(v) \leq \Delta(u)/k$ whenever v is a child of u in T , where $\Delta(v)$ denotes the diameter of the subtree rooted at v (w.l.o.g. we may assume that each non-leaf has degree at least 2, and so $\Delta(v)$ equals the distance of v to the nearest leaves). *Warning:* This is a newer definition introduced in [BBM01]. Older papers, such as [Bar96, Bar98], used another definition, but the difference is merely technical, and the notion remains essentially the same.

8.4.1 PROBABILISTIC EMBEDDINGS IN TREES

A convex combination $\overline{D} = \sum_{i=1}^r \alpha_i T_i$ of some metrics $T_1, \dots, T_r$ on X can be thought of as a **probabilistic metric** (this concept was suggested by Karp). Namely, $\overline{D}(x, y)$ is the expectation of $T_i(x, y)$ for $i \in \{1, 2, \dots, r\}$ chosen at random according to the distribution given by the α_i . Of particular interest are embeddings in convex combinations of *dominating* metrics. The domination requirement is crucial for many applications. In particular, it enables one to solve many problems over the original metric (X, D) by solving them on a (simple) metric chosen at random from $T_1, \dots, T_r$ according to the distribution defined by the α_i .

The usefulness of probabilistic metrics comes from the fact that a sum of metrics is much more powerful than each individual metric. For example, it is not difficult to

show that there are metrics (e.g., cycles [RR98, Gup01]) that cannot be embedded in tree metrics with $o(n)$ distortion. In contrast, we have the following result:

THEOREM 8.4.1 *Fakcharoenphol, Rao, and Talwar [FRT03]*

Let (X, D) be any n -point metric space. For every $k > 1$, there exist a natural number r , k -HST metrics $T_1, T_2, \dots, T_r$ on X , and coefficients $\alpha_1, \dots, \alpha_r > 0$ summing to 1 such that each T_i dominates D , and the (identity) embedding of (X, D) into $(X, \overline{D})$, where $\overline{D} = \sum_{i=1}^r \alpha_i T_i$, has distortion $O((k/\log k) \cdot \log n)$.

The first result of this type was obtained by Alon et al [AKPW95]. Their embedding has distortion $2^{O(\sqrt{\log n \log \log n})}$, and uses convex combinations of the metrics induced by spanning trees of M . A few years later Bartal [Bar96] improved the distortion bound considerably, to $O(\log^2 n)$ and later even to $O(\log n \log \log n)$ [Bar98]. The bound on the distortion in the theorem above is optimal up to a constant factor for every fixed k , since any convex combination of tree metrics embeds isometrically into ℓ_1 .

The constructions in [Bar96, Bar98, FRT03] generate trees with Steiner nodes (i.e., nodes that do not belong to X). However, one can get rid of such nodes in *any* tree while increasing the distortion by at most 8 [Gup01].

An interesting extra feature of the construction of Alon et al. mentioned above is that if the metric D is given as the shortest-path metric of a (weighted) graph G on the vertex set X , then all the T_i are spanning trees of this G . None of the constructions in [Bar96, Bar98, FRT03] share this property.

The embedding algorithms in Bartal's papers [Bar96, Bar98] are randomized and run in polynomial time. A deterministic algorithm for the same problem was given in [CCG⁺98]. The latter algorithm constructs a distribution over $O(n \log n)$ trees (the number of trees in Bartal's construction was exponential in n).

8.4.2 RAMSEY-TYPE THEOREMS

Many Ramsey-type questions can be asked in connection with low-distortion embeddings of metric spaces. For example, given classes $\mathcal{X}$ and $\mathcal{Y}$ of finite metric spaces, one can ask whether for every n -point space $Y \in \mathcal{Y}$ there is an m -point $X \in \mathcal{X}$ such that X can be α -embedded in Y , for given n, m, α .

Important results were obtained in [BBM01], and later greatly improved and extended in [BLMN03], for $\mathcal{X}$ the class of all k -HST and $\mathcal{Y}$ the class of all finite metric spaces; they were used for a lower bound in a significant algorithmic problem (metrical task systems). Let us quote some of the numerous results of Bartal et al.:

THEOREM 8.4.2 *Bartal, Linial, Mendel, and Naor [BLMN03]*

Let $R_{\text{UM}}(n, \alpha)$ denote the largest m such that for every n -point metric space Y there exists an m -point 1-HST (i.e., ultrametric) that α -embeds in Y , and let $R_2(n, \alpha)$ be defined similarly with “ultrametric” replaced with “Euclidean metric.”

- (i) *There are positive constants C, C_1, c such that for every $\alpha > 2$ and all n ,*

$$n^{1-C_1(\log \alpha)/\alpha} \leq R_{\text{UM}}(n, \alpha) \leq R_2(n, \alpha) \leq Cn^{1-c/\alpha}.$$

- (ii) *(Sharp threshold at distortion 2) For every $\alpha > 2$, there exists $c(\alpha) > 0$ such that $R_2(n, \alpha) \geq R_{\text{UM}}(n, \alpha) \geq n^{c(\alpha)}$ for all n , while for every $\alpha \in (1, 2)$, we*

have $c'(\alpha) \log n \leq R_{\text{UM}}(n, \alpha) \leq R_2(n, \alpha) \leq 2 \log n + C'(\alpha)$ for all n , with suitable positive $c'(\alpha)$ and $C'(\alpha)$.

For embedding a k -HST in a given space, one can use the fact that every ultrametric is k -equivalent to a k -HST. For an earlier result similar to the second part of (ii), showing that the largest Euclidean subspace $(1+\varepsilon)$ -embeddable in a general n -point metric space has size $\Theta(\log n)$ for all sufficiently small fixed $\varepsilon > 0$, see [BFM86].

8.4.3 APPROXIMATION BY SPARSE GRAPHS

GLOSSARY

t -spanner: A subgraph H of a graph G (possibly with weighted edges) is a t -spanner of G if $D_H(u, v) \leq t \cdot D_G(u, v)$ for every $u, v \in V(G)$.

Sparse spanners are useful as a more economic representation of a given graph (note that if H is a t -spanner of G , then the identity map $V(G) \rightarrow V(H)$ is a t -embedding).

THEOREM 8.4.3 *Althöfer et al.* [ADD⁺93]

For every integer $t \geq 2$, every n -vertex graph G has a t -spanner with at most $m(t, n)$ edges, where $m(g, n) = O(n^{1+1/\lfloor g/2 \rfloor})$ is the maximum possible number of edges of an n -vertex graph of girth $g + 1$.

The proof is extremely simple: Start with empty H , consider the edges of G one by one from the shortest to the longest, and insert each edge into the current H unless it creates a cycle with at most t edges. It is also immediately seen that the bound $m(t, n)$ is the best possible in the worst case.

Rabinovich and Raz [RR98] proved that there are (unweighted) n -vertex graphs G that cannot be t -embedded in graphs (possibly weighted) with fewer than $m(\Omega(t), n)$ edges (for t sufficiently large and n sufficiently large in terms of t). Their main tool is the following lemma, proved by elementary topological considerations: If H is a simple unweighted connected n -vertex graph of girth g and G is a (possibly weighted) graph on at least n vertices with $\chi(G) < \chi(H)$, then H cannot be c -embedded in G for $c < g/4 - 3/2$; here $\chi(G)$ denotes the **Euler characteristic** of a graph G , which, for G connected, equals $|E(G)| - |V(G)| + 1$.

8.5 ALGORITHMIC APPLICATIONS OF EMBEDDINGS

In this section we give a brief overview of the scenarios in which embeddings have been used in the design of algorithms and for determining computational complexity. For a more detailed survey, see [Ind01].

The most typical scenario is as follows. Suppose we have a problem defined over a set of points in a metric space M . If the metric space is “complex” enough, the problem is likely to be NP-hard. To solve the problem, we embed the metric in a “simple” metric M' , and solve the problem there. This gives an approximation

algorithm for the original problem, whose approximation factor depends on the distortion of the embedding.

The implementation of this general paradigm depends on “complex” and “simple” metrics M and M' . The most frequent scenarios are as follows:

1. *General metrics* $\rightarrow$ *tree metrics*. This approach uses the theorems of [Bar98, FRT03], which enable the embedding of an arbitrary finite metric space, in a “probabilistic” way, in tree metrics, with low distortion. It is not difficult to see that if the goal of the original problem is to minimize a linear function of the interpoint distances, then the properties guaranteed by the above embedding are sufficient to show that given a c -approximation algorithm for HST’s (or trees, resp.), one can construct an $O(c \log n \log \log n)$ -approximation (or $O(c \log n)$ -approximation, resp.) algorithm for the original metric. Since the random choice of a tree does not depend on the function to be optimized, this approach works even if the optimization function is not known in advance. Thus, this approach has been very successful for both *offline* and *online* problems. In particular, it led to a polylog(n)-competitive algorithm [BBBT97] for metrical task systems, resolving a long-standing conjecture. In the latter paper, the embedding in HST’s (as opposed to general trees) is crucial to obtain the result.
2. *General metric* $\rightarrow$ *low-dimensional normed spaces*. In this case we use Bourgain’s or Matoušek’s theorem to obtain a low-dimensional approximate representation of a metric. Since the host metric is low-dimensional, each point can be represented using a small number of bits. This has interesting consequences for approximate proximity-preserving labeling [Pel99, GPPR01].
3. *Specific metrics* $\rightarrow$ *normed spaces*. This approach uses the results of Section 8.3.2, which provide embeddings of certain metrics (e.g., Hausdorff or Levenshtein metrics) in normed spaces. This enables the use of algorithmic tools designed for normed spaces (see, e.g., Chapter 39 of this Handbook) for problems defined over more complex metrics.
4. *High-dimensional spaces* $\rightarrow$ *low dimensional spaces*. Here, we use dimensionality reduction techniques, notably the Johnson-Lindenstrauss theorem. In this way, we reduce the dimension of the original space to $O(\log n)$, which yields significant savings in the running time and/or space. The improvement is particularly impressive if an algorithm for the original problem uses space/time *exponential* in the dimension (see, e.g., Chapter 39).

We note, however, that for most applications, the embedding properties listed in the statement of Theorem 8.2.3 are not sufficient. Instead, one must often use additional properties of the embedding, such as:

- The embedding is chosen at random, independently of the input point set. This property is crucial in situations where not all points are known in advance (e.g., for the nearest neighbor problem).
- The mapping is linear. This property is used, e.g., for dimensionality reduction theorems for hyperplanes (i.e., when the input set can consist of points, lines, planes etc.) [Mag02], and for low-space computation as described below.

- The coefficients of the mapping matrix are chosen independently of each other (this property holds for *some* but not *all* proofs of dimensionality reduction theorems). This property is useful, e.g., if we want to obtain deterministic versions of dimensionality reduction theorems [Ind00, Siv02, EIO02], which have applications to the derandomization of approximation algorithms based on semidefinite programming.

5. “Complex” normed spaces $\rightarrow$ “simple” normed spaces. The “complexity” of a normed space clearly depends on the problem we want to solve. For example, if we want to find the *diameter* of a set of points, it is very helpful if the interpoint distances are induced by the l_∞^d norm. In this case, the diameter of the point set is equal to the maximum diameter of all one-dimensional point sets, obtained by projecting the (d -dimensional) points onto one of the coordinates. This approach gives an $O(nd)$ time for computing the diameter in l_∞^d . However, from Section 8.1 we know that the space l_1^d can be isometrically embedded in $l_\infty^{2^{d-1}}$. Thus, we obtain a linear-time (assuming constant dimension) algorithm for computing the diameter in the l_1 norm. Other embedding results described in Section 8.2 have similar algorithmic applications as well.

A second type of result involves using the embeddings in the “reverse” directions, in order to derive *lower* bounds. Specifically, in order to show a hardness result for a metric M' , it suffices to show that a given problem is hard (to approximate) in a metric M that can be embedded in M' . This approach has been used to prove the following results:

- In [Tre01, GI03], it was shown that certain geometric problems (e.g., TSP) are hard to approximate even in $\Theta(\log n)$ dimensions. This was achieved by embedding $(1, 2)$ - B metrics (known to be the “hard” cases) in $l_p^{O(\log n)}$.
- In [BBM01], it was shown that certain online problems (metrical task systems) do not have $\Omega(\log n / \log^{O(1)} \log n)$ -competitive algorithms. This was achieved by showing that “large” HST metrics can be embedded in arbitrary finite metrics, and proving a lower bound for HST metrics.

Finally, embeddings can be used for problems that, at first sight, do not seem to be “metric” in nature. Notable examples of such an application are approximation algorithms for graph problems, such as the algorithm of [LLR95] for the sparsest cut problem and for graph bandwidth [Fei00]. In particular, the former problem can be phrased as finding a cut metric minimizing a certain objective function. Although the problem is NP-hard, its relaxation that requires finding just a metric (minimizing the same objective function) can be solved in polynomial time via linear programming. The algorithm proceeds by embedding the solution metric in l_1 (with low distortion) and decomposing it into a convex combination of cut metrics. It can be shown that that one of those cut metrics provides an approximate solution to the sparsest cut problem.

Another area whose relation to embeddings is not *a priori* apparent is low-space computing. A prototypical example of such a problem is a data structure that maintains a d -dimensional vector x (under increments/decrements of x ’s coordinates). When queried, the data structure reports an approximate value of $\|x\|_p$. In particular, the case $p = 0$ corresponds to maintaining an approximate number of nonzero coordinates. Alternatively, one could request a succinct (e.g., piecewise

constant with few pieces) approximation of x , viewed as a function from $\{1, \dots, d\}$ into the reals. Such problems are motivated by database applications.

In order to obtain low-storage algorithms solving such problems, we can apply dimensionality reduction techniques to reduce the dimension, while approximately preserving important properties of x (e.g., its norm, or its best succinct approximation). In this way, we only need to store the image Ax of x . Since the update operations on x are linear, they can be easily transformed into operations on Ax . One also has to ensure that there is no need to store the description of A explicitly; this is done by showing that a “pseudorandom” matrix A is good enough [AMS99, Ind00].

TABLE 8.5.1 A summary of approximate embeddings.

FROM	TO	DISTORTION	REFERENCE
any constant-degree expander k -reg. graph, $k \geq 3$, girth g	ℓ_p , $1 \leq p < \infty$ ℓ_p , $p < \infty$ fixed ℓ_2	$O(\log n)$ $\Omega(\log n)$ $\Omega(\sqrt{g})$	[Bou85] [LLR95] [LMN02]

any	convex comb. of dom. trees (HSTs)	$O(\log n)$	[FRT03]
any	convex comb. of spanning trees	$2^{O(\sqrt{\log n \log \log n})}$	[AKPW95]

8.6 OPEN PROBLEMS AND WORK IN PROGRESS

The time of writing of this chapter (2002) seems to be a period of particularly rapid development in the area of low-distortion embeddings of metric spaces. Many significant results have recently been achieved, and some of them are still unpublished (or not yet even written). We have tried to mention at least some of them, but it is clear that some parts of the chapter will become obsolete very soon.

Instead of stating open problems here, we refer to a list recently compiled by the second author [Mat02b]. It is available on the Web, and it might occasionally be updated to reflect new developments.

8.7 SOURCES AND RELATED MATERIAL

Discrete metric spaces have been studied from many different points of view, and the area is quite wide and diverse. The low-distortion embeddings treated in this chapter constitute only one particular (although very significant) direction. For recent results in some other directions the reader may consult [Cam00, DDL98, DD96], for instance. For more detailed overviews of the topics surveyed here, with many more references, the reader is referred to Chapter 15 in [Mat02a] (including proofs of basic results) and [Ind01] (with emphasis on algorithmic applications), as well as to [Lin02]. Approximate embeddings of normed spaces are treated, e.g., in [MS86]. A recent general reference for isometric embeddings, especially embeddings in ℓ_1 , is [DL97].

9 GEOMETRY AND TOPOLOGY OF POLYGONAL LINKAGES

Robert Connelly and Erik D. Demaine

INTRODUCTION

There is a long and involved history of linkages starting at least in the nineteenth century with the advent of very complicated and intricate machinery. Some of the practical problems involved led to interesting, nontrivial geometric problems, and even recently there has been progress on some very basic questions. We will attempt to point the reader to some of the results that we know in this direction.

There are several points of view and groups of people working on various aspects of the theory of linkages, but they seem to be disjointed, with each group unaware of other groups that are in related or even overlapping fields. Despite that, we will also try to point out connections when we can.

9.1 MATHEMATICAL THEORY OF LINKAGES

The underlying principles and definitions are mathematical and in particular geometric. Despite the long history of kinematics, even of theoretical kinematics (see, e.g., Bottema and Roth [BR79a]), only since the 1970s does there seem to be any systematic attempt to explore the mathematical and geometric foundations of a theory of linkages.

We begin with some definitions, some of which follow those in rigidity theory described in [Chapter 60](#). The rough, intuitive notions are as follows. A *linkage* is a combinatorial structure plus edge lengths, and we often distinguish three special types of linkages: arcs, cycles, and trees. A *configuration* realizes a linkage in Euclidean space, a *reconfiguration* (or *flex*) is a continuum of such configurations, and the *configuration space* embodies all reconfigurations. The configuration space can be considered as either allowing or disallowing bars to intersect each other.

GLOSSARY

Bar linkage or **linkage**: A graph $G = (V, E)$ and an assignment $\ell : E \rightarrow \mathbb{R}^+$ of positive real *lengths* to edges.

Vertex or **joint**: A vertex of a linkage.

Bar or **link**: An edge e of a linkage, which has a specified fixed length $\ell(e)$.

FIGURE 9.1.1

Different types of linkages, according to whether the underlying graph is a path, cycle, or tree, or whether the graph is arbitrary.

FIGURE 9.1.2

Snapshots of a reconfiguration of a polygonal arc.

Polygonal arc: A linkage whose underlying graph is a single path. (Also called an *open chain* or a *ruler*.)

Polygonal cycle: A linkage whose underlying graph is a single cycle. (Also called a *closed chain* or a *polygon*.)

Polygonal tree: A linkage whose underlying graph is a single tree.

Configuration of a linkage in d -space: A mapping $p : V \rightarrow \mathbb{R}^d$ specifying a point $p(v) \in \mathbb{R}^d$ for each vertex v of the linkage, such that each bar $\{v, w\} \in E$ has the desired length $\ell(e)$, i.e., $|p(v) - p(w)| = \ell(e)$.

A configuration can be viewed as a point p in $\mathbb{R}^{d|V|}$ by arbitrarily ordering the vertices in V and assigning the coordinates of the i th vertex ($0 \leq i < |V|$) to coordinates $id + 1, id + 2, \dots, id + d$ of p .

Framework or bar framework: A linkage together with a configuration.

Reconfiguration or motion or flex of a linkage: A continuous function $f : [0, 1] \rightarrow \mathbb{R}^{d|V|}$ specifying a configuration of the linkage for every moment in time between 0 and 1.

Configuration space or moduli space of a linkage: The set $\mathcal{M}$ of all configurations (treated as points in $\mathbb{R}^{d|V|}$) of the linkage.

Self-intersecting configuration: A configuration in which two bars intersect but are not incident in the underlying graph of the linkage.

Reconfiguration avoiding self-intersection: A reconfiguration f in which no configuration $f(t)$ self-intersects.

Configuration space of a linkage, disallowing self-intersection: The subset $\mathcal{F}$ of the configuration space $\mathcal{M}$ in which no configuration self-intersects. (Also called the *free space* of the linkage.)

Paths in the configuration space of a linkage capture the key notion of reconfiguration (either allowing or disallowing self-intersection as appropriate). Many important questions about linkages can be most easily phrased in terms of the configuration space. For example, we are often interested in whether the configuration space is connected (every configuration can be reconfigured into every other configuration), or in the topology of the configuration space.

9.2 CONFIGURATION SPACES OF ARCS AND CYCLES WITH POSSIBLE INTERSECTIONS

One fundamental problem is to compute the topology of the configuration space of planar polygonal cycles (polygons), allowing possible self-intersections. There is a long list of results in increasing generality for computing information about the algebraic topological invariants of this configuration space. One approach is through Morse Theory, which reveals some of the basic information, in particular, the connectivity and some of the easier invariants such as the Euler characteristic.

CONNECTIVITY

The following is an early result possibly first due to [Hau91], but rediscovered by [Jag92], and then rediscovered again or generalized considerably by many others, in particular, [Kam99, KT99, MS00, KM95, LW95].

THEOREM 9.2.1 *Connectivity for planar polygons* [Hau91]

Let $s_1 \leq s_2 \leq \dots \leq s_n$ be the cyclic sequence of bar lengths in a polygon, and let $s = s_1 + s_2 + \dots + s_n$. Then

- i) The configuration space is nonempty if and only if $s_n \leq s/2$.
- ii) The configuration space, modulo orientation-preserving congruences, is connected if and only if $s_{n-2} + s_{n-1} \leq s/2$. If the space is not connected, there are exactly two connected components, where each configuration in one component is the reflection of a configuration in the other component.

The configuration space is a smooth manifold if and only if there is some configuration p with all its vertices on a line, which in turn is determined by the edge lengths as described above. Also, the configuration space remains congruent no matter how we permute the cyclic sequence of bar lengths. When the linkage is not allowed to self-intersect, it is common to consider the configuration space modulo all congruences of the plane (including reflections); but when self-intersections are allowed, and condition ii) above is satisfied, it is possible to move the linkage from any configuration to its mirror image.

For polygons in dimensions higher than two, the situation is simpler:

THEOREM 9.2.2 *Connectivity for nonplanar polygons* [LW95]

The configuration space of a polygon in d -dimensional space, for $d > 2$, is always connected.

HOMOLOGY, COHOMOLOGY, AND HOMOTOPY

After connectivity, there remains the calculation of the higher homology groups, cohomology groups, and the homotopy type of the configuration space. Here is one special case as an example:

THEOREM 9.2.3 *Configuration space of equilateral polygons* [KT99]

Let $\mathcal{M}$ be the configuration space of a polygon with n equal bar lengths, modulo congruences of the plane. The homology of $\mathcal{M}$ is a torsion-free module given explicitly in [KT99]. When n is odd, $\mathcal{M}$ is a smooth manifold; and when $n = 5$, $\mathcal{M}$ is the compact, orientable two-dimensional manifold of genus 4 (originally shown in [Hav91], as well as in [Jag92]).

See also especially [KM95] for some of the basic techniques. For calculating the configuration space of graphs other than a polygon, see in particular the article [TW84], where a particular linkage, with some pinned vertices, has a configuration space that is an orientable two-dimensional manifold of genus 6.

Another case that has been considered is an equilateral polygon in 3-space with angles between incident edges fixed. This fixed-angle model arises in chemistry [CH88] and in particular in protein folding (see [Section 9.7](#)). Alternatively, a fixed angle can be simulated by adding bars between vertices of distance two along the polygon. The configuration space behaves similarly to the planar case:

THEOREM 9.2.4 *Fixed-angle equilateral 3D polygons* [CJ]

Let $\mathcal{M}$ be the configuration space of an equilateral polygon with $n \geq 6$ equal bar lengths and fixed equal angles, modulo congruences of $\mathbb{R}^3$. Suppose further that every turn angle is within an additive ϵ of $2\pi/n$ for ϵ sufficiently small (i.e., configurations are forced nearly planar). Then $\mathcal{M}$ has at most two components. When n is odd, $\mathcal{M}$ is a smooth manifold of dimension $n-6$. When n is even, $\mathcal{M}$ is singular.

When $n = 6$, the underlying graph is the graph of an octahedron, and there are cases when it is rigid and cases when it is not. This linkage corresponds to cyclohexane in chemistry, and its flexibility was studied by [Bri96] and [Con78].

The restriction of the polygon configurations being almost planar leads to the following problem:

PROBLEM 9.2.5 *General equilateral equi-angular 3D polygons* [Cri92]

How many components does $\mathcal{M}$ have in the theorem above if ϵ is allowed to be large?

9.3 CONFIGURATION SPACES WITHOUT SELF-INTERSECTIONS

When the linkage is not permitted to self-intersect, the main question that has been studied is when it can be locked. Three main classes of linkages have been studied in this context: arcs, cycles, and trees. When the linkage is planar and has cycles, we assume that the clockwise/counterclockwise orientation is given and fixed, for otherwise the linkage is trivially locked: no cycle can be “flipped over” in the plane without self-intersection.

GLOSSARY

Locked linkage: A linkage whose configuration space has multiple connected components when self-intersections are disallowed.

Lockable class of linkages: There is a locked linkage in the class.

Unlockable class of linkages: No linkage in the class is locked.

FIGURE 9.3.1

The problems of arc straightening, cycle convexifying, and tree flattening.

Straightening an arc: A motion bringing a polygonal arc from a given configuration to its **straight configuration** in which every joint angle is π .

Convexifying a cycle: A motion bringing a polygonal arc from a given configuration to a **convex configuration** in which every joint angle is at most π .

Flattening a tree: A motion bringing a polygonal tree from a given configuration to a **flat configuration** in which every joint angle is either 0, π , or 2π , and every bar points “away” from a designated root node.

WHICH LINKAGES ARE LOCKED?

Which of the main classes of linkages can be locked is summarized in [Table 9.3.1](#). In short, the existence of locked arcs and locked unknotted cycles is equivalent to the existence of knots in that dimension: this happens just in 3D. However, this equivalence is by no means obvious, especially in 2D, as evidenced by the existence of knotted trees in 2D.

One main approach for determining whether a linkage is locked is to consider the equivalent problem of finding a motion from any configuration to a **canonical configuration**. Because linkage motions are reversible and concatenable, if every configuration can be canonicalized, then every configuration can be brought to any other configuration, routing through the canonical configuration. Conversely, if

TABLE 9.3.1 Summary of what types of linkages can be locked.

	ARCS AND CYCLES	TREES
2D	Not lockable [CDR03, Str00, CDIO02]	Lockable [BDD ⁺ 02, CDR02]
3D	Lockable [CJ98, BDD ⁺ 01, Tou01]	Lockable [arcs are a special case]
4D ⁺	Not lockable [CO01]	Not lockable [CO01]

some configuration cannot be canonicalized, then we know a pair of configurations that cannot reach each other, and therefore the linkage is locked.

This idea leads to the notions of straightening arcs, convexifying cycles, and flattening trees, as defined above. There is only one straight configuration of an arc, but there are multiple convex configurations of cycles and flat configurations of trees; fortunately, it is fairly easy to reconfigure between any pair of convex configurations of a cycle [ADE⁺01] or between any pair of flat configurations of a tree [BDD⁺02].

LOCKED LINKAGES

The first results along these lines were negative (see Figure 9.3.2): polygonal arcs in 3D and unknotted polygonal cycles in 3D can be locked [CJ98], and planar polygonal trees can be locked [BDD⁺02]. Since these results, other examples of unknotted but locked 3D polygonal cycles [BDD⁺01, Tou01] and locked 2D polygonal trees [CDR02] have been discovered.

More generally and recently, Alt, Knauer, Rote, and Whitesides [AKRW03] constructed a large family of locked 2D trees and 3D arcs in which it is PSPACE-hard to determine whether one configuration can reach another configuration via a continuous motion that avoids self-intersection. Their construction combines several gadgets, many of which resemble the examples in Figure 9.3.2, as well as the “interlocked” linkages of [DLOS03, DLOS02]. However, this work leaves open a closely related problem, deciding whether *every* pair of configurations can reach each other:

PROBLEM 9.3.1 *Complexity of testing if a linkage is locked [BDD⁺01]*
What is the complexity of deciding whether a linkage is locked? Particular cases of interest are 3D arcs, unknotted 3D cycles, and 2D trees.

UNLOCKED LINKAGES

Unlockability was first established in 4D and higher [CO01], where one-dimensional arcs, cycles, and trees have so much freedom that they can never lock. Intuitively, the barriers (self-intersecting configurations) that might prevent, e.g., straightening the vertex between the first two bars of an arc have dimension at least 2 lower than the configuration space of that vertex, and hence all barriers can be avoided. Thus, the only problem with straightening an arc vertex-by-vertex is that the configuration that results from straightening one extreme vertex might have self-intersections; in this case, the linkage can be perturbed to remove the problem. Convexifying cy-

FIGURE 9.3.2

Known examples of locked linkages.

cles in 4D and higher is more difficult, but follows a similar idea.

The last cell of [Table 9.3.1](#) to be filled was that 2D arcs and cycles never lock [CDR03]. Indeed, the following more general theorem holds:

THEOREM 9.3.2 *Straightening 2D arcs and convexifying 2D cycles* [CDR03]

*Given a disjoint collection of polygonal arcs and polygonal cycles in the plane, there is a motion that avoids self-intersection and, after finite time, straightens every outermost arc and convexifies every outermost cycle. (An arc or cycle is **outermost** if it is not contained within another cycle.)*

In this theorem, arcs and cycles contained within other cycles may not straighten or convexify—they simply “come along for the ride”—but this is the best we could

hope for in general.

There are now three methods for solving this problem. See Figure 9.3.3 for a visual comparison on a simple example. The first method is based on flow through an ordinary differential equation defined implicitly by a convex optimization problem [CDR03]. The second method is more combinatorial and is based on algebraic motions defined by single-degree-of-freedom mechanisms given by pseudotriangulations [Str00]. The third method is based on energy minimization via gradient descent [CDIO02].

FIGURE 9.3.3

Converifying a common polygon via all three convexification methods.

The first two motions have the additional property of being *expansive*—the distance between every pair of vertices never decreases over time—while the third motion only relies on the existence of such a motion. The first and last motions, being flow-based, preserve any initial symmetries of the linkage. Characterizing by continuity, the three motions are respectively piecewise- C^1 , piecewise- C^∞ , and C^∞ . Only the last motion has a corresponding finite-time algorithm to compute a motion that is *piecewise-linear* through configuration space, i.e., the motion can be decomposed into steps where each angle in each step changes at a constant rate. This algorithm is also easy to implement.

SPECIAL CLASSES OF LINKAGES

In addition to these results for general classes of linkages, various special classes have been shown to have different properties. Polygonal arcs in 3D that lie on

the surface of a convex polyhedron, or having a non-self-intersecting orthogonal projection, are never locked [BDD⁺01]. Polygonal cycles in 3D having a non-self-intersecting orthogonal projection are also never locked [CKM⁺01].

FLIPS AND FLIPTURNS

One of the first papers essentially about unlocking linkages is by Erdős [Erd35], who asked whether a particular “flipping” algorithm always convexifies a planar polygon by motions through 3D in a finite number of steps. A **flip** rotates by 180° a subchain of the polygon, called a **pocket**, whose endpoints are consecutive vertices along the convex hull of the polygon. Each such flip never causes the polygon to self-intersect.¹ Nagy [Nag39] was the first to prove that a polygon admits only finitely many flips before convexifying. Thus, pocket flipping is one suitable strategy for convexifying a 2D polygon by motions in 3D. This result was subsequently rediscovered several times; see [Tou99, Grü95].

FIGURE 9.3.4

Flipping a polygon until it is convex.

Joss and Shannon (1973) first proved that the number of flips required to convexify a polygon cannot be bounded in terms of the number of vertices, but this work remains unpublished; see [Grü95, Tou99]. However, it may still be possible to bound the number of flips using other metrics:

PROBLEM 9.3.3 *Bounding the number of flips* [M. Overmars, Feb. 1998]

Bound the maximum number of flips a polygon admits in terms of natural measures of geometric closeness such as the sharpest angle, the diameter, and the minimum distance between two nonincident edges.

¹Erdős [Erd35] originally proposed flipping multiple pockets at once, but such an operation can lead to self-intersection; Nagy [Nag39] fixed this problem by proposing flipping only one pocket at once.

A related computational problem is to compute the extreme numbers of flips:

PROBLEM 9.3.4 *Maximizing or minimizing flips* [Dem02]

What is the complexity of minimizing or maximizing the length of a convexifying sequence of flips for a given polygon?

Several variations on flips have also been considered. Grünbaum and Zaks [GZ01] generalized Nagy's results to polygons with self-intersections; still they can be convexified by finitely many flips. Wegner [Weg93] introduced the notion of **deflations**, which are the exact reverse of flips, and Fevens et al. [FHM⁺01] showed that some polygons admit infinitely many deflations.

Flipturns are similar to flips, except that the pocket is temporarily severed from the rest of the linkage and rotated 180° in the plane around the midpoint of the hull edge. Such an operation is not a valid linkage motion, but it has the advantage that the number of flipturns that a polygon admits before convexification is $O(n^2)$ [ACD⁺02, ABC⁺00]. This bound is tight up to a constant factor [Bie00], and there is extensive work on finding the precise constants [ACD⁺02], though some gaps remain to be closed. Also, related to Problem 9.3.4, it is known that maximizing the length of a convexifying flipturn sequence is weakly NP-hard [ACD⁺02]. Minimizing the number of flipturns leads to the following interesting problem:

PROBLEM 9.3.5 *Number of required flipturns* [Bie00]

Is there a polygon that requires $\Omega(n^2)$ flipturns to convexify, or can all polygons be convexified by $o(n^2)$ carefully chosen flipturns?

The best known lower bound is $\Omega(n)$.

INTERLOCKED LINKAGES

Combinations of polygonal arcs and cycles in 3D that can or cannot be locked (or, more accurately, “interlocked”) are studied in [DLOS03, DLOS02]. More precisely, this work studies the shortest (fewest-bar) 3D arcs and cycles that can interlock with each other. For example, three 3-arcs (arcs with three bars each) can interlock, as can a 3-arc and a 4-arc, or a 3-cycle and a 4-arc, or a 3-arc and a 4-cycle. However, two 3-arcs and arbitrarily many 2-arcs never interlock, nor can a 3-cycle and a 3-arc. Also considered in [DLOS02] is the case that some of the pieces have restricted motion, e.g., all angles are fixed, or only rigid motions are allowed.

9.4 UNIVERSALITY RESULTS

TRACING CURVES

The classic motivation of building linkages is to design a planar linkage in which one of the vertices traces a portion of a desired curve given by some polynomial function. In particular, Watt posed the problem of finding a linkage with some vertices pinned so that one vertex would trace out a line (segment). Watt's problem, at first thought

to be impossible, was finally solved by Peaucellier in [Pea73], as well as by Lipkin in [Lip71]. See also [Kem77] and [Har74].

Later, Kempe [Kem76] described a linkage that would trace out a portion of any algebraic curve in the plane. However, his description is very brief and it leaves unspecified what portion of the algebraic curve is actually traced out, and whether there are other, possibly unwanted components or pieces of other algebraic curves that can also be traced out. This question also arises for the linkages that trace a line segment.

GLOSSARY

Real algebraic set: A subset of $\mathbb{R}^N$ given by a finite number of polynomial equations with real coefficients.

Real semialgebraic set: A subset of $\mathbb{R}^N$ given by a finite number of polynomial equations and inequalities with real coefficients.

It is important to realize the distinction between an algebraic set and a semialgebraic set. For example, a circle (excluding its interior) is an algebraic set, while a (closed) line segment is a semialgebraic set but not an algebraic set. The linear projection of an algebraic set is always a semialgebraic set, but it may not be an algebraic set. The configuration space of a linkage is an algebraic set, but the locus of possible positions of one of its vertices is only guaranteed to be a semialgebraic set, because it represents the projection onto the coordinates corresponding to one of the vertices of the linkage.

ARBITRARY CONFIGURATION SPACES

One of the more precise results related to Kempe's result is the following:

THEOREM 9.4.1 *Creating linkage configuration spaces* [KM95]

Let M be any compact smooth manifold. Then there is a planar linkage whose configuration space is diffeomorphic to a disjoint union of some number of copies of M .

This result was also claimed by Thurston, but there does not seem to be a written proof by him. As a consequence of this result, we obtain the following precise version of what Kempe was trying to claim. This consequence is proved by King [Kin99] using the techniques of Kapovich-Millson [KM02] and Thurston.

THEOREM 9.4.2 *Tracing out an algebraic curve* [Kin99]

Let X be any set in the plane that is the polynomial image of a closed interval. Then there is a linkage in the plane with some pinned vertices such that one of the vertices traces out X exactly.

See [JS99, BM56] for other discussions of how to create linkages to trace out at least a portion of a given algebraic curve. King [Kin] also generalizes this result to higher dimensions and to the semialgebraic sets arising from projecting the

configuration space down to consider some subset of the vertices. See also [KM02] for connections to universality theorems concerning configuration spaces of lines in the plane, for example, as in the work of [Mnë88]. Finally, the complexity results of [HJW85] described in Section 9.5 build off a universality construction similar to those mentioned above.

9.5 COMPUTATIONAL COMPLEXITY

There are a variety of algorithmic questions that can be asked about a given linkage. Most of these questions are computationally difficult to answer, either NP-hard or PSPACE-hard. Nonetheless, given the importance of these problems, there is work on developing (exponential-time) algorithms.

GLOSSARY

Ruler folding problem: Given a polygonal arc (i.e., a sequence of bar lengths) and a desired length L , is there a configuration of the arc (ruler) in which the bars lie along a common line segment of length L ? If so, find such a configuration. (The problem can also be phrased as reconfiguration, provided the linkage is permitted to self-intersect.)

Reachability problem: Given a configuration of a linkage, a distinguished vertex, and a point in the plane, is it possible to reconfigure the linkage so that the distinguished vertex touches the given point? If so, find such a reconfiguration. In this problem, the linkage has one or more vertices pinned to particular locations in the plane.

Reconfiguration problem: Given two configurations of a linkage, is it possible to reconfigure one into the other? If so, find such a reconfiguration.

Locked decision problem: Given a linkage, is it locked?

HARDNESS RESULTS

One of the simplest complexity results is about the ruler folding problem, obtained via a reduction from set partition:

THEOREM 9.5.1 *Complexity of ruler folding* [HJW85]

The ruler folding problem is NP-complete.

Building on this result, the same authors establish

THEOREM 9.5.2 *Complexity of arc reachability* [HJW85]

The reachability problem is NP-hard for a planar polygonal arc in the presence of four line-segment obstacles and permitting the arc to self-intersect.

For general linkages instead of arcs, stronger complexity results exist:

THEOREM 9.5.3 *Complexity of reachability* [HJW84]

The reachability problem is PSPACE-hard for a planar linkage without obstacles and permitting the linkage to self-intersect.

On the other hand, a similar result holds for a polygonal arc among obstacles:

THEOREM 9.5.4 *Complexity of arc reachability among obstacles* [JP85]

The reachability problem is PSPACE-hard for a planar polygonal arc in the presence of polygonal obstacles and permitting the arc to self-intersect.

Finally, when the linkage is not permitted to self-intersect, and there are no obstacles, hardness is known in cases when the linkage can be locked; see [Section 9.3](#).

THEOREM 9.5.5 *Complexity of non-self-intersecting arc reconfiguration* [AKRW03]

The reconfiguration problem is PSPACE-hard for a 3D polygonal arc or a 2D polygonal tree when the linkage is not permitted to self-intersect.

ALGORITHMS

Algorithms for linkage reconfiguration problems can be obtained from the general motion-planning results in [Chapter 47](#) (Section 47.1.1). This connection seems to have only recently been made explicit [AKRW03]. To apply the roadmap algorithm of Canny [Can87] (Theorem 47.1.2), we first phrase the algorithmic linkage problems into the motion-planning framework.

The configuration space of a given linkage is the subset of $\mathbb{R}^{vc}$ in which every point satisfies certain bar-length constraints and, if desired, non-intersection constraints between all pairs of bars. Both types of constraints can be phrased using constant-degree polynomial equations and inequalities, e.g., the former by setting the squared length of each bar to the desired value. (There are also embeddings of the configuration space into Euclidean spaces with fewer than vc dimensions, dependent on the number of degrees of freedom in the linkage, but the vc -dimensional parameterization is most naturally semialgebraic.)

Returning to the motion-planning framework, the polynomial equations and inequalities are precisely the obstacle surfaces. The configuration space has dimension $k = vc$, and there are $n \leq b^2$ obstacle surfaces where b is the number of bars, each with degree $d = O(1)$. We can factor out the trivial rigid motions by supposing that one bar of the linkage is pinned, reducing k to $(v - 2)c$. Now running the roadmap algorithm produces a representation of the entire configuration space. By path planning within this space, we can solve the reconfiguration problem. By a simple pass through the representation, we can tell whether the space is connected, solving the locked decision problem. By slicing the space with a polynomial specifying that a particular vertex is located at a particular point in the plane, we can solve the reachability problem.

Plugging $k \leq vc$, $n \leq b^2$, and $d = O(1)$ into the roadmap algorithm with deterministic running time $O(n^k (\log n) d^{O(k^4)})$ and randomized expected running time $O(n^k (\log n) d^{O(k^2)})$, we obtain:

COROLLARY 9.5.6 *Roadmap algorithm applied to linkages* [AKRW03]

The reachability, reconfiguration, and locked decision problems can be solved for an arbitrary linkage with v vertices and b bars in $\mathbb{R}^c$ using $O(b^{2vc}(\log b)2^{O(vc)^4})$ deterministic time or $O(b^{2vc}(\log b)2^{O(vc)^2})$ expected randomized time.

9.6 KINEMATICS

According to Bottema and Roth [BR79b], “kinematics is that branch of mechanics which treats the phenomenon of motion without regard to the cause of the motion. In kinematics there is no reference to mass or force; the concern is only with relative positions and their changes.” Kinematics is a subject with a long history and which has had, at various times, notable influence on and has to some extent has been partially identified with such areas as algebraic geometry, differential geometry, mechanics, singularity theory, and Lie theory. It has often been a subject studied from an engineering point of view, and there are many detailed calculations with respect to particular mechanisms of interest. As a representative example, we consider four-bar mechanisms (Figure 9.6.1):

GLOSSARY

Mechanism: A linkage with one degree of freedom, modulo global translation and rotation.

Four-bar mechanism: A four-bar polygonal cycle; see Figure 9.6.1 for an example. Sometimes called a *three-bar mechanism*.

Frame: We generally fix a frame of reference for a mechanism by pinning one bar, fixing its position in the plane. This bar is called the frame. In Figure 9.6.1, bar AB is pinned.

Coupler: A distinguished bar other than the frame. In Figure 9.6.1, we consider the coupler CD .

Coupler motion: The motion of the entire plane induced by the relative motion of the coupler with respect to the frame.

Coupler curve: The path traced during the coupler motion by any point rigidly attached to the coupler (e.g., via two additional bars). Figure 9.6.1 shows the coupler curve of the midpoint E of the coupler bar CD .

FOUR-BAR MECHANISM

Coupler curves can be surprisingly complex. In the generic case, a coupler curve of a four-bar mechanism is an algebraic curve of degree 6. Substantial effort has been put into cataloging the different shapes of coupler curves that can arise from four-bar and other mechanisms. A sample theorem in this context is the following:

THEOREM 9.6.1 *Multiplicity of coupler curves* [Rob75]

Any coupler curve of a four-bar mechanism can be generated by two other four-bar mechanisms.

FIGURE 9.6.1

The coupler curve of the midpoint E of the coupler CD as it moves relative to the frame AB in a four-bar mechanism.

GLOSSARY

Infinitesimal motion or **first-order flex**: The first derivative of a motion at a moment in time, assigning a velocity vector to each point involved in the motion. (See [Chapter 60](#) for a more thorough explanation in the context of rigidity.)

Pole or **instantaneous pole**: The instantaneous fixed point of a first-order motion of the plane. For a rotation, the pole is the center of rotation. For a translation, the pole is a point at infinity in the projective plane. A combination of rotation and translation can be rewritten as a pure rotation.

Polode: The locus of poles over time during a motion of the plane.

POLES

Some of the central theorems in kinematics treat the instantaneous case. Poles characterize the first-order action of a motion at each moment in time. Together, the polode can be viewed relative to either the fixed plane of the frame (the **fixed polode**) or the moving plane of the coupler (**moving polode**). Apart from degenerate cases, a planar motion can be described by the moving polode rolling along the fixed polode. A basic theorem in the context of poles is the following:

THEOREM 9.6.2 *Three-Pole Theorem*

For any three motions of the plane, the instantaneous poles of the three mutual relative motions are collinear at any moment in time.

For some typical examples from an engineering viewpoint, see, e.g., [CP91, Che02, Ler00]. See also Section 59.4 of this Handbook.

9.7 APPLICATIONS

Applications of linkages arise throughout science and engineering. We highlight three modern applications: robotics, manufacturing, and protein folding.

APPLICATIONS IN ENGINEERING

The study of linkages in fact originated in the context of mechanical engineering, e.g., for the purpose of converting circular motion into linear motion. Today, one of the driving applications for linkages is *robotics*, in particular *robotic arms*.

A robotic arm can be modeled as a linkage, typically a polygonal chain. Some robotic arms have hinges that force the bars to remain coplanar, modeled by 2D chains; other arms have universal joints, modeled by 3D chains; other arms pose additional constraints (such as incident bars being coplanar, without the whole linkage necessarily being coplanar), leading to other models of linkage folding. Some planar robotic arms reserve slightly offset planar planes for the bars, modeled by a planar polygonal chain that permits self-intersection. Most other robotic arms are modeled by disallowing self-intersection.

The reachability problem is largely motivated by robotic arms, where the “hand” at one end of the arm must be placed at a particular location, e.g., to pick up an object, but the rest of the configuration is secondary. In other contexts, the entire configuration of the arm is important, and we need to plan a motion to a target configuration, leading to the reconfiguration problem. The locked decision problem is the first question one might ask about the simplicity/complexity of motion planning for a particular type of linkage. However, all of these problems are typically studied in the context of linkages without obstacles, yet in robotics there are almost always obstacles. Some obstacles, such as a halfplane representing the floor, can often be avoided; but more generally the problems become much more complicated. See [Chapter 47](#).

Another area with linkage applications is *manufacturing*. Given a straight hydraulic tube or piece of wire, a typical goal is to produce a desired folded configuration. In these contexts, we want to bend the wire as little as possible. In particular, a typical constraint is to bend the wire only monotonically: once it is bent one way, it cannot be bent the other way. This constraint forces straight segments of the target shape to remain straight throughout the motion. Thus, the problem can be modeled as straightening a polygonal chain, either in 2D or 3D depending on the application, with additional constraints. For example, the expansive motions described in Section 9.3 fold all joints monotonically; however, their reliance on bending most joints simultaneously may be undesirable. Arkin et al. [AFMS01] consider the restriction in which only a single joint can be rotated at once, together with additional realistic constraints arising in wire bending.

APPLICATIONS IN BIOLOGY

A crude model of a protein backbone is a polygonal chain in 3D, and a similarly crude model of an entire protein is a polygonal tree in 3D. In both cases, the

vertices represent atoms, and the bars represent bonds between atoms (which in reality stay roughly the same length). In proteins, these bar/bond lengths are typically all within a factor of 2 of each other. Two atoms cannot occupy the same space, which can be roughly modeled by disallowing self-intersection. One interesting open problem in this context is the following:

PROBLEM 9.7.1 *Equilateral or near-equilateral locked linkages* [BDD⁺01]

Is there a locked equilateral arc, cycle, or tree in 3D? More generally, what is the smallest value of $\alpha \geq 1$ for which there is a locked arc/cycle/tree in 3D with all edge lengths between 1 and α ?

These crude models may lead to some biological insight, but they do not capture several aspects of real protein folding.

One aspect that can easily be incorporated into linkage folding is that the angles between incident bars is typically fixed. This *fixed-angle constraint* can alternatively be viewed as adding bars between vertices originally at distance two from each another. Soss et al. [Sos01, SEO03, ST00] initiated the study of such fixed-angle linkages in computational geometry, in particular establishing the NP-hardness of deciding reconfigurability or flattenability. Aloupis et al. [ADD⁺02, ADM⁺02] consider when fixed-angle linkages are not locked in the sense that all flat states are reachable from each other by motions avoiding self-intersection.

A more challenging aspect of protein folding is the *thermodynamic hypothesis* [Anf73]: that folding is encouraged to follow energy-minimizing pathways. Indeed, the bars are not strictly binding, nor are they completely fixed in length; they are merely encouraged to do so, and sometimes violate these constraints. Unfortunately, these properties are difficult to model, and the energy functions defined so far are either incomplete or difficult to manipulate. Also, the implications for linkage-folding problems remain unclear.

One particularly simple energy-based model of protein folding that has received substantial attention in computer science and biology is the HP (Hydrophilic-Hydrophobic) model; see, e.g., [ABD⁺, CD93, Dil90, Hay98]. This model is particularly discrete, modeling a protein as an equilateral chain on a lattice, typically a square or cubic grid, but possibly also a triangular or tetrahedral lattice. The model captures only hydrophobic bonds and forces, clustering to avoid external water. Finding the optimal folding even in this simple model is NP-complete [BL98, CGP⁺98], though there are several constant-factor approximation algorithms [HI96, New02, ABD⁺97]. One interesting open problem is whether designing a protein to fold into a particular shape is easier than finding the shape to which a particular protein folds [ABD⁺]:

PROBLEM 9.7.2 *HP protein design* [ABD⁺]

What is the complexity of deciding whether a given subset of the lattice is an optimal folding of some HP protein, and, if so, finding such a protein? What if it must be the unique optimal folding of the HP protein?

A result related to the second half of this problem is that arbitrarily long HP proteins with unique optimal foldings exist, at least for open and closed chains in a 2D square grid [ABD⁺].

10 GEOMETRIC GRAPH THEORY

János Pach

INTRODUCTION

In the traditional areas of graph theory (Ramsey theory, extremal graph theory, random graphs, etc.), graphs are regarded as abstract binary relations. The relevant methods are often incapable of providing satisfactory answers to questions arising in geometric applications. Geometric graph theory focuses on combinatorial and geometric properties of graphs drawn in the plane by straight-line edges (or, more generally, by edges represented by simple Jordan arcs). It is a fairly new discipline abounding in open problems, but it has already yielded some striking results that have proved instrumental in the solution of several basic problems in combinatorial and computational geometry (including the k -set problem and metric questions discussed in Sections 1.1 and 1.2, respectively, of this Handbook). This chapter is partitioned into extremal problems (Section 10.1), crossing numbers (Section 10.2), and generalizations (Section 10.3).

10.1 EXTREMAL PROBLEMS

Turán's classical theorem [Tur54] determines the maximum number of edges that an abstract graph with n vertices can have without containing, as a subgraph, a complete graph with k vertices. In the spirit of this result, one can raise the following general question. Given a class $\mathcal{H}$ of so-called *forbidden geometric subgraphs*, what is the maximum number of edges that a geometric graph of n vertices can have without containing a geometric subgraph belonging to $\mathcal{H}$? Similarly, Ramsey's theorem [Ram30] for abstract graphs has some natural analogues for geometric graphs. In this section we will be concerned mainly with problems of these two types.

GLOSSARY

Geometric graph: A graph drawn in the plane by (possibly crossing) straight-line segments; i.e., a pair $(V(G), E(G))$, where $V(G)$ is a set of points ('vertices'), no three of which are collinear, and $E(G)$ is a set of segments ('edges') whose endpoints belong to $V(G)$.

Convex geometric graph: A geometric graph whose vertices are in *convex position*; i.e., they form the vertex set of a convex polygon.

Cyclic chromatic number of a convex geometric graph: The minimum number $\chi_c(G)$ of colors needed to color all vertices of G so that each color class consists of consecutive vertices along the boundary of the convex hull of the vertex set.

Convex matching: A convex geometric graph consisting of disjoint edges, each of which belongs to the boundary of the convex hull of its vertex set.

- Parallel matching:** A convex geometric graph consisting of disjoint edges, the convex hull of whose vertex set contains only two of the vertices on its boundary.
- Complete geometric graph:** A geometric graph G whose edge set consists of all $\binom{|V(G)|}{2}$ segments between its vertices.
- Complete bipartite geometric graph:** A geometric graph G with $V(G) = V_1 \cup V_2$, whose edge set consists of all segments between V_1 and V_2 .
- Geometric subgraph of G :** A geometric graph H , for which $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$.
- Crossing:** A common interior point of two edges of a geometric graph.
- (k, l) -grid:** $k + l$ vertex-disjoint edges in a geometric graph such that each of the first k edges crosses all of the last l edges.
- Disjoint edges:** Edges of a geometric graph that do not cross and do not even share an endpoint.
- Parallel edges:** Edges of a geometric graph whose supporting lines are parallel or intersect at points not belonging to any of the edges (including their endpoints).
- x -monotone curve:** A continuous curve that intersects every vertical line in at most one point.
- Outerplanar graph:** A (planar) graph that can be drawn in the plane without crossing so that all points representing its vertices lie on the outer face of the resulting subdivision of the plane. A **maximal outerplanar graph** is a triangulated cycle.
- Hamiltonian path:** A path going through all elements of a finite set S . If the elements of S are colored by two colors, and no two adjacent elements of the path have the same color, then it is called an *alternating* path.
- Hamiltonian cycle:** A cycle going through all elements of a finite set S .
- Caterpillar:** A tree consisting of a path P and of some extra edges, each of which is adjacent to a vertex of P .

CROSSING-FREE GEOMETRIC GRAPHS

1. Hanani's theorem: Any graph that can be drawn in the plane so that its edges are represented by simple Jordan arcs any two of which either share an endpoint or properly cross an even number of times is planar [Cho34].
2. Fáry's theorem: Every planar graph admits a crossing-free straight-line drawing [Fár48, Tut60, Ste22]. Moreover, every 3-connected planar graph and its dual have simultaneous straight-line drawings in the plane such that only dual pairs of edges cross and every such pair is perpendicular [BS93].
3. Koebe's theorem: The vertices of every planar graph can be represented by nonoverlapping disks in the plane such that two of them are tangent to each other if and only if the corresponding two vertices are adjacent [Koe36, Thu78]. This immediately implies Fáry's theorem.
4. Pach-Tóth theorem: Any graph that can be drawn in the plane so that its edges are represented by x -monotone curves with the property that any two of them either share an endpoint or properly cross an even number of times admits a crossing-free straight-line drawing, in which the x -coordinates of the vertices remain the same [PT03].

5. Grid drawings of planar graphs: Every planar graph of n vertices admits a straight-line drawing such that the vertices are represented by points belonging to an $(n-1) \times (n-1)$ grid [dFPP90, Sch90]. Furthermore, such a drawing can be found in $O(n)$ time.
6. Straight-line drawings of outerplanar graphs: For any outerplanar graph H with n vertices and for any set P of n points in the plane in general position, there is a crossing-free geometric graph G with $V(G) = P$, whose underlying graph is isomorphic to H [GMPP91]. For any rooted tree T and for any set P of $|V(T)|$ points in the plane in general position with a specified element $p \in P$, there is a crossing-free straight-line drawing of T such that every vertex of T is represented by an element of P and the root is represented by p [IPTT94]. This theorem generalizes to any *pair* of rooted trees, T_1 and T_2 : for any set P of $n = |V(T_1)| + |V(T_2)|$ points in general position in the plane, there is a crossing-free mapping of $T_1 \cup T_2$ that takes the roots to arbitrarily prespecified elements of P . Such a mapping can be found in $O(n^2 \log n)$ time [KK00]. The analogous statement for *triples* of trees is false.
7. Alternating paths: Given n red points and n blue points in general position in the plane, separated by a straight line, they always admit a noncrossing alternating Hamiltonian path [KK03].

TURÁN-TYPE PROBLEMS

By Euler's Polyhedral Formula, if a geometric graph G with $n \geq 3$ vertices has no 2 crossing edges, it cannot have more than $3n - 6$ edges. It was shown in [AAP⁺97] that under the weaker condition that no 3 edges are *pairwise crossing*, the number of edges of G is still $O(n)$. It is not known whether this statement remains true even if we assume only that no 4 edges are pairwise crossing. As for the analogous problem when the forbidden configuration consists of k pairwise *disjoint edges*, the answer is linear for every k [PT94]. In particular, for $k = 2$, the number of edges of G cannot exceed the number of vertices [HP34]. The best lower and upper bounds known for the number of edges of a geometric graph with n vertices, containing no *forbidden* geometric subgraph of a certain type, are summarized in Table 10.1.1. The letter k always stands for a *fixed* positive integer parameter and n tends to infinity. Wherever k does not appear in the asymptotic bounds, it is hidden in the constants involved in the O - and Ω -notations.

Better results are known for *convex* geometric graphs, i.e., when the vertices are in convex position. The relevant bounds are listed in Table 10.1.2. For any convex geometric graph G , let $\chi_c(G)$ denote its *cyclic chromatic number*. Furthermore, let $\text{ex}(n, K_k)$ stand for the maximum number of edges of a graph with n vertices that does not have a complete subgraph with k vertices. By Turán's theorem [Tur54] mentioned above, $\text{ex}(n, K_k) = \frac{k-2}{k-1} \binom{n}{2} + O(n)$ is equal to the number of edges of a complete $(k-1)$ -partite graph with n vertices whose vertex classes are of size $\lfloor n/(k-1) \rfloor$ or $\lceil n/(k-1) \rceil$. Two disjoint self-intersecting paths of length 3, $xyvz$ and $x'y'v'z'$, in a convex geometric graph are said to be of the *same orientation* if the cyclic order of their vertices is $x, v, x', v', y', z', y, z$ ($\bowtie$). They are said to have *opposite orientations* if the cyclic order of their vertices is $x, v, v', x', z', y', y, z$ (*type 1*: $\bowtie$) or $v, x, x', v', y', z', z, y$ (*type 2*: $\bowtie$).

noncrossing caterpillar C of k vertices	$\lfloor (k-2)n/2 \rfloor$	$\lfloor (k-2)n/2 \rfloor$	Perles [BKV03]

RAMSEY-TYPE PROBLEMS

In classical Ramsey theory, one wants to find large monochromatic subgraphs in a complete graph whose edges are colored with several colors [GRS90]. Most questions of this type can be generalized to complete geometric graphs, where the monochromatic subgraphs are required to satisfy certain geometric conditions.

1. Károlyi-Pach-Tóth theorem [KPT97]: If the edges of a finite complete geometric graph are colored by two colors, there exists a noncrossing spanning tree, all of whose edges are of the same color. (This statement was conjectured by Bialostocki and Dierker [BV]. The analogous assertion for abstract graphs follows from the fact that any graph or its complement is connected.)
2. Geometric Ramsey numbers: Let $\mathcal{G}_1, \dots, \mathcal{G}_k$ be not necessarily different classes of geometric graphs. Let $R(\mathcal{G}_1, \dots, \mathcal{G}_k)$ denote the smallest positive number R with the property that any complete geometric graph of R vertices whose edges are colored with k colors ($1, \dots, k$, say) contains, for some i , an i -colored subgraph belonging to $\mathcal{G}_i$. If $\mathcal{G}_1 = \dots = \mathcal{G}_k = \mathcal{G}$, we write $R(\mathcal{G}; k)$ instead of $R(\mathcal{G}_1, \dots, \mathcal{G}_k)$. If $k = 2$, for the sake of simplicity, let $R(\mathcal{G})$ stand for $R(\mathcal{G}; 2)$. Some known results on the numbers $R(\mathcal{G}_1, \mathcal{G}_2)$ are listed in Table 10.1.3. In line 3 of the table, we have a better result if we restrict our attention to *convex* geometric graphs: For any 2-coloring of the edges of a complete convex geometric graph with $2k - 1$ vertices, there exists a noncrossing monochromatic path of length $k \geq 2$, and this result cannot be improved. The bounds in line 4 also hold when $\mathcal{G}_1 = \mathcal{G}_2$ consists of all noncrossing cycles of length k , triangulated from one of their vertices. The geometric Ramsey numbers of convex geometric graphs, when $\mathcal{G}_1 = \mathcal{G}_2$ consists of all isomorphic copies of a given convex geometric graph with at most 4 vertices, can be found in [BH96].

TABLE 10.1.3 Geometric Ramsey numbers $R(\mathcal{G}_1, \mathcal{G}_2)$ from [KPT97] and [KPTV98].

$\mathcal{G}_1$	$\mathcal{G}_2$	LOWER BOUND	UPPER BOUND
all noncrossing trees of k vertices	all noncrossing trees of k vertices	k	k
k disjoint edges	l disjoint edges	$k + l + \max\{k, l\} - 1$	$k + l + \max\{k, l\} - 1$
noncrossing paths of length k	noncrossing paths of length k	$\Omega(k)$	$O(k^{3/2})$
noncrossing cycles of length k	noncrossing cycles of length k	$(k - 1)^2$	$2(k - 1)(k - 2) + 2$

3. Pairwise disjoint copies: For any positive integer k , let $k\mathcal{G}$ denote the class of all geometric graphs that can be obtained by taking the union of k pairwise disjoint members of $\mathcal{G}$. If k is a power of 2 then

$$R(k\mathcal{G}) \leq (R(\mathcal{G}) + 1)k - 1.$$

In particular, if $\mathcal{G} = \mathcal{T}$ is the class of triangles, we have $R(\mathcal{T}) = 6$. Thus, the above bound yields that

$$R(k\mathcal{T}) \leq 7k - 1,$$

provided that k is a power of 2. This result cannot be improved [KPTV98].

Furthermore, for any $k > 0$, we have

$$R(k\mathcal{G}) \leq \left\lceil \frac{3(R(\mathcal{G}) + 1)}{2} \right\rceil k - \left\lceil \frac{R(\mathcal{G}) + 1}{2} \right\rceil.$$

For the corresponding quantities for convex geometric graphs, we have

$$R_c(k\mathcal{G}) \leq (R_c(\mathcal{G}) + 1)k - 1.$$

4. Constructive vertex- and edge-Ramsey numbers: Given a class of geometric graphs $\mathcal{G}$, let $R_v(\mathcal{G})$ denote the smallest number R such that *there exists* a (complete) geometric graph of R vertices that, for any 2-coloring of its edges, has a monochromatic subgraph belonging to $\mathcal{G}$. Similarly, let $R_e(\mathcal{G})$ denote the minimum number of *edges* of a geometric graph with this property. $R_v(\mathcal{G})$ and $R_e(\mathcal{G})$ are called the **vertex-** and **edge-Ramsey number** of $\mathcal{G}$, respectively. Clearly, we have

$$R_v(\mathcal{G}) \leq R(\mathcal{G}), \quad R_e(\mathcal{G}) \leq \binom{R(\mathcal{G})}{2}.$$

(For abstract graphs, similar notions are discussed in [EFRS78, Bec83].)

For $\mathcal{P}_k$, the class of noncrossing paths of length k , we have $R_v(\mathcal{P}_k) = O(k^{3/2})$ and $R_e(\mathcal{P}_k) = O(k^2)$.

OPEN PROBLEMS

1. What is the smallest number $u = u(n)$ such that there exists a “universal” set U of u points in the plane with the property that every planar graph of n vertices admits a noncrossing straight-line drawing on a suitable subset of U [dFPP90]? It follows from the existence of a small grid drawing (see above) that $u(n) \leq n^2$. From below we have only $u(n) > 1.01n$.

2. Can the vertices of every planar graph G be represented by straight-line segments in the plane so that two segments intersect if and only if the corresponding vertices are adjacent? The answer is known to be in the affirmative if the chromatic number of G is 2 [dFdMP94] or 3 (de Fraysseix-de Mendez).
3. (Erdős, Kaneko-Kano) What is the largest number $A = A(n)$ such that any set of n red and n blue points in the plane admits a noncrossing alternating path of length A ? It is known that $A(n) \leq (4/3 + o(1))n$.
4. Is it true that, for any fixed k , the maximum number of edges of a geometric graph with n vertices that does not have k pairwise crossing edges is $O(n)$?
5. (Aronov et al.) Is it true that any complete geometric graph with n vertices has at least $\Omega(n)$ pairwise crossing edges? It was shown in [AEG⁺94] that one can always find $\sqrt{n/12}$ pairwise crossing edges. On the other hand, any complete geometric graph with n vertices has a noncrossing Hamiltonian path, hence $\lfloor n/2 \rfloor$ pairwise disjoint edges.
6. (Larman-Matoušek-Pach-Töröcsik) What is the smallest positive number $r = r(n)$ such that any family of r closed segments in general position in the plane has n members that are either pairwise disjoint or pairwise crossing? It is known [LMPT94, KPT97] that $n^{\log 5 / \log 2} \approx n^{2.322} \leq r(n) \leq n^5$.

10.2 CROSSING NUMBERS

The investigation of crossing numbers started during WWII with Turán's Brick Factory Problem [Tur77]: how should one redesign the routes of railroad tracks between several kilns and storage places in a brick factory so as to minimize the number of crossings? In the early 1980s, it turned out that the chip area required for the realization (VLSI layout) of an electrical circuit is closely related to the crossing number of the underlying graph [Lei83]. This discovery gave an impetus to research in the subject. More recently, it has been realized that general bounds on crossing numbers can be used to solve a large variety of problems in discrete and computational geometry.

GLOSSARY

Drawing of a graph: A representation of the graph in the plane such that its vertices are represented by distinct points and its edges by simple continuous arcs connecting the corresponding point pairs. In a drawing (a) no edge passes through any vertex other than its endpoints, (b) no two edges touch each other (i.e., if two edges have a common interior point, then at this point they properly cross each other), and (c) no three edges cross at the same point.

Crossing: A common interior point of two edges in a graph drawing. Two edges may have several crossings.

Crossing number of a graph: The smallest number of crossings in any drawing of G , denoted by $\text{CR}(G)$. Clearly, $\text{CR}(G) = 0$ if and only if G is planar.

Rectilinear crossing number: The minimum number of crossings in a drawing of G in which every edge is represented by a straight-line segment. It is denoted by $\text{LIN-CR}(G)$.

Pairwise crossing number: The minimum number of crossing pairs of edges over all drawings of G , denoted by $\text{PAIR-CR}(G)$. (Here the edges can be represented by arbitrary continuous curves, so that two edges may cross more than once, but every pair of edges can contribute at most one to $\text{PAIR-CR}(G)$.)

Odd crossing number: The minimum number of those pairs of edges that cross an odd number of times, over all drawings of G . It is denoted by $\text{ODD-CR}(G)$.

Biplanar crossing number: The minimum of $\text{CR}(G_1) + \text{CR}(G_2)$ over all partitions of the graph into two edge-disjoint subgraphs G_1 and G_2 .

Bisection width: The minimum number $b(G)$ of edges whose removal splits the graph G into two roughly equal subgraphs. More precisely, $b(G)$ is the minimum number of edges running between V_1 and V_2 over all partitions of the vertex set of G into two disjoint parts $V_1 \cup V_2$ such that $|V_1|, |V_2| \geq |V(G)|/3$.

Cut width: The minimum number $c(G)$ such that there is a drawing of G in which no two vertices have the same x -coordinate and every vertical line crosses at most $c(G)$ edges.

Path width: The minimum number $p(G)$ such that there is a sequence of at most $(p(G) + 1)$ -element sets $V_1, V_2, \dots, V_r \subseteq V(G)$ with the property that both endpoints of every edge belong to some V_i and, if a vertex occurs in V_i and V_k ($i < k$), then it also belongs to every V_j , $i < j < k$.

GENERAL ESTIMATES

Garey and Johnson [GJ83] showed that the determination of the crossing number is an *NP-complete* problem. Analogous results hold for the rectilinear crossing number [Bie91], for the pair crossing number [SSŠ02], and for the odd crossing number [PT00b]. The exact determination of crossing numbers of relatively small graphs of a simple structure (such as complete or complete bipartite graphs) is a hopelessly difficult task, but there are several useful bounds. There is an algorithm [EGS03] for computing a drawing of a bounded-degree graph with n vertices, for which n plus the number of crossings is $O(\log^3 n)$ times the optimum.

1. For a simple graph G with $n \geq 3$ vertices and e edges, $\text{CR}(G) \geq e - 3n + 6$. From this inequality, a simple probabilistic argument shows that $\text{CR}(G) \geq ce^3/n^2$, for a suitable positive constant c . This important bound, due to Ajtai-Chvátal-Newborn-Szemerédi [ACNS82] and, independently, to Leighton [Lei83], is often referred to as the **crossing lemma**. We know that $0.03 \leq c \leq 0.09$ [PT97, PRTT04]. The lower bound follows from line 6 in [Table 10.1.1](#). Similar statements hold for $\text{PAIR-CR}(G)$ and $\text{ODD-CR}(G)$ [PT00b].
2. Crossing lemma for multigraphs [Szé97]: Let G be a **multigraph** with n vertices and e edges, i.e., the same pair of vertices can be connected by more than one edge. Let m denote the maximum multiplicity of an edge. Then

$$\text{CR}(G) \geq c \frac{e^3}{mn^2} - m^2n,$$

where c denotes the same constant as in the previous paragraph.

3. Midrange crossing constant: Let $\kappa(n, e)$ denote the minimum crossing number of a graph G with n vertices and at least e edges. That is,

$$\kappa(n, e) = \min_{\substack{n(G) = n \\ e(G) \geq e}} \text{CR}(G).$$

It follows from the crossing lemma that, for $e \geq 4n$, $\kappa(n, e)n^2/e^3$ is bounded from below and from above by two positive constants. Erdős and Guy [EG73] conjectured that if $e \gg n$ then $\lim_{n \rightarrow \infty} \kappa(n, e)n^2/e^3$ exists. (We use the notation $f(n) \gg g(n)$ to mean that $\lim_{n \rightarrow \infty} f(n)/g(n) = \infty$.) This was partially settled in [PST00]: if $n \ll e \ll n^2$, then

$$\lim_{n \rightarrow \infty} \kappa(n, e) \frac{n^2}{e^3} = C > 0$$

exists. Moreover, the same result is true with the same constant C , for drawings on every other orientable surface.

4. Graphs with monotone properties: A graph property $\mathcal{P}$ is said to be **monotone** if (i) for any graph G satisfying $\mathcal{P}$, every subgraph of G also satisfies $\mathcal{P}$; and (ii) if G_1 and G_2 satisfy $\mathcal{P}$, then their disjoint union also satisfies $\mathcal{P}$. For any monotone property $\mathcal{P}$, let $\text{ex}(n, \mathcal{P})$ denote the maximum number of edges that a graph of n vertices can have if it satisfies $\mathcal{P}$. In the special case when $\mathcal{P}$ is the property that the graph does not contain a subgraph isomorphic to a fixed forbidden subgraph H , we write $\text{ex}(n, H)$ for $\text{ex}(n, \mathcal{P})$.

Let $\mathcal{P}$ be a monotone graph property with $\text{ex}(n, \mathcal{P}) = O(n^{1+\alpha})$ for some $\alpha > 0$. In [PST00], it was proved that there exist two constants $c, c' > 0$ such that the crossing number of any graph G with property $\mathcal{P}$ that has n vertices and $e \geq cn \log^2 n$ edges satisfies

$$\text{CR}(G) \geq c' \frac{e^{2+1/\alpha}}{n^{1+1/\alpha}}.$$

This bound is asymptotically tight, up to a constant factor. In particular, if $e > 4n$ and G has no cycle of length at most $2r$, then the crossing number of G satisfies

$$\text{CR}(G) \geq c_r \frac{e^{r+2}}{n^{r+1}},$$

where $c_r > 0$ is a suitable constant. For $r = 2, 3$, and 5 , these bounds are asymptotically tight, up to a constant factor. If G does not contain a complete bipartite subgraph $K_{r,s}$ with r and s vertices in its classes, $s \geq r$, then we have

$$\text{CR}(G) \geq c_{r,s} \frac{e^{3+1/(r-1)}}{n^{2+1/(r-1)}},$$

where $c_{r,s} > 0$ is a suitable constant. These bounds are tight up to a constant factor if $r = 2, 3$, or if r is arbitrary and $s > (r-1)!$.

5. Crossing number vs. bisection width $b(G)$: For any vertex $v \in V(G)$, let $d(v)$ denote the degree of v in G . It was shown in [PSS96] and [SV94] that

$$\text{CR}(G) + \frac{1}{16} \sum_{v \in V(G)} d^2(v) \geq \frac{1}{40} b^2(G).$$

A similar statement holds with a worse constant for the cut width $c(G)$ of G [DV02]. This, in turn, implies that the same is true for $p(G)$, the path width of G , as we have $p(G) \leq c(G)$ for every G [Kin92].

6. Relations between different crossing numbers: Clearly, we have

$$\text{ODD-CR}(G) \leq \text{PAIR-CR}(G) \leq \text{CR}(G) \leq \text{LIN-CR}(G).$$

It was shown [BD93] that there are graphs with crossing number 4 whose rectilinear crossing numbers are arbitrarily large. On the other hand, we cannot rule out the possibility that

$$\text{ODD-CR}(G) = \text{PAIR-CR}(G) = \text{CR}(G)$$

for every graph G . It was established in [PT00b] that

$$\text{CR}(G) \leq 2 (\text{ODD-CR}(G))^2.$$

Recently, Kolman and Matoušek found a slightly better upper bound on $\text{CR}(G)$, in terms of $\text{PAIR-CR}(G)$.

7. Crossing numbers of random graphs: Let $G = G(n, p)$ be a **random graph** with n vertices, whose edges are chosen independently with probability $p = p(n)$. Let e denote the *expected number* of edges of G , i.e., $e = p \cdot \binom{n}{2}$. It is not hard to see that if $e > 10n$, then almost surely $b(G) \geq e/10$. It therefore follows from the above relation between the crossing number and the bisection width that almost surely we have $\text{LIN-CR}(G) \geq \text{CR}(G) \geq e^2/4000$. Evidently, the order of magnitude of this bound cannot be improved. A similar inequality was proved in [ST02] for the pairwise crossing number, under the stronger condition that $e > n^{1+\epsilon}$ for some $\epsilon > 0$.
8. Biplanar crossing number vs. crossing number: It is known [SSV] that the biplanar crossing number of every graph is at most $3/8$ times its crossing number. The best value of the constant may be as small as $7/24$.
9. Harary-Kainen-Schwenk conjecture [HKS73]: For every $n \geq m \geq 3$ and cycles C_n and C_m , $\text{CR}(C_n \times C_m)$ is equal to $n(m-2)$. This was proved in [GS] for every m and for all sufficiently large n . For the crossing number of the skeleton of the n -dimensional hypercube Q_n , we have $1/20 + o(1) \leq \text{CR}(Q_n)/4^n \leq 163/1024$ [FdF00, SV93].

OPEN PROBLEMS

1. Is it true that $\text{ODD-CR}(G) = \text{PAIR-CR}(G) = \text{CR}(G)$ for every graph G ?
2. Zarankiewicz's conjecture [Guy69]: The crossing number of the complete bipartite graph $K_{n,m}$ with n and m vertices in its classes satisfies

$$\text{CR}(K_{n,m}) = \left\lfloor \frac{m}{2} \right\rfloor \cdot \left\lfloor \frac{m-1}{2} \right\rfloor \cdot \left\lfloor \frac{n}{2} \right\rfloor \cdot \left\lfloor \frac{n-1}{2} \right\rfloor.$$

Kleitman [Kle70] verified this conjecture in the special case when $\min\{m, n\} \leq 6$ and Woodall [Woo93] for $m = 7$, $n \leq 10$.

It is also conjectured that the crossing number of the complete graph K_n satisfies

$$\text{CR}(K_n) = \frac{1}{4} \left\lfloor \frac{n}{2} \right\rfloor \cdot \left\lfloor \frac{n-1}{2} \right\rfloor \cdot \left\lfloor \frac{n-2}{2} \right\rfloor \cdot \left\lfloor \frac{n-3}{2} \right\rfloor.$$

FIGURE 10.2.1

Complete bipartite graph $K_{5,6}$ with 24 crossings.

3. Rectilinear crossing numbers of complete graphs: Determine the value

$$\kappa = \lim_{n \rightarrow \infty} \frac{\text{LIN-CR}(K_n)}{\binom{n}{4}}.$$

The best known bounds $3/8 = 0.375 < \kappa \leq 0.381$ are due to Lovász-Vesztergombi-Wagner-Welzl and Ábrego-Fernández and to Aichholzer et al. [AAK01], resp. The known exact values of $\text{LIN-CR}(G)$ are listed in Table 10.2.1 [BDG01].

TABLE 10.2.1

4	0
5	1
6	3
7	9
8	19
9	36
10	62
11	102
12	153

4. Let $G = G(n, p)$ be a *random* graph with n vertices, whose edges are chosen independently with probability $p = p(n)$. Let $e = p \cdot \binom{n}{2}$. Is it true that the pairwise crossing number, the odd crossing number, and the biplanar crossing number are bounded from below by a constant times e^2 , provided that $e \gg n$?

10.3 GENERALIZATIONS

The concept of geometric graph can be generalized in two natural directions. Instead of straight-line drawings, we can consider curvilinear drawings. If we put them at the focus of our investigations and we wish to emphasize that they are objects of independent interest rather than planar representations of abstract graphs, we call these drawings *topological graphs*. In this sense, the results in the previous section about crossing numbers belong to the theory of topological graphs. Instead of systems of segments induced by a planar point set, we can also consider systems of simplices in the plane or in higher-dimensional spaces. Such a system is called a *geometric hypergraph*.

GLOSSARY

Topological graph: A graph drawn in the plane so that its vertices are distinct points and its edges are simple continuous arcs connecting the corresponding vertices. In a topological graph (a) no edge passes through any vertex other than its endpoints, (b) any two edges have only a finite number of interior points in common, at which they properly cross each other, and (c) no three edges cross at the same point. (Same as *drawing of a graph*.)

Weakly isomorphic topological graphs: Two topological graphs, G and H , such that there is an incidence-preserving one-to-one correspondence between $(V(G), E(G))$ and $(V(H), E(H))$ in which two edges of G intersect if and only if the corresponding edges of H do.

Thrackle: A topological graph in which any two nonadjacent edges cross precisely once and no two adjacent edges cross.

Generalized thrackle: A topological graph in which any two nonadjacent edges cross an odd number of times and any two adjacent edges cross an even number of times (not counting their common endpoint).

d -dimensional geometric r -hypergraph H_r^d : A pair (V, E) , where V is a set of points in general position in d -space, and E is a set of *closed* $(r-1)$ -dimensional simplices induced by some r -tuples of V . The sets V and E are called the *vertex set* and *(hyper)edge set* of H_r^d , respectively. Clearly, a geometric graph is a 2-dimensional geometric 2-hypergraph.

Forbidden geometric hypergraphs: A class $\mathcal{F}$ of geometric hypergraphs not permitted to be contained in the geometric hypergraphs under consideration. Given a class $\mathcal{F}$ of forbidden geometric hypergraphs, $\text{ex}_r^d(\mathcal{F}, n)$ denotes the maximum number of edges that a d -dimensional geometric r -hypergraph H_r^d of n vertices can have without containing a geometric subhypergraph belonging to $\mathcal{F}$.

Nontrivial intersection: k simplices are said to have a nontrivial intersection if their relative interiors have a point in common.

Crossing of k simplices: A common point of the relative interiors of k simplices, all of whose vertices are *distinct*. The simplices are called *crossing simplices* if such a point exists. A set of simplices may be *pairwise crossing* but not necessarily crossing. If we want to emphasize that they *all* cross, we say that they cross in the *strong sense* or, in brief, that they *strongly cross*.

TOPOLOGICAL GRAPHS

The fairly extensive literature on topological graphs focuses on very few special questions, and there is no standard terminology. Most of the methods developed for the study of geometric graphs break down for topological graphs, unless we make some further structural assumptions. For example, many arguments go through for x -monotone drawings such that any two edges cross at most once. Sometimes it is sufficient to assume the latter condition.

1. An Erdős-Szekeres type theorem: A classical theorem of Erdős and Szekeres states that every complete geometric graph with n vertices has a complete geometric subgraph, weakly isomorphic to a convex complete graph C_m with $m \geq c \log n$ vertices. For complete *topological* graphs with n vertices, any two

of whose edges cross at most once, one can prove the existence of a complete topological subgraph with $m \geq c \log^{1/8} n$ vertices that is weakly isomorphic either to a convex complete graph C_m or to a so-called *twisted* complete graph T_m , as depicted in Figure 10.3.1 [PT01].

FIGURE 10.3.1

The twisted drawing T_m discovered by Harborth and Mengersen [HM92].

2. Every topological complete graph with n vertices, any two of whose edges cross at most once, has a noncrossing subgraph isomorphic to any given tree T with at most $c \log^{1/6} n$ vertices. In particular, it contains a noncrossing path with at least $c \log^{1/6} n$ vertices [PT01].
3. Number of topological complete graphs: Let $\overline{\Phi}(n)$, $\Phi(n)$, and $\Phi_d(n)$ denote the number of different (i.e., pairwise weakly nonisomorphic) geometric complete graphs, topological complete graphs, and topological complete graphs in which every pair of edges cross at most d times, resp. We have $\log \overline{\Phi}(n) = \Theta(n \log n)$, $\log \Phi(n) = \Theta(n^4)$, $\Omega(n^2) \leq \log \Phi_1(n) \leq O(n^2 \log n)$, and $\Omega(n^2 \log n) \leq \log \Phi_d(n) \leq o(n^4)$ for every $d \geq 2$ (Pach-Tóth).
4. Reducing the number of crossings [PT02, ŠS01]: Given an abstract graph $G = (V, E)$ and a set of pairs of edges $P \subseteq \binom{E}{2}$, we say that a topological graph K is a **weak realization** of G if no pair of edges not belonging to P cross each other. If G has a weak realization, then it also has a weak realization in which every edge crosses at most $2^{|E|}$ other edges. There is an almost matching lower bound for this quantity [KM91].
5. Every cycle of length different from 4 can be drawn as a thrackle [Woo71]. A bipartite graph can be drawn in the plane as a generalized thrackle if and only if it is planar [LPS97]. Every generalized thrackle with $n > 2$ vertices has at most $2n - 2$ edges, and this bound is sharp [CN00].

FIGURE 10.3.2

Cycles C_5 and C_{10} drawn as thrackles.

GEOMETRIC HYPERGRAPHS

If we want to generalize the results in the first two sections to higher dimensional geometric hypergraphs, we face some unexpected difficulties. Even if we restrict our attention to systems of triangles induced by 3-dimensional point sets in general

position, it is not completely clear how a “crossing” should be defined. If two segments cross, they do not share an endpoint. Should this remain true for triangles? In this subsection, we describe some scattered results in this direction, but it will require further research to identify the key notions and problems.

1. Let $\mathcal{D}_k^r$ denote the class of all geometric r -hypergraphs consisting of k pairwise disjoint edges (closed $(r-1)$ -dimensional simplices). Let $\mathcal{I}_k^r$ (respectively, $\mathcal{SI}_k^r$) denote the class of all geometric r -hypergraphs consisting of k simplices, any two of which have a nontrivial intersection (respectively, all of which are strongly intersecting). Similarly, let $\mathcal{C}_k^r$ (respectively, $\mathcal{SC}_k^r$) denote the class of all geometric r -hypergraphs consisting of k pairwise crossing (respectively, strongly crossing) edges. In Table 10.3.1, we summarize the known estimates on $\text{ex}_r^d(\mathcal{F}, n)$, the maximum number of hyperedges (or, simply, edges) that a d -dimensional geometric r -hypergraph of n vertices can have without containing any forbidden subconfiguration belonging to $\mathcal{F}$. We assume $d \geq 3$. In the first line of the table, the lower bound is conjectured to be tight. The upper bounds in the second line are tight for $d = 2, 3$.

TABLE 10.3.1 Estimates on $\text{ex}_r^d(\mathcal{F}, n)$, the maximum number of edges of a d -dimensional geometric r -hypergraph of n vertices containing no forbidden subconfigurations belonging to $\mathcal{F}$.

r	$\mathcal{F}$	LOWER BOUND	UPPER BOUND	SOURCE
d	$\mathcal{D}_k^d$	$\Omega(n^{d-1})$	$n^{d-(1/k)^{d-1}}$	[AA89]
d	$\mathcal{I}_k^d (k = 2, 3)$	?	$O(n^{d-1})$	[DP98]
d	$\mathcal{I}_k^d (k > 3)$	?	$O(n^{d-1} \log n)$	[Val98]
d	$\mathcal{C}_2^d$	$\Omega(n^{d-1})$	$O(n^{d-1})$	[DP98]
d	$\mathcal{C}_k^d (k > 2)$	?	$O(n^{d-(1/d)^{k-2}})$	[DP98]
$d+1$	$\mathcal{I}_k^{d+1}$	$\Omega(n^{\lceil d/2 \rceil})$	$O(n^{\lceil d/2 \rceil})$	[BF87, DP98]
$d+1$	$\mathcal{SI}_k^{d+1}$	$\Omega(n^{\lceil d/2 \rceil})$	$O(n^{\lceil d/2 \rceil})$	[BF87, DP98]
$d+1$	$\mathcal{C}_2^{d+1}$	$\Omega(n^d)$	$O(n^d)$	[DP98]

2. Akiyama-Alon theorem [AA89]: Let $V = V_1 \cup \dots \cup V_d$ ($|V_1| = \dots = |V_d| = n$) be a dn -element set in general position in d -space, and let E consist of all $(d-1)$ -dimensional simplices having exactly one vertex in each V_i . Then E contains n disjoint simplices. This result can be applied to deduce the upper bound in the first line of Table 10.3.1.
3. Assume that, for suitable constants c_1 and $0 \leq \delta \leq 1$, we have $\text{ex}_r^d(\mathcal{SC}_k^r, n) < c_1 \binom{n}{r} / n^\delta$ and $e \geq (c_1 + 1) \binom{n}{r} / n^\delta$. Then there exists $c_2 > 0$ such that the minimum number of strongly crossing k -tuples of edges in a d -dimensional r -hypergraph with n vertices and e edges is at least

$$c_2 \binom{n}{kr} e^\gamma / \binom{n}{r}^\gamma,$$

where $\gamma = 1 + (k-1)r/\delta$. This result can be used to deduce the upper bound in line 5 of Table 10.3.1.

4. A Ramsey-type result [DP98]: Let us 2-color all $(d-1)$ -dimensional simplices induced by $(d+1)n-1$ points in general position in $\mathbb{R}^d$. Then one can always find n disjoint simplices of the same color. This result cannot be improved.
5. Convex geometric hypergraphs in the plane [Bra04]: If we choose triangles from points in convex position in the plane, then the concept of isomorphism is much clearer than in the higher-dimensional cases. Thus two triangles without a common vertex can occur in three mutual positions, and we have $\text{ex}(n, \triangleleft\!\!\!\triangleleft) = \Theta(n^3)$, $\text{ex}(n, \triangleleft\!\!\!\triangle) = \Theta(n^2)$, $\text{ex}(n, \triangleleft\!\!\!\triangleright) = \Theta(n^2)$. Similarly, two triangles with one common vertex can occur again in three positions and we have $\text{ex}(n, \triangleleft\!\!\!\triangleright\!\!\!\triangleright) = \Theta(n^3)$, $\text{ex}(n, \triangleleft\!\!\!\triangleright\!\!\!\triangle) = \Theta(n^2)$, $\text{ex}(n, \triangleleft\!\!\!\triangleright\!\!\!\triangleleft) = \Theta(n^2)$, which is surprising, since the underlying hypergraph has a linear Turán function. Finally, two triangles with two common vertices have two possible positions, and we have $\text{ex}(n, \triangleleft\!\!\!\triangleright\!\!\!\triangleright) = \Theta(n^3)$, $\text{ex}(n, \triangleleft\!\!\!\triangleright\!\!\!\triangle) = \Theta(n^2)$. Larger sets of forbidden convex geometric subhypergraphs occur as the combinatorial core of several combinatorial geometry problems.

OPEN PROBLEMS

1. (Ringel, Harborth) For any k , determine or estimate the smallest integer $n = n(k)$ for which there is a complete topological graph with n vertices, every pair of whose edges intersect at most once (including possibly at their common endpoints), and every edge of which crosses at least k others. It is known that $n(1) = 8$, $7 \leq n(2) \leq 11$, $7 \leq n(3) \leq 14$, $7 \leq n(4) \leq 16$, and $n(k) \leq 4k/3 + O(\sqrt{k})$ [HT94]. Does $n(k) = o(k)$ hold?
2. (Harborth) Is it true that each vertex of a complete topological graph with n vertices, every pair of whose edges cross at most once (including possibly at their common endpoints), is a vertex of at least *two* empty triangles? (A triangle bounded by all edges connecting three vertices is said to be *empty*, if there is no point in its interior or exterior.) It is known [Har98] that every complete topological graph with the above property has at least two empty triangles.
3. (Conway) Is it true that the number of edges of a thrackle can never exceed its number of vertices? It is known that every thrackle with n vertices has at most $1.5(n-1)$ edges [CN00].
4. (Kalai) What is the maximum number $\mu(n)$ of hyperedges that a 3-dimensional geometric 3-hypergraph of n vertices can have, if any pair of its hyperedges either are disjoint or share at most one vertex? Is it true that $\mu(n) = o(n^2)$? Károlyi and Solymosi [KS02] showed that $\mu(n) = \Omega(n^{3/2})$.

10.4 SOURCES AND RELATED MATERIAL

SURVEYS

All results not given an explicit reference above may be traced in these surveys.

[PA95]: Monograph devoted to combinatorial geometry. [Chapter 14](#) is dedicated to geometric graphs.

[Pac99] The most extensive survey on geometric graph theory.

[Pac91, DP98]: The first surveys of results in geometric graph theory and geometric hypergraph theory, respectively.

[PT00a, Pac00, Szé, SSSV97]: Surveys on open problems and on crossing numbers.

[BETT99]: Monograph on graph drawing algorithms.

[BMP04]: Survey of representative results and open problems in discrete geometry, originally started by the Moser brothers.

[Grü72]: Monograph containing many results and conjectures on configurations and arrangements of points and arcs.

11 EUCLIDEAN RAMSEY THEORY

R.L. Graham

INTRODUCTION

Ramsey theory typically deals with problems of the following type. We are given a set S , a family $\mathcal{F}$ of subsets of S , and a positive integer r . We would like to decide whether or not for every partition of $S = C_1 \cup \cdots \cup C_r$ into r subsets, it is always true that some C_i contains some $F \in \mathcal{F}$. If so, we abbreviate this by writing $S \xrightarrow{r} \mathcal{F}$ (and we say S is r -Ramsey). If not, we write $S \not\xrightarrow{r} \mathcal{F}$. (For a comprehensive treatment of Ramsey theory, see [GRS90].)

In Euclidean Ramsey theory, S is usually taken to be the set of points in some Euclidean space $\mathbb{E}^N$, and the sets in $\mathcal{F}$ are determined by various geometric considerations. The case most studied is the one in which $\mathcal{F} = \text{Cong}(X)$ consists of all *congruent* copies of a fixed finite configuration $X \subset S = \mathbb{E}^N$. In other words, $\text{Cong}(X) = \{gX \mid g \in SO(N)\}$, where $SO(N)$ denotes the special orthogonal group acting on $\mathbb{E}^N$.

Further, we say that X is *Ramsey* if, for all r , $\mathbb{E}^N \xrightarrow{r} \text{Cong}(X)$ holds provided N is sufficiently large (depending on X and r). This we indicate by writing $\mathbb{E}^N \longrightarrow X$.

Another important case we will discuss (in Section 11.4) is that in which $\mathcal{F} = \text{Hom}(X)$ consists of all *homothetic* copies $aX + \bar{t}$ of X , where a is a positive real and $\bar{t} \in \mathbb{E}^N$. Thus, in this case $\mathcal{F}$ is just the set of all images of X under the group of positive homotheties acting on $\mathbb{E}^N$.

It is easy to see that any Ramsey (or r -Ramsey) set must be finite. A standard compactness argument shows that if $\mathbb{E}^N \xrightarrow{r} X$ then there is always a *finite* set $Y \subseteq \mathbb{E}^N$ such that $Y \xrightarrow{r} X$. Also, if X is Ramsey (or r -Ramsey) then so is any homothetic copy $aX + \bar{t}$ of X .

GLOSSARY

$\mathbb{E}^N \xrightarrow{r} \text{Cong}(X)$: For any partition $\mathbb{E}^N = C_1 \cup \cdots \cup C_r$, some C_i contains a set congruent to X . We say that X is ***r*-Ramsey**. When $\text{Cong}(X)$ is understood we will usually write $\mathbb{E}^N \xrightarrow{r} X$.

$\mathbb{E}^N \longrightarrow X$: For every r , $\mathbb{E}^N \xrightarrow{r} \text{Cong}(X)$ holds, provided N is sufficiently large. We say in this case that X is ***Ramsey***.

11.1 r -RAMSEY SETS

In this section we focus on low-dimensional r -Ramsey results. We begin by stating three conjectures.

CONJECTURE 11.1.1

For any nonequilateral triangle T (i.e., the set of 3 vertices of T),

$$\mathbb{E}^2 \xrightarrow{2} T.$$

CONJECTURE 11.1.2 (stronger)

For any partition $\mathbb{E}^2 = C_1 \cup C_2$, every triangle occurs (up to congruence) in C_1 , or else the same holds for C_2 , with the possible exception of a single equilateral triangle.

The partition $\mathbb{E}^2 = C_1 \cup C_2$ with

$$\begin{aligned} C_1 &= \{(x, y) \mid -\infty < x < \infty, 2m \leq y < 2m + 1, m = 0, \pm 1, \pm 2, \dots\} \\ C_2 &= \mathbb{E}^2 \setminus C_1 \end{aligned}$$

into alternating half-open strips of width 1 prevents the equilateral triangle of side $\sqrt{3}$ from occurring in a single C_i . In fact, it is conjectured that except for some freedom in assigning the boundary points (x, m) , m an integer, this is the only way of avoiding *any* triangle.

CONJECTURE 11.1.3

For any triangle T ,

$$\mathbb{E}^2 \xrightarrow{3} T.$$

In the positive direction, we have [EGM⁺75b]:

THEOREM 11.1.4

(a) $\mathbb{E}^2 \xrightarrow{2} T$ if T is a triangle satisfying:

- (i) T has a ratio between two sides equal to $2 \sin \theta / 2$ with $\theta = 30^\circ, 72^\circ, 90^\circ$, or 120°
- (ii) T has a $30^\circ, 90^\circ$, or 150° angle [Sha76]
- (iii) T has angles $(\alpha, 2\alpha, 180^\circ - 3\alpha)$ with $0 < \alpha < 60^\circ$
- (iv) T has angles $(180^\circ - \alpha, 180^\circ - 2\alpha, 3\alpha - 180^\circ)$ with $60^\circ < \alpha < 90^\circ$
- (v) T is the degenerate triangle $(a, 2a, 3a)$
- (vi) T has sides (a, b, c) satisfying

$$a^6 - 2a^4b^2 + a^2b^4 - 3a^2b^2c^2 + b^2c^2 = 0$$

or

$$a^4c^2 + b^4a^2 + c^4b^2 - 5a^2b^2c^2 = 0$$

- (vii) T has sides (a, b, c) satisfying

$$c^2 = a^2 + 2b^2 \quad \text{with } a < 2b \quad [\text{Sha76}]$$

- (viii) T has sides (a, b, c) satisfying

$$a^2 + c^2 = 4b^2 \quad \text{with } 3b^2 < 2a^2 < 5b^2 \quad [\text{Sha76}]$$

- (ix) T has sides equal in length to the sides and circumradius of an isosceles triangle;
- (b) $\mathbb{E}^3 \xrightarrow{2} T$ for any nondegenerate triangle T
- (c) $\mathbb{E}^3 \xrightarrow{3} T$ for any nondegenerate right triangle T [BT96]
- (d) $\mathbb{E}^3 \not\xrightarrow{12} T$, a triangle with angles $(30^\circ, 60^\circ, 90^\circ)$ [Bón93]
- (e) $\mathbb{E}^2 \not\xrightarrow{2} Q^2$ (4 points forming a square)
- (f) $\mathbb{E}^4 \not\xrightarrow{2} Q^2$ [Can96a]
- (g) $\mathbb{E}^5 \xrightarrow{2} R^2$, any rectangle [Tót96]
- (h) $\mathbb{E}^n \not\xrightarrow{4} \circ \text{---}^1 \circ \text{---}^1 \circ$ for any n (a degenerate $(1, 1, 2)$ triangle)
- (i) $\mathbb{E}^n \not\xrightarrow{16} \circ \text{---}^a \circ \text{---}^b \circ$ for any n (a degenerate $(a, b, a + b)$ triangle).

It is not known whether the 4 in (h) or the 16 in (i) can be replaced by smaller values. Other results of this type can be found in [EGM⁺73], [EGM⁺75a], [EGM⁺75b], [Sha76], [CFG91].

The 2-point set X_2 consisting of two points a unit distance apart is the simplest set about which such questions can be asked, and has a particularly interesting history (see [Soi91] for details). It is clear that

$$\mathbb{E}^1 \not\xrightarrow{2} X_2 \quad \text{and} \quad \mathbb{E}^2 \xrightarrow{2} X_2.$$

To see that $\mathbb{E}^2 \xrightarrow{3} X_2$, consider the 7-point Moser graph shown in Figure 11.1.1. All edges have length 1. On the other hand, $\mathbb{E}^2 \not\xrightarrow{7} X_2$, which can be seen by an appropriate periodic 7-coloring (= partition into 7 parts) of a tiling of $\mathbb{E}^2$ by regular hexagons of diameter 0.9 (see Figure 1.3.1).

FIGURE 11.1.1
The Moser graph.

Definition: The *chromatic number* of $\mathbb{E}^n$, denoted by $\chi(\mathbb{E}^n)$, is the least m such that $\mathbb{E}^n \xrightarrow{m} X_2$.

By the above remarks,

$$4 \leq \chi(\mathbb{E}^2) \leq 7.$$

These bounds have remained unchanged for over 50 years.

Some evidence that $\chi(\mathbb{E}^2) \geq 5$ (in the author's opinion) is given by the following result of O'Donnell:

THEOREM 11.1.5 [O'D00a], [O'D00b]

For any $g > 0$, there is 4-chromatic unit distance graph in $\mathbb{E}^2$ with girth greater than g .

Note that the Moser graph has girth 3.

PROBLEM 11.1.6

Determine the exact value of $\chi(\mathbb{E}^2)$.

The best bounds currently known for $\mathbb{E}^n$ are:

$$(6/5 + o(1))^n < \chi(\mathbb{E}^n) < (3 + o(1))^n$$

(see [FW81], [CFG91]).

A “near miss” for showing $\chi(\mathbb{E}^2) < 7$ was found by Soifer [Soi92]. He shows that there exists a partition $\mathbb{E}^2 = C_1 \cup \dots \cup C_7$ where C_i contains no pair of points at distance 1 for $1 \leq i \leq 6$, while C_7 has no pair at distance $1/\sqrt{5}$.

The best bounds known for $\chi(\mathbb{E}^3)$ are:

$$6 \leq \chi(\mathbb{E}^3) \leq 15.$$

The lower bound is due to Nechushtan [Nech02] and the the upper bound is due to R. Radoicic and G. Tóth [RT03] (improving earlier results of Székely/Wormald [SW89] and Bóna/Tóth [BT96]).

See [Section 1.3](#) of this Handbook for more details.

11.2 RAMSEY SETS

Recall that X is Ramsey (written $\mathbb{E}^N \longrightarrow X$) if, for all r , if $\mathbb{E}^N = C_1 \cup \dots \cup C_r$ then some C_i must contain a congruent copy of X , provided only that $N \geq N_0(X, r)$.

GLOSSARY

Spherical: X is spherical if it lies on the surface of some sphere.

Rectangular: X is rectangular if it is a subset of the vertices of a rectangular parallelepiped.

Simplex: X is a simplex if it spans $\mathbb{E}^{|X|-1}$.

THEOREM 11.2.1 [EGM⁺73]

If X and Y are Ramsey then so is $X \times Y$.

Thus, since any 2-point set is Ramsey (for any r , consider the unit simplex S_{2r+1} in $\mathbb{E}^{2r}$ scaled appropriately), then so is any rectangular parallelepiped. This implies:

THEOREM 11.2.2

Any rectangular set is Ramsey.

Frankl and Rödl strengthen this significantly in the following way.

Definition: A set $A \subset \mathbb{E}^n$ is called **super-Ramsey** if there exist positive constants c and ϵ and subsets $X = X(N) \subset \mathbb{E}^N$ for every $N \geq N_0(X)$ such that:

- (i) $|X| < c^n$;
- (ii) $|Y| < |X|/(1 + \epsilon)^n$ holds for all subsets $Y \subset X$ containing no congruent copy of A .

THEOREM 11.2.3 [FR90]

- (i) *All two-element sets are super-Ramsey.*
- (ii) *If A and B are super-Ramsey then so is $A \times B$.*

COROLLARY 11.2.4

If X is rectangular then X is super-Ramsey.

In the other direction we have:

THEOREM 11.2.5

Any Ramsey set is spherical.

The simplest nonspherical set is the degenerate $(1, 1, 2)$ triangle.

Concerning simplices, we have the result of Frankl and Rödl:

THEOREM 11.2.6 [FR90]

Every simplex is Ramsey.

In fact, they show that for any simplex X , there is a constant $c = c(X)$ such that for all r ,

$$\mathbb{E}^{c \log r} \xrightarrow{r} X,$$

which follows from their result:

THEOREM 11.2.7

Every simplex is super-Ramsey.

It was an open problem for more than 20 years as to whether the set of vertices of a regular pentagon was Ramsey. This was finally settled by Křiž [Kři91] who proved the following two fundamental results:

THEOREM 11.2.8 [Kři91]

Suppose $X \subseteq \mathbb{E}^N$ has a transitive solvable group of isometries. Then X is Ramsey.

COROLLARY 11.2.9

Any set of vertices of a regular polygon is Ramsey.

THEOREM 11.2.10 [Kři91]

Suppose $X \subseteq \mathbb{E}^N$ has a transitive group of isometries that has a solvable subgroup with at most two orbits. Then X is Ramsey.

COROLLARY 11.2.11

The vertex sets of the Platonic solids are Ramsey.

CONJECTURE 11.2.12

Any 4-point subset of a circle is Ramsey.

Křiž [Kři92] has shown this holds if a pair of opposite sides of the 4-point set are parallel (i.e., form a trapezoid).

Certainly, the outstanding open problem in Euclidean Ramsey theory is to determine the Ramsey sets. The author (bravely?) makes the following:

CONJECTURE 11.2.13 (\$1000)

Any spherical set is Ramsey.

If true then this would imply that the Ramsey sets are exactly the spherical sets.

11.3 SPHERE-RAMSEY SETS

Since spherical sets play a special role in Euclidean Ramsey theory, it is natural that the following concept arises.

GLOSSARY

$S^N(\rho)$: A sphere in $\mathbb{E}^N$ with radius ρ .

Sphere-Ramsey: X is sphere-Ramsey if, for all r , there exist $N = N(X, r)$ and $\rho = \rho(X, r)$ such that

$$S^N(\rho) \xrightarrow{r} X.$$

In this case we write $S^N(\rho) \longrightarrow X$.

For a spherical set X , let $\rho(X)$ denote its circumradius, i.e., the radius of the smallest sphere containing X as a subset.

Remark. If X and Y are sphere-Ramsey then so is $X \times Y$.

THEOREM 11.3.1 [Gra83]

If X is rectangular then X is sphere-Ramsey.

In [Gra83], it was conjectured that in fact if X is rectangular and $\rho(X) = 1$ then $S^N(1 + \epsilon) \longrightarrow X$ should hold. This was proved by Frankl and Rödl [FR90] in a much stronger “super-Ramsey” form.

Concerning simplices, Matoušek and Rödl proved the following spherical analogue of simplices being Ramsey:

THEOREM 11.3.2 [MR95]

For any simplex X with $\rho(X) = 1$, any r , and any $\epsilon > 0$, there exists $N = N(X, r, \epsilon)$ such that

$$S^N(1 + \epsilon) \xrightarrow{r} X.$$

The proof uses an interesting mix of techniques from combinatorics, linear algebra, and Banach space theory.

The following results show that the “blowup factor” of $1 + \epsilon$ is really needed.

THEOREM 11.3.3 [Gra83]

Let $X = \{x_1, \dots, x_m\} \subset \mathbb{E}^N$ such that:

- (i) for some nonempty $I \subseteq \{1, 2, \dots, m\}$, there exist nonzero a_i , $i \in I$, with

$$\sum_{i \in I} a_i x_i = 0 \in \mathbb{E}^N$$

- (ii) for all nonempty $J \subseteq I$,

$$\sum_{j \in J} a_j \neq 0.$$

Then X is not sphere-Ramsey.

This implies that $X \subset S^N(1)$ is not sphere-Ramsey if the convex hull of X contains the center of $S^N(1)$.

Definition: A simplex $X \subset \mathbb{E}^N$ is called **exceptional** if there is a subset $A \subseteq X$, $|A| \geq 2$, such that the affine hull of A translated to the origin has a nontrivial intersection with the linear span of the points of $X \setminus A$ regarded as vectors.

THEOREM 11.3.4 [MR95]

If X is a simplex with $\rho(X) = 1$ and $S^N(1) \rightarrow X$ then X must be exceptional.

It is not known whether it is true for exceptional X that $S^N(1) \rightarrow X$. The simplest nontrivial case is for the set of three points $\{a, b, c\}$ lying on some great circle of $S^N(1)$ (with center o) so that the line joining a and b is parallel to the line joining o and c .

We close with a fundamental conjecture:

CONJECTURE 11.3.5

If X is Ramsey, then X is sphere-Ramsey.

11.4 EDGE-RAMSEY SETS

In this variant (introduced in [EGM⁺75b]), we color all the line segments $[a, b]$ in $\mathbb{E}^n$ rather than coloring the points. Analogously to our earlier definition, we will say that a configuration E of line segments is **edge-Ramsey** if for any r , there is an $N = N(r)$ such any r -coloring of the line segments in $\mathbb{E}^N$ contains a monochromatic congruent copy of E (up to some Euclidean motion). The main results known for edge-Ramsey configurations are the following:

THEOREM 11.4.1 [EGM⁺75b]

If E is edge-Ramsey then all edges of E must have the same length.

THEOREM 11.4.2 [Gra83]

If E is edge-Ramsey then the endpoints of the edges of E must lie on two spheres.

THEOREM 11.4.3 [Gra83]

If the endpoints of E do not lie on a sphere and the graph formed by E is not bipartite then E is not edge-Ramsey.

It is clear that the edge set of an n -dimensional simplex is edge-Ramsey. Less obvious (but equally true) are the following.

THEOREM 11.4.4 [Can96b]

The edge set of an n -cube is edge-Ramsey.

THEOREM 11.4.5 [Can96b]

The edge set of an n -dimensional cross polytope is edge-Ramsey.

This set, a generalization of the octahedron, has as its edges all $2n(n-1)$ line segments of the form $[(0, 0, \dots, \pm 1, \dots, 0), (0, 0, \dots, 0, \pm 1, \dots, 0)]$ where the two ± 1 's occur in different positions.

THEOREM 11.4.6 [Can96b]

The edge set of a regular n -gon is not edge-Ramsey if $n = 5$ or $n \geq 7$.

Since regular n -gons are edge-Ramsey for $n = 2, 3$, and 4 , the only undecided value is $n = 6$.

PROBLEM 11.4.7 *Is the edge set of a regular hexagon edge-Ramsey?*

The situation is not as simple as one might hope since as pointed out by Cantwell [Can96b]:

(i) If AB is a line segment with C as its midpoint, then the set E_1 consisting of the line segments AC and CB is not edge-Ramsey, even though its graph is bipartite and A, B, C lie on two spheres.

(ii) There exist nonspherical sets that are edge-Ramsey.

PROBLEM 11.4.8 *Characterize edge-Ramsey configurations.*

It is not clear at this point what a reasonable conjecture might be. For more results on these topics, see [Can96b] or [Gra83].

11.5 HOMOTHETIC RAMSEY SETS AND DENSITY THEOREMS

In this section we will survey various results of the type $\mathbb{E}^N \xrightarrow{r} \text{Hom}(X)$, the set of positive homothetic images $aX + \vec{t}$ of a given set X . Thus, we are allowed to dilate and translate X but we cannot rotate it. The classic result of this type is van der Waerden's theorem, which asserts the following:

THEOREM 11.5.1 [vdW27]

If $X = \{1, 2, \dots, m\}$ then $\mathbb{E} \xrightarrow{r} \text{Hom}(X)$.

(Note that $\text{Hom}(X)$ is just the set of m -term arithmetic progressions.)

By the compactness theorem mentioned in the Introduction there exists, for each m , a minimum value $W(m)$ such that

$$\{1, 2, \dots, W(m)\} \xrightarrow{2} \text{Hom}(X).$$

The determination or even estimation of $W(m)$ seems to be extremely difficult. The known values are:

m	1	2	3	4	5
$W(m)$	1	3	9	35	178

The best general result from below (due to Berlekamp—see [GRS90]) is

$$W(p+1) > p \cdot 2^p, \quad p \text{ prime.}$$

The best upper bound known follows from a spectacular result of Gowers [Gow01]:

$$W(m) < 2^{2^{2^{2^m+9}}}$$

This settled a long-standing \$1000 conjecture of the author. This result is a corollary of Gowers’s new quantitative form of Szemerédi’s theorem mentioned in the next section. It improves on the earlier bound of Shelah: [She88]:

Diagram illustrating the recursive construction of a sequence of numbers. The sequence starts with 2, and at each step, a new number is formed by concatenating the previous number with a 2. The diagram shows the sequence 2, 22, 222, ..., 22...2 (m levels). The sequence is shown as a tree structure where each level represents a step in the construction. The top level is labeled 'm levels' and shows the sequence 2, 22, 222, ..., 22...2. The bottom level is labeled 'W(m) ≤' and shows the sequence 2, 22, 222, ..., 22...2. The diagram illustrates that the sequence grows exponentially, with the number of levels being m.

The following conjecture of the author has been open for more than 30 years:

CONJECTURE 11.5.2 (\$1000)

For all m ,

$$W(m) \leq 2^{m^2}$$

The generalization to $\mathbb{E}^N$ is due independently to Gallai and Witt (see [GRS90]).

THEOREM 11.5.3

For any finite set $X \subset \mathbb{E}^n$,

$$\mathbb{E}^N \longrightarrow \mathrm{Hom}(X).$$

We remark here that a number of results in (Euclidean) Ramsey theory have stronger so-called *density* versions. As an example, we state the well-known theorem of Szemerédi.

GLOSSARY

$\mathbb{N}$: The set of natural numbers $\{1, 2, 3, \dots\}$.

$\bar{\delta}(A)$: The **upper density** of a set $A \subseteq \mathbb{N}$ is defined by:

$$\bar{\delta}(A) = \limsup_{n \rightarrow \infty} \frac{|A \cap \{1, 2, \dots, n\}|}{n}.$$

THEOREM 11.5.4 (Szemerédi [Sze75])

If $A \subseteq \mathbb{N}$ has $\bar{\delta}(A) > 0$ then A contains arbitrarily long arithmetic progressions.

That is, $A \cap \text{Hom}\{1, 2, \dots, m\} \neq \emptyset$ for all m . This clearly implies van der Waerden's theorem since $\mathbb{N} = C_1 \cup \dots \cup C_r \Rightarrow \max_i \bar{\delta}(C_i) \geq 1/r$.

Furstenberg [Fur77] has given a quite different proof of Szemerédi's theorem, using tools from ergodic theory and topological dynamics. This approach has proved to be very powerful, allowing Furstenberg, Katznelson, and others to prove density versions of the Hales-Jewett theorem (see [FK91]), the Gallai-Witt theorem, and many others. Recently, Gowers has given a strong quantitative version of Szemerédi's theorem:

THEOREM 11.5.5 [Gow01]

For every $k > 0$, any subset of $1, 2, \dots, N$ of size at least $N(\log \log N)^{-c(k)}$ contains a k -term arithmetic progression, where $c(k) = 2^{-2^{k+9}}$.

There are other ways of expressing the fact that A is relatively dense in $\mathbb{N}$ besides the condition that $\bar{\delta}(A) > 0$. One would expect that these could also be used as a basis for a density version of van der Waerden or Gallai-Witt. Very little is currently known in this direction, however. We conclude this section with several conjectures of this type.

CONJECTURE 11.5.6 (Erdős)

If $A \subseteq \mathbb{N}$ satisfies $\sum_{a \in A} 1/a = \infty$ then A contains arbitrarily long arithmetic progressions.

CONJECTURE 11.5.7 (Graham)

If $A \subseteq \mathbb{N} \times \mathbb{N}$ with $\sum_{(x,y) \in A} 1/(x^2 + y^2) = \infty$ then A contains the 4 vertices of an axes-parallel square.

More generally, I expect that A will always contain a homothetic image of $\{1, 2, \dots, m\} \times \{1, 2, \dots, m\}$ for all m .

Finally, we mention a direction in which the group $SO(n)$ is enlarged to allow dilatations as well.

Definition: For a set $W \subseteq \mathbb{E}^k$, define the **upper density** $\bar{\delta}(W)$ of W by

$$\bar{\delta}(W) := \limsup_{R \rightarrow \infty} \frac{m(B(o, R) \cap W)}{m(B(o, R))},$$

where $B(o, R)$ denotes the k -ball $\left\{ (x_1, \dots, x_k) \in \mathbb{E}^k \mid \sum_{i=1}^k x_i^2 \leq R^2 \right\}$ centered at the origin, and m denotes Lebesgue measure.

THEOREM 11.5.8 (Bourgain [Bou86])

Let $X \subseteq \mathbb{E}^k$ be a simplex. If $W \subseteq \mathbb{E}^k$ with $\bar{\delta}(W) > 0$ then there exists t_0 such that for all $t > t_0$, W contains a congruent copy of tX .

Some restrictions on X are necessary as the following result shows.

THEOREM 11.5.9 (Graham [Gra94])

Let $X \subseteq \mathbb{E}^k$ be nonspherical. Then for any N there exist a set $W \subseteq \mathbb{E}^N$ with $\bar{\delta}(W) > 0$ and a set $T \subseteq \mathbb{R}$ with $\underline{\delta}(T) > 0$ such that W contains no congruent copy of tX for any $t \in T$.

Here $\underline{\delta}$ denotes *lower density*, defined similarly to $\bar{\delta}$ but with $\liminf$ replacing $\limsup$.

It is clear that much remains to be done here.

11.6 VARIATIONS

There are quite a few variants of the preceding topics that have received attention in the literature (e.g., see [Sch93]). We mention some of the more interesting ones.

ASYMMETRIC RAMSEY THEOREMS

Typical results of this type assert that for given sets X_1 and X_2 (for example), for every partition of $\mathbb{E}^N = C_1 \cup C_2$, either C_1 contains a congruent copy of X_1 , or C_2 contains a congruent copy of X_2 . We can denote this by

$$\mathbb{E}^N \xrightarrow{2} (X_1, X_2).$$

Here is a sampling of results of this type (more of which can be found in [EGM⁺73], [EGM⁺75a], [EGM⁺75b]).

- (i) $\mathbb{E}^2 \xrightarrow{2} (T_2, T_3)$ where T_i is any subset of $\mathbb{E}^2$ with i points, $i = 2, 3$.
- (ii) $\mathbb{E}^2 \xrightarrow{2} (P_2, P_4)$ where P_2 is a set of two points at a distance 1, and P_4 is a set of four collinear points with distance 1 between consecutive points.
- (iii) $\mathbb{E}^3 \xrightarrow{2} (T, Q^2)$ where T is an isosceles right triangle and Q^2 is a square.
- (iv) $\mathbb{E}^2 \xrightarrow{2} (P_2, T_4)$ where P_2 is as in (ii) and T_4 is any set of four points [Juh79].
- (v) There is a set T_8 of 8 points such that

$$\mathbb{E}^2 \not\xrightarrow{2} (P_2, T_8) \quad [\text{CT94}].$$

This strengthens an earlier result of Juhász [Juh79], which proved this for a certain set of 12 points.

POLYCHROMATIC RAMSEY THEOREMS

Here, instead of asking for a copy of the target set X in a single C_i , we require only that it be contained in the union of a small number of C_i , say at most m of the C_i .

Let us indicate this by writing $\mathbb{E}^N \xrightarrow[m]{N} X$.

(i) If $\mathbb{E}^N \xrightarrow[m]{N} X$ then X must be embeddable on the union of m concentric spheres [EGM⁺73].

(ii) Suppose X_i is finite and $\mathbb{E}^N \xrightarrow[m_i]{N} X_i$, $1 \leq i \leq t$. Then

$$\mathbb{E}^N \xrightarrow[m_1 m_2 \cdots m_t]{N} X_1 \times X_2 \times \cdots \times X_t \quad [\text{ERS83}].$$

(iii) If X_6 is the 6-point set formed by taking the four vertices of a square together with the midpoints of two adjacent sides then $\mathbb{E}^2 \not\xrightarrow{2} X_6$ but $\mathbb{E}^2 \xrightarrow[2]{2} X_6$.

(iv) If X is the set of vertices of a regular simplex in $\mathbb{E}^N$ together with the trisection points of each of its edges then

$$\mathbb{E}^2 \not\xrightarrow{3} X_6 \quad \text{but} \quad \mathbb{E}^2 \xrightarrow[3]{2} X_6.$$

It is not known if $\mathbb{E}^2 \xrightarrow[2]{2} X_6$. Many other results of this type can be found in [ERS83].

PARTITIONS OF $\mathbb{E}^n$ WITH ARBITRARILY MANY PARTS

Since $\mathbb{E}^2 \not\xrightarrow[7]{2} P_2$, where P_2 is a set of two points with unit distance, one might ask whether there is any nontrivial result of the type $\mathbb{E}^2 \xrightarrow[m]{m} \mathcal{F}$ when m is allowed to go to infinity. Of course, if $\mathcal{F}$ is sufficiently large, then there certainly are. There are some interesting geometric examples for which $\mathcal{F}$ is not too large.

THEOREM 11.6.1 [Gra80a]

For any partition of $\mathbb{E}^n$ into finitely many parts, some part contains, for all $\alpha > 0$ and all sets of lines $L_1, \dots, L_n$ that span $\mathbb{E}^n$, a simplex having volume α and edges through one vertex parallel to the L_i .

Many other theorems of this type are possible (see [Gra80a]).

PARTITIONS WITH INFINITELY MANY PARTS

Results of this type tend to have a strong set-theoretic flavor. For example: $\mathbb{E}^2 \not\xrightarrow[\aleph_0]{2} T_3$ where T_3 is an equilateral triangle [Ced69]. In other words, $\mathbb{E}^2$ can be partitioned into countably many parts so that no part contains the vertices of an equilateral triangle. In fact, this was recently strengthened by Schmerl [Sch94b]

who showed that for all N ,

$$\mathbb{E}^N \not\stackrel{\aleph_0}{\rightarrow} T_3.$$

In fact, this result holds for *any* fixed triangle T in place of T_3 [Sch94b]. Schmerl also has shown [Sch94a] that there is a partition of $\mathbb{E}^N$ into countably many parts such that no part contains the vertices of *any* isosceles triangle.

Another result of this type is this:

THEOREM 11.6.2 [Kun]

*Assuming the Continuum Hypothesis, it is possible to partition $\mathbb{E}^2$ into countably many parts, none of which contains the vertices of a triangle with **rational** area.*

We also note the interesting result of Erdős and Komjáth:

THEOREM 11.6.3 [EK90]

*The existence of a partition of $\mathbb{E}^2$ into countably many sets, none of which contains the vertices of a **right** triangle is equivalent to the Continuum Hypothesis.*

The reader can consult Komjáth [Kom97] for more results of this type.

COMPLEXITY ISSUES

S. Burr [Bur82] has shown that the algorithmic question of deciding if a given set $X \subset \mathbb{N} \times \mathbb{N}$ can be partitioned $X = C_1 \cup C_2 \cup C_3$ so that $x, y \in C_i \Rightarrow \text{distance}(x, y) \geq 6, i = 1, 2, 3$, is NP-complete. (Also, he shows that a certain infinite version of this is undecidable.)

Finally, we make a few remarks about the celebrated problem of Esther Klein (who became Mrs. Szekeres), which, in some sense, initiated this whole area (see [Sze73] for a charming history).

THEOREM 11.6.4 [ES35]

There is a minimum function $f : \mathbb{N} \rightarrow \mathbb{N}$ such that any set of $f(n)$ points in $\mathbb{E}^2$ in general position contains the vertices of a convex n -gon.

This result of Erdős and George Szekeres actually spawned an independent genesis of Ramsey theory.

The best bounds currently known for $f(n)$ are:

$$2^{n-2} + 1 \leq f(n) \leq \binom{2n-5}{n-3} + 2.$$

The lower bound appears in [ES35], while the upper, improved by G. Tóth and P. Valtr from the original $\binom{2n-4}{n-2+1}$, appears in [TV98].

CONJECTURE 11.6.5

Prove (or disprove) that $f(n) = 2^{n-2} + 1, n \geq 3$.

(See [Chapter 1](#) of this Handbook for more details.)

11.7 SOURCES AND RELATED MATERIAL

SURVEYS

The principal surveys for results in Euclidean Ramsey theory are [GRS90], [Gra80b], [Gra85], and [Gra94]. The first of these is a monograph on Ramsey theory in general, with a section devoted to Euclidean Ramsey theory, while the last three are specifically about the topics discussed in the present chapter.

12 DISCRETE ASPECTS OF STOCHASTIC GEOMETRY

Rolf Schneider

INTRODUCTION

Stochastic geometry studies randomly generated geometric objects. The present chapter deals with some discrete aspects of stochastic geometry. We describe work that has been done on familiar objects of discrete geometry, such as finite point sets, their convex hulls, discrete point sets, arrangements of flats, and tessellations of space, under various assumptions of randomness. Most of the results to be mentioned concern expectations of geometrically defined random variables, or probabilities of events defined by random geometric configurations. The selection of topics must necessarily be restrictive. We leave out the great number of special elementary geometric probability problems which can be solved explicitly by direct, though possibly intricate, analytic calculations. We pay special attention to either asymptotic results, where the number of points considered tends to infinity, or to inequalities, or to identities where the proofs involve more delicate geometric or combinatorial arguments. The close ties of discrete geometry to convexity are reflected: we consider convex hulls of random points, intersections of random halfspaces, and tessellations of space into convex sets generated either by discrete random hyperplane systems or, as Voronoi or Delaunay mosaics, by discrete random point sets. Topics not covered are, for example, optimization problems with random data, and the average-case analysis of geometric algorithms.

12.1 CONVEX HULLS OF RANDOM POINTS

The setup for this section is a finite number of random points in a topological space Σ . Mostly the space Σ is $\mathbb{R}^d$, the d -dimensional Euclidean space, with scalar product $\langle \cdot, \cdot \rangle$ and norm $\|\cdot\|$. Other spaces that occur are the sphere $S^{d-1} := \{x \in \mathbb{R}^d \mid \|x\| = 1\}$ or more general submanifolds of $\mathbb{R}^d$. By $B^d := \{x \in \mathbb{R}^d \mid \|x\| \leq 1\}$ we denote the unit ball of $\mathbb{R}^d$. The volume of B^d is denoted by κ_d .

GLOSSARY

Random point in Σ : A Borel-measurable mapping from some probability space into Σ .

Distribution of a random point X in Σ : The probability measure μ on Σ such that $\mu(B)$, for a Borel set $B \subset \Sigma$, is the probability that $X \in B$.

i.i.d. random points: Stochastically independent random points (on the same probability space) with the same distribution.

NOTATION

$X_1, \dots, X_n$	i.i.d. random points in $\mathbb{R}^d$
μ	the common probability distribution of X_i
φ	a measurable real function defined on polytopes in $\mathbb{R}^d$
$\varphi(\mu, n)$	the random variable $\varphi(\text{conv}\{X_1, \dots, X_n\})$
$\varphi(K, n)$	$= \varphi(\mu, n)$, if μ is the uniform distribution in K
$\mathbb{E}$	expectation of a random variable
f_k	number of k -faces
ψ_j	1 on polytopes with j vertices, 0 otherwise
V_j	j th intrinsic volume (see Chapter 16); in particular:
V_d	d -dimensional volume
S	$= 2V_{d-1}$, surface area; dS element of surface area
$D_j(K, n)$	$= V_j(K) - V_j(K, n)$

12.1.1 DISTRIBUTION-INDEPENDENT RESULTS

There are a few general results on convex hulls of i.i.d. random points in $\mathbb{R}^d$ that do not require special assumptions on the distribution of these points. A classical result due to Wendel [Wen62] concerns the probability, say $p_{d,n}$, that $0 \notin \text{conv}\{X_1, \dots, X_n\}$. If the distribution of the i.i.d. random points $X_1, \dots, X_n \in \mathbb{R}^d$ is symmetric with respect to 0 and assigns measure zero to every hyperplane through 0, then

$$p_{d,n} = \frac{1}{2^{n-1}} \sum_{k=0}^{d-1} \binom{n-1}{k}. \quad (12.1.1)$$

This follows from a combinatorial result of Schläfli, on the number of d -dimensional cells in a partition of $\mathbb{R}^d$ by n hyperplanes through 0 in general position. It was proved surprisingly late that the symmetric distributions are extremal: Wagner and Welzl [WaW01] showed that if the distribution of the points is absolutely continuous with respect to Lebesgue measure, then $p_{d,n}$ is at least the right-hand side of (12.1.1).

The expected values $\mathbb{E}V_d(\mu, n)$ for different numbers n are connected by a sequence of identities. For an arbitrary probability distribution μ on $\mathbb{R}^d$, Buchta [Buc90] proved the recurrence relations

$$\mathbb{E}V_d(\mu, d+2m) = \frac{1}{2} \sum_{k=1}^{2m-1} (-1)^{k+1} \binom{d+2m}{k} \mathbb{E}V_d(\mu, d+2m-k)$$

and, consequently,

$$\mathbb{E}V_d(\mu, d+2m) = \sum_{k=1}^m (2^{2k} - 1) \frac{B_{2k}}{k} \binom{d+2m}{2k-1} \mathbb{E}V_d(\mu, d+2m-2k+1)$$

for $m \in \mathbb{N}$, where the constants B_{2k} are the Bernoulli numbers.

12.1.2 NATURAL DISTRIBUTIONS

In geometric problems about random points, a few distributions have been considered as particularly natural, for different reasons. Such reasons may be invariance

properties, or relations to measures of geometric significance, but there are also more subtle viewpoints, as explained, for example, in Ruben and Miles [RuM80]. The distributions of a random point in $\mathbb{R}^d$ shown in Table 12.1.1 underlie many investigations.

TABLE 12.1.1 Natural distributions of a random point in $\mathbb{R}^d$.

NAME OF DISTRIBUTION	PROBABILITY DENSITY AT $x \in \mathbb{R}^d$
Uniform in K	$\propto$ indicator function of K at x
Standard normal	$\propto \exp\left(-\frac{1}{2}\ x\ ^2\right)$
Beta type 1	$\propto (1 - \ x\ ^2)^q \times$ indicator function of B^d at x , $q > -1$
Beta type 2	$\propto \ x\ ^{\alpha-1} (1 + \ x\)^{-(\alpha+\beta)}$, $\alpha, \beta > 0$
Spherically symmetric	function of $\ x\ $

Here $K \subset \mathbb{R}^d$ is a given closed set of positive, finite volume, often a **convex body** (a compact, convex set with interior points). Usually the name of the distribution of a random point is also associated with the random point itself. General rotationally symmetric distributions have mostly been considered under additional tail assumptions. If F is a smooth compact hypersurface in $\mathbb{R}^d$, a random point is uniform on F if its distribution is proportional to the area measure on F . This distribution is particularly natural for the unit sphere S^{d-1} , since it is the unique rotation-invariant probability measure on S^{d-1} .

For combinatorial problems about n -tuples of random points in $\mathbb{R}^d$, the following approach leads to a natural distribution. Every configuration of $n > d$ numbered points in general position in $\mathbb{R}^d$ is affinely equivalent to the orthogonal projection of the set of numbered vertices of a fixed regular simplex $T^{n-1} \subset \mathbb{R}^{n-1}$ onto a unique d -dimensional linear subspace of $\mathbb{R}^{n-1}$. This establishes a one-to-one correspondence between the (orientation-preserving) affine equivalence classes of such configurations and an open dense subset of the Grassmannian $G(n-1, d)$ of oriented d -spaces in $\mathbb{R}^{n-1}$. The unique rotation-invariant probability measure on $G(n-1, d)$ thus leads to a probability distribution on the set of affine equivalence classes of n -tuples of points in general position in $\mathbb{R}^d$. References for this **Grassmann approach**, which was proposed by Vershik and by Goodman and Pollack, are given in Affentranger and Schneider [AfS92]. Baryshnikov and Vitale [BaV94] proved that an affine-invariant functional of n -tuples with this distribution is stochastically equivalent to the same functional taken at an i.i.d. n -tuple of standard normal points in $\mathbb{R}^d$. Baryshnikov [Bar97] has made clear, in a strong sense, the unique role that is played in this correspondence by the vertex sets of regular simplices.

12.1.3 UNIFORM RANDOM POINTS IN CONVEX BODIES

A considerable amount of work has been done on convex hulls of a finite number of i.i.d. random points with uniform distribution in a given convex body K in $\mathbb{R}^d$.

Some of the expectations of $\varphi(K, n)$ for different functions φ are connected by

identities. Two classical results of Efron [Efr65],

$$\mathbb{E}\psi_{d+1}(K, n) = \binom{n}{d+1} \frac{\mathbb{E}V_d^{n-d-1}(K, d+1)}{V_d^{n-d-1}(K)} \quad (12.1.2)$$

and

$$\mathbb{E}f_0(K, n+1) = \frac{n+1}{V_d(K)} \mathbb{E}D_d(K, n), \quad (12.1.3)$$

have found far-reaching generalizations in work of Buchta's [Buc02]. He extended (12.1.3) to higher moments of the volume, showing that

$$\frac{\mathbb{E}V_d^k(K, n)}{V_d^k(K)} = \mathbb{E} \prod_{i=1}^k \left(1 - \frac{f_0(K, n+i)}{n+i} \right)$$

for $k \in \mathbb{N}$. As a consequence, the k th moment of $V_d(K, n)$ can be expressed linearly by the first k moments of $f_0(K, n+k)$. Further consequences are variance estimates for $D_d(K, n)$ and $f_0(K, n)$ for sufficiently smooth convex bodies K .

Of combinatorial interest is the expectation $\mathbb{E}\psi_i(K, n)$, which is the probability that the convex hull of n i.i.d. uniform random points in K has exactly i vertices. For this, Buchta [Buc02] proved that

$$\mathbb{E}\psi_i(K, n) = (-1)^i \binom{n}{i} \sum_{j=1}^i (-1)^j \binom{i}{j} \frac{\mathbb{E}V_d^{n-j}(K, j)}{V_d^{n-j}(K)},$$

which for $i = d+1$ reduces to (12.1.2). Sylvester's classical problem asked for $\mathbb{E}\psi_3(K, 4)$ (or the complementary probability) for a convex body $K \subset \mathbb{R}^2$. More generally, one may ask for $\mathbb{E}\psi_{d+1}(K, n)$ for a convex body $K \subset \mathbb{R}^d$ and $n > d+1$, the probability that the convex hull of n i.i.d. uniform points in K is a simplex. From (12.1.2) and results of Miles [Mil71b], the values $\mathbb{E}\psi_{d+1}(B^d, n)$ are known. At the other end, $\mathbb{E}\psi_n(K, n)$ is of interest, the probability that n i.i.d. uniform points in K are in convex position. Valtr [Val95] determined $\mathbb{E}\psi_n(P, n)$ if P is a parallelogram, and in [Val96] if P is a triangle. For convex bodies $K \subset \mathbb{R}^2$ of area one, Bárány [Bár99] obtained the astonishing limit relation

$$\lim_{n \rightarrow \infty} n^2 \sqrt[n]{\mathbb{E}\psi_n(K, n)} = \frac{1}{4} e^2 A^3(K),$$

where $A(K)$ is the supremum of the affine perimeters of all convex bodies contained in K . Bárány has even established a law of large numbers for convergence to a limit shape. There is a unique convex body $\tilde{K} \subset K$ with affine perimeter $A(K)$. If K_n denotes the convex hull of n i.i.d. uniform points in K and δ is the Hausdorff metric, then Bárány's result says that

$$\lim_{n \rightarrow \infty} \text{Prob}\{\delta(K_n, \tilde{K}) > \epsilon \mid f_0(K_n) = n\} = 0$$

for every $\epsilon > 0$.

For balls in increasing dimensions, earlier work of Buchta was extended by Bárány and Füredi [BáF88], who proved that

$$\begin{aligned} \mathbb{E}\psi_{n(d)}(B^d, n(d)) &\rightarrow 1 & \text{if } n(d) &= 2^{d/2} d^{-\epsilon}, \\ \mathbb{E}\psi_{m(d)}(B^d, m(d)) &\rightarrow 0 & \text{if } m(d) &= 2^{d/2} d^{(3/4)+\epsilon} \end{aligned}$$

when $d \rightarrow \infty$, for every fixed $\epsilon > 0$. The authors also investigated k -neighborliness of the convex hull.

We turn to random variables $\varphi(K, n)$ connected with intrinsic volumes and face numbers. First we mention the rare instances where information on the whole distribution is available. Some special results for $d = 2$ due to Alagar, Reed, and Henze are quoted in [Sch88, Section 4]. For example, Henze showed that the distribution function F_K of $V_2(K, 3)$ for a convex body $K \subset \mathbb{R}^2$ satisfies $F_T \leq F_K \leq F_E$, where T is a triangle and E is an ellipse, provided that K, T, E have the same area. Results on the distribution of $V_r(B^d, r + 1)$ for $r = 1, \dots, d$ are listed in a more general context in Section 12.1.5.

In the plane, a few remarkable central limit type theorems have been obtained. For a convex polygon $P \subset \mathbb{R}^2$ with r vertices, Groeneboom [Gro88] proved that

$$\frac{f_0(P, n) - \frac{2}{3}r \log n}{\sqrt{\frac{10}{27}r \log n}} \xrightarrow{\mathcal{D}} \mathcal{N}(0, 1)$$

for $n \rightarrow \infty$, where $\xrightarrow{\mathcal{D}}$ denotes convergence in distribution and $\mathcal{N}(0, 1)$ is the standard normal distribution. From this, Massé [Mas00] deduced that

$$\lim_{n \rightarrow \infty} \frac{3f_0(P, n)}{2r \log n} = 1 \quad \text{in probability.}$$

For the circular disk, Groeneboom showed

$$\frac{f_0(B^2, n) - 2\pi c_1 n^{1/3}}{\sqrt{2\pi c_2 n^{1/3}}} \xrightarrow{\mathcal{D}} \mathcal{N}(0, 1)$$

with $c_1 = (\frac{2}{3\pi})^{1/3} \Gamma(\frac{5}{3}) \approx 0.53846$ and c_2 given by an integral which was evaluated numerically. For a polygon P with r vertices, a result of Cabo and Groeneboom [CaG94], in a version suggested by Buchta [Buc02], says that

$$\frac{V_2(P)^{-1} D_2(P, n) - \frac{2}{3}r \frac{\log n}{n}}{\sqrt{\frac{28}{27}r \frac{\log n}{n^2}}} \xrightarrow{\mathcal{D}} \mathcal{N}(0, 1).$$

For the circular disk, a result of Hsing [Hsi94] was made more explicit by Buchta [Buc02] and now gives, as $n \rightarrow \infty$, $\pi^{-2} \text{var} D_2(B^2, n) \sim 2\pi(\frac{1}{3}c_1 + c_2)n^{-5/3}$ and

$$\frac{\pi^{-1} D_2(B^2, n) - 2\pi c_1 n^{-2/3}}{\sqrt{2\pi(\frac{1}{3}c_1 + c_2)n^{-5/3}}} \xrightarrow{\mathcal{D}} \mathcal{N}(0, 1).$$

A thorough study of the asymptotic properties of $D_2(\mu, n)$ and $D_1(\mu, n)$ was presented by Bräker and Hsing [BH98], for rather general distributions μ (including the uniform distribution) concentrated on a convex body K in the plane, where K is either sufficiently smooth and of positive curvature or a polygon. Bräker, Hsing, and Bingham [BHB98] investigated the asymptotic distribution of the Hausdorff distance between a planar convex body K (either smooth or a polygon) and the convex hull of n i.i.d. uniform points in K .

Küfer [Küf94] studied the asymptotic behavior of $D_d(B^d, n)$ and showed, in particular, that its variance is at most of order $n^{-(d+3)/(d+1)}$, as $n \rightarrow \infty$.

Most of the known results about the random variables $\varphi(K, n)$ concern their expectations. Explicit formulas for $\mathbb{E} \varphi(K, n)$ for convex bodies $K \subset \mathbb{R}^d$ and arbitrary $n \geq d + 1$ are known in the cases listed in Table 12.1.2.

TABLE 12.1.2 Expected value of $\varphi(K, n)$.

DIMENSION d	CONVEX BODY K	FUNCTIONAL φ	SOURCES
2	polygon	V_2	Buchta [Buc84a]
2	polygon	f_0	Buchta and Reitzner [BuR97a]
2	ellipse	V_2	Buchta [Buc84b]
3	ellipsoid	V_3	Buchta [Buc84b]
≥ 2	ball	S , mean width, f_{d-1}	Buchta and Müller [BuM84]
≥ 2	ball	V_d	Affentranger [Aff88]

Affentranger’s result is given in the form of an integral, which can be evaluated for given d and n ; it implies the corresponding result for ellipsoids.

A well-known problem, popularized by Klee, is the explicit determination of $\mathbb{E}V_d(T^d, d+1)$ for a d -simplex T^d . Klee’s opinion that $\mathbb{E}V_3(T^3, 4)$ “might yield to brute force” was justified. The result

$$\mathbb{E}V_3(T^3, 4) = \frac{13}{720} - \frac{\pi^2}{15015} = 0.0173982 \dots \quad (12.1.4)$$

was announced by Buchta and Reitzner [BuR92], as well as a more general formula for $\mathbb{E}V_3(T^3, n)$. Independently, (12.1.4) was established by Mannion [Man94], who made heavy use of computer algebra. Finally, Buchta and Reitzner [BuR01] published a readable version of their admirable proof for the formula

$$\mathbb{E}V_3(T^3, n) = p_n - \pi^2 r_n,$$

with explicitly given rational numbers p_n, r_n .

If explicit formulas for $\mathbb{E}\varphi(K, n)$ are not available, one can try to obtain inequalities or asymptotic expansions for increasing n . For $\mathbb{E}V_d(K, n)$, the following estimates are known. The quotient $\mathbb{E}V_d(K, n)/V_d(K)$, for $n \geq d+1$, is minimal for ellipsoids (Groemer). The conjecture that it is maximal for simplices is only proved for $d=2$. (References for these and related results are given in the survey part of [BaS95].) If the convex body $K \subset \mathbb{R}^d$ is not a simplex, then the quotient $\mathbb{E}V_d(K, n)/V_d(K)$ is strictly less than its value for a simplex, for all $n \geq n_0(K)$, see [BáB93]. If $V_d(K) = 1$ and f is a continuous strictly increasing function, the expectation $\mathbb{E}f(V_j(K, n))$ is minimal if K is a ball; this was proved by Hartzoulaki and Paouris [HaP03].

We turn to asymptotic results for expectations. Buchta [Buc84c] considered the perimeter and proved for plane polygons P that

$$\mathbb{E}D_1(P, n) = c(P) \left(\frac{n}{V_2(P)} \right)^{-1/2} + o(n^{\epsilon-1})$$

for any fixed $\epsilon > 0$, where the constant $c(P)$ is given explicitly in terms of the angles of P . For a convex polygon P with r vertices (and area one), Buchta and Reitzner [BuR97a] obtained

$$\mathbb{E}f_0(P, n) = \frac{2r}{3} \log n + c_0(P) + \frac{c_1(P)}{n} + \frac{c_2(P)}{n^2} + \dots$$

as $n \rightarrow \infty$, with explicit constants $c_i(K)$; this strengthens a result of Rényi and Sulanke. Further work of the latter authors for the plane is described in [Sch88,

Section 5], as well as some particular results for $\mathbb{R}^d$, in part superseded by the following ones. For d -dimensional polytopes P , Bárány and Buchta [BáB93] were able to show that

$$\mathbb{E}f_0(P, n) = \frac{T(P)}{(d+1)^{d-1}(d-1)!} \log^{d-1} n + O(\log^{d-2} n \log \log n), \quad (12.1.5)$$

where $T(P)$ denotes the number of chains $F_0 \subset F_1 \subset \dots \subset F_{d-1}$ where F_i is an i -dimensional face of P . They establish a corresponding relation for the volume, from which (12.1.5) follows by (12.1.3). This work was the culmination of a series of papers by other authors, among them Affentranger and Wieacker [AfW91], who settled the case of simple polytopes, which is applied in [BáB93]. Bárány and Buchta mention that their methods permit one to extend (12.1.5) to $\mathbb{E}f_k(P, n)$ for $k = 0, \dots, d-1$, with the denominator replaced by a constant depending on d and k .

For convex bodies $K \subset \mathbb{R}^d$ with a boundary of class C^3 and positive Gauss-Kronecker curvature κ , Bárány [Bár92] obtained relations of the form

$$\mathbb{E}D_j(K, n) = c_2^{(j,d)}(K)n^{-2/(d+1)} + O(n^{-3/(d+1)} \log^2 n) \quad (12.1.6)$$

for $j = 1, \dots, d$. For $j = 1$, such a result (with explicit $c_2^{(1,d)}$) was obtained earlier by Schneider and Wieacker [ScWi80]. For simplicity, one can assume that $V_d(K) = 1$. Then, for $j = d$, the coefficient is given by

$$c_2^{(d,d)}(K) = c_2^{(d,d)} \int_{\partial K} \kappa^{1/(d+1)} dS$$

and thus is a constant multiple ($c_2^{(d,d)}$ depending only on d) of the affine surface area of K . The limit relation

$$\lim_{n \rightarrow \infty} n^{2/(d+1)} \mathbb{E}D_d(K, n) = c_2^{(d,d)} \int_{\partial K} \kappa^{1/(d+1)} dS$$

was extended by Schütt [Schü94] to arbitrary convex bodies (of volume one), with the Gauss-Kronecker curvature generalized accordingly. The other coefficients $c_2^{(j,d)}(K)$ in (12.1.6) are given by

$$c_2^{(j,d)}(K) = c_2^{(j,d)} \int_{\partial K} \kappa^{1/(d+1)} H_{d-j} dS,$$

where H_{d-j} denotes the $(d-j)$ th normalized elementary symmetric function of the principal curvatures of ∂K and $c_2^{(j,d)}$ depends only on j and d . These values were given by Reitzner [Rei01b], thus correcting the coefficients shown in [Bár92].

Under stronger differentiability assumptions, more precise asymptotic expansions are possible. If K has a boundary of class C^{k+3} , $k \geq 2$, and positive curvature (and is of volume one), then

$$\begin{aligned} \mathbb{E}D_j(K, n) \\ = c_2^{(j,d)}(K)n^{-2/(d+1)} + \dots + c_k^{(j,d)}(K)n^{-k/(d+1)} + O(n^{-(k+1)/(d+1)}) \end{aligned}$$

as $n \rightarrow \infty$, where additional information on the coefficients is available. This was proved by Reitzner [Rei01b] (for $d = j = 2$, see also Reitzner [Rei01a]). Under the same assumptions on K , Gruber [Gru96] had obtained earlier an analogous asymptotic expansion for $\eta(C) - \mathbb{E}\eta(C, n)$, where $\eta(C)$ is the value of the support function of the convex body C at a given vector $u \in S^{d-1}$.

For general convex bodies K , the approximation behavior is typically irregular, hence the main interest will be in sharp estimates. A first result concerns V_1 (essentially the mean width). For a convex body $K \subset \mathbb{R}^d$, Schneider [Sch87] showed the existence of positive constants $a_1(K), a_2(K)$ such that

$$a_1(K)n^{-2/(d+1)} < \mathbb{E}D_1(K, n) < a_2(K)n^{-1/d} \quad (12.1.7)$$

for $n \in \mathbb{N}$. Smooth bodies (left) and polytopes (right) show that the orders are best possible.

For general convex bodies K , a powerful method for investigating the polytopes $K_n := \text{conv}\{X_1, \dots, X_n\}$, for i.i.d. uniform points $X_1, \dots, X_n$ in K , was invented by Bárány and Larman [BáL88]. For K of volume one and for sufficiently small $t > 0$, they introduced the floating body $K[t] := \{x \in K \mid V_d(K \cap H) \geq t \text{ for every halfspace } H \text{ with } x \in H\}$. Their main result says that K_n and $K[1/n]$ approximate K of the same order and that $K \setminus K_n$ is close to $K \setminus K[1/n]$ in a precise sense. From this, several results on the expectations $\mathbb{E}\varphi(K, n)$ for various φ were obtained by Bárány and Larman [BáL88], by Bárány [Bár89], for example

$$c_1(d)(\log n)^{d-1} < \mathbb{E}f_j(K, n) < c_2(d)n^{(d-1)/(d+1)} \quad (12.1.8)$$

for $j \in \{0, \dots, d\}$ with positive constants $c_i(d)$ (the orders are best possible), and by Bárány and Vitale [BáV93].

The inequalities (12.1.7) show that for general K the approximation, measured in terms of $D_1(K, \cdot)$, is not worse than for polytopes and not better than for smooth bodies. For approximation measured by $D_d(K, \cdot)$, the class of polytopes and the class of smooth bodies interchange their roles, since

$$b_1(K)n^{-1}(\log n)^{d-1} < \mathbb{E}D_d(K, n) < b_2(K)n^{-2/(d+1)},$$

as follows from [BáL88] (or from (12.1.8) for $j = 0$ and (12.1.3)). This observation lends additional interest to Problem 12.1.3 below.

OPEN PROBLEMS

PROBLEM 12.1.1 (Valtr [Val96])

Is it true, for a convex body $K \subset \mathbb{R}^2$ and for $n \geq 4$, that $\mathbb{E}\psi_n(K, n)$, the probability that n uniform i.i.d. points in K are in convex position, is minimal if K is a triangle and maximal if K is an ellipse?

PROBLEM 12.1.2

For a convex body $K \subset \mathbb{R}^d$ with a boundary of class C^3 and positive Gauss-Kronecker curvature κ , and for the numbers of k -faces, one expects that

$$\mathbb{E}f_k(K, n) = b(d, k) \int_{\partial K} \kappa^{1/(d+1)} dS \left(\frac{n}{V_d(K)} \right)^{(d-1)/(d+1)} (1 + o(1)) \quad (12.1.9)$$

with a constant $b(d, k)$. For $k = 0$, this follows from (12.1.6); for $k = d - 1$ (which implies the case $k = d - 2$) the result goes back to Raynaud and Wieacker; see [Bár92] and [Sch88, p. 222] for references.

PROBLEM 12.1.3 (Bárány [Bár89])

Is it true for a general convex body $K \subset \mathbb{R}^d$ that the surface area satisfies

$$c_1(K)n^{-1/2} < \mathbb{E}D_{d-1}(K, n) < c_2(K)n^{-2/(d+1)}$$

with positive constants $c_1(K), c_2(K)$?

12.1.4 RANDOM POINTS ON CONVEX SURFACES

If μ is a probability distribution on the boundary ∂K of a convex body K and μ has density h with respect to the area measure of ∂K , we write $\varphi(\mu, n) =: \varphi(\partial K, h, n)$ and $D_j(\partial K, h, n) := V_j(K) - V_j(\partial K, h, n)$. Some references concerning $\mathbb{E}\varphi(\partial K, h, n)$ are given in [Sch88, p. 224]. Most of them are superseded by an investigation of Reitzner [Rei02a]. For K with a boundary of class C^2 and positive Gauss curvature, $j \in \{1, \dots, d\}$, and continuous $h > 0$, he showed that

$$\mathbb{E}D_j(\partial K, h, n) = b_2^{(j,d)} \int_{\partial K} h^{-2/(d-1)} \kappa^{1/(d-1)} H_{d-j} dS \cdot n^{-2/(d-1)} + o(n^{-2/(d-1)})$$

as $n \rightarrow \infty$. Under stronger differentiability assumptions on K and h , an asymptotic expansion with more terms was established. Similar results for support functions were obtained earlier by Gruber [Gru96].

For $j = d$, there is an asymptotic relation for general convex bodies K satisfying only a weak regularity assumption. In a long and intricate proof, Schütt and Werner [ScWe03] proved that

$$\lim_{n \rightarrow \infty} n^{2/(d-1)} \mathbb{E}D_d(\partial K, h, n) = b_2^{(d,d)} \int_{\partial K} h^{-2/(d-1)} \kappa^{1/(d-1)} dS,$$

provided that the lower and upper curvatures of K are between two fixed positive and finite bounds.

Let $(X_k)_{k \in \mathbb{N}}$ be an i.i.d. sequence of uniform random points on the boundary ∂K of a convex body K . Let δ denote the Hausdorff metric. Dümbgen and Walther [DüW96] showed that $\delta(K, \text{conv}\{X_1, \dots, X_n\})$ is almost surely of order $O((\log n/n)^{1/(d-1)})$ for general K , and of order $O((\log n/n)^{2/(d-1)})$ under a smoothness assumption.

OPEN PROBLEM

PROBLEM 12.1.4

Let $K \subset \mathbb{R}^d$ be a convex body with a boundary of class C^3 and positive Gauss-Kronecker curvature κ . Let $(X_k)_{k \in \mathbb{N}}$ be an i.i.d. sequence of random points in ∂K , the distribution of which has a continuous positive density h with respect to the area measure. We conjecture that

$$\lim_{n \rightarrow \infty} \left(\frac{n}{\log n} \right)^{2/(d-1)} \delta(K, \text{conv}\{X_1, \dots, X_n\}) = \frac{1}{2} \left(\frac{1}{\kappa_{d-1}} \max \frac{\sqrt{\kappa}}{h} \right)^{2/(d-1)}$$

with probability one. For $d = 2$, this is true, and similar results hold with the Hausdorff distance replaced by area or perimeter difference; this was proved by Schneider [Sch88]. For $d > 2$ and with convergence in probability instead of almost sure convergence, the result was proved by Glasauer and Schneider [GlS96].

12.1.5 CONVEX HULLS FOR OTHER DISTRIBUTIONS

Convex hulls of i.i.d. random points have been investigated for each of the distributions listed in Table 12.1.1, and occasionally for more general ones. The following setup has been studied repeatedly. For $0 \leq p \leq r + 1 \leq d - 1$, one considers $r + 1$ independent random points, of which the first p are uniform in the ball B^d and the last $r + 1 - p$ are uniform on the boundary sphere S^{d-1} . Precise information on the moments and the distribution of the r -dimensional volume of the convex hull is available; see the references in [Sch88, pp. 219, 224] and the work of Affentranger [Aff88].

Among spherically symmetric distributions, the beta distributions are particularly tractable. For these, again, the r -dimensional volume of the convex hull of $r + 1$ i.i.d. random points has frequently been studied. We refer to the references given in [Sch88] and Chu [Chu93]. Affentranger [Aff91] determined the asymptotic behavior, as $n \rightarrow \infty$, of the expectation $\mathbb{E}V_j(\mu, n)$, where μ is either the beta type-1 distribution, the uniform distribution in B^d , or the standard normal distribution in $\mathbb{R}^d$. The asymptotic behavior of $\mathbb{E}f_{d-1}(\mu, n)$ was also found for these cases. Further information is contained in the book of Mathai [Mat99].

For normally distributed points in the plane, Hueter [Hue94] proved central limit type results for the number of vertices, the perimeter, and the area of the convex hull. For $d \geq 2$, she obtained in [Hue99] a central limit theorem for $f_0(\mu, n)$, for a class of spherically symmetric distributions μ in $\mathbb{R}^d$ including the normal family. For the normal distribution μ_2 in the plane, Massé [Mas00] derived from [Hue94] that

$$\lim_{n \rightarrow \infty} \frac{f_0(\mu_2, n)}{\sqrt{8\pi \log n}} = 1 \quad \text{in probability.}$$

For the expectations $\mathbb{E}f_k(\mu_d, n)$ ($k \in \{0, \dots, d-1\}$), where μ_d is the standard normal distribution in $\mathbb{R}^d$, one knows that

$$\mathbb{E}f_k(\mu_d, n) \sim \frac{2^d}{\sqrt{d}} \binom{d}{k+1} \beta_{k,d-1} (\pi \log n)^{(d-1)/2} \quad (12.1.10)$$

as $n \rightarrow \infty$, where $\beta_{k,d-1}$ is the interior angle of the regular $(d-1)$ -dimensional simplex at one of its k -dimensional faces. This follows from [Afs92], where the Grassmann approach was used, due to the equivalence of [BaV94] explained in Section 12.1.2. For the Grassmann approach, Vershik and Sporyshev [VeS92] have made a careful study of the asymptotic behavior of the number of k -faces, if k and the dimension d grow linearly with the number n .

Relation (12.1.10) also describes the asymptotic behavior of the number of k -faces of the orthogonal projection of a regular $(n-1)$ -simplex onto a randomly chosen isotropic d -subspace. In a similar investigation, Böröczky and Henk [BöH99] replaced the regular simplex by the regular crosspolytope and found, surprisingly, the same asymptotic behavior.

For more general spherically symmetric distributions μ , the asymptotic behavior of the random variables $\varphi(\mu, n)$ will essentially depend on the tail behavior

of the distribution. Extending work of Carnal (1970), Dwyer [Dwy91] obtained asymptotic estimates for $\mathbb{E}f_0(\mu, n)$, $\mathbb{E}f_{d-1}(\mu, n)$, $\mathbb{E}V_d(\mu, n)$, and $\mathbb{E}S(\mu, n)$. Devroye [Dev91] showed that for any monotone sequence $\omega_n \uparrow \infty$ and for every $\epsilon > 0$, there is a radially symmetric distribution μ in the plane for which $\mathbb{E}f_0(\mu, n) \geq n/\omega_n$ infinitely often and $\mathbb{E}f_0(\mu, n) \leq 4 + \epsilon$ infinitely often. For $\omega_n \uparrow \infty$ strictly increasing and satisfying $\omega_n \leq n$, Massé [Mas99] constructed a distribution μ in the plane such that the variance satisfies $\text{var}f_0(\mu, n) \geq n^2/\omega_n$ infinitely often. Aldous *et al.* [AlFGP91] considered an i.i.d. sequence $(X_k)_{k \in \mathbb{N}}$ in $\mathbb{R}^2$ with a spherically symmetric (or more general) distribution. Under an assumption of slowly varying tail, they determined a limiting distribution for $f_0(\mu, n)$. Massé [Mas00] constructed a distribution μ in the plane for which $\mathbb{E}f_0(\mu, n) \rightarrow \infty$ for $n \rightarrow \infty$, but $(f_0(\mu, n)/\mathbb{E}f_0(\mu, n))_{n \in \mathbb{N}}$ does not converge to 1 in probability.

12.2 RANDOM POINTS – OTHER ASPECTS

For a finite set of points, the relative position of its elements may be viewed under various geometric and combinatorial aspects. For randomly generated point sets, the probabilities of particular configurations may be of interest, but are in general hard to obtain. We list some contributions to problems of this type.

For infinite sets of points in the whole space, the natural generalization of i.i.d. points in a compact domain are homogeneous Poisson processes.

12.2.1 GEOMETRIC CONFIGURATIONS

Bokowski *et al.* [BoRS92] made a simulation study to estimate the probabilities of certain order types, using the Grassmann approach.

Related to k -sets (see [Chapter 1](#) of this Handbook) is the following investigation of Bárány and Steiger [Bás94]. If X is a set of n points in general position in $\mathbb{R}^d$, a subset $S \subset X$ of d points is called a k -simplex if X has exactly k points on one side of the affine hull of S . The authors study $E_d(k, n)$, the expected number of k -simplices for n i.i.d. random points. For continuous spherically symmetric distributions they show that

$$E_d(k, n) \leq c(d)n^{d-1}.$$

Further results concern the uniform distribution in a convex body in $\mathbb{R}^2$.

For a given distribution μ on $\mathbb{R}^2$, let $P_1, \dots, P_j, Q_1, \dots, Q_k$ be i.i.d. points distributed according to μ . Let $p_{jk}(\mu)$ be the probability that the convex hull of $P_1, \dots, P_j$ is disjoint from the convex hull of $Q_1, \dots, Q_k$. Continuing earlier work of L.C.G. Rogers and of Buchta, Buchta and Reitzner [BuR97a] investigated $p_{jk}(\mu)$. For the uniform distribution μ in a convex domain K , they connected $p_{jk}(\mu)$ to equiaffine inner parallel curves of K , found an explicit representation in the case of polygons, and proved, among other results, that

$$\lim_{n \rightarrow \infty} \frac{p_{nn}(\mu)}{n^{3/2}4^{-n}} \geq \frac{8\sqrt{\pi}}{3},$$

with equality if K is centrally symmetric. The investigation was continued by Buchta and Reitzner in [BuR97b].

Various elementary geometric questions can be asked, even about a small number of random points. For example, if three uniform i.i.d. points in a convex body K are given, what is the probability that the triangle formed by them is obtuse, or what is the probability that the circle (almost surely) determined by these points is contained in K ? Known results on probabilities of these types are listed in [BaS95]. The following result is due to Affentranger. The probability that the sphere spanned (almost surely) by $d + 1$ i.i.d. uniform random points in a convex body K is entirely contained in K attains its maximum precisely if K is a ball. In [BaS95] it is shown that the probability that the circumball of $n \geq 2$ i.i.d. uniform points in K is contained in K is maximal if and only if K is a ball. The value of this maximum is $n/(2n - 1)$ if $d = 2$, but is unknown for $d > 2$.

Many special problems are treated, and references are given, in the book of Mathai [Mat99].

12.2.2 SHAPE

Two subsets of $\mathbb{R}^d$ may be said to have the same shape if they differ only by a similarity. D.G. Kendall's theory of shape yields natural probability distributions on shapes of labeled n -tuples of points in $\mathbb{R}^d$. The possible shapes of such n -tuples of points (not all coincident) can canonically be put in one-to-one correspondence with points of a certain topological space, and the resulting "shape spaces" carry natural probability measures. For this extensive theory and its statistical applications, we refer to the survey given by Kendall [Ken89] and to the book of Kendall *et al.* [KeBCL99].

A different approach to more general notions of shape and probability distributions for them is followed by Ambartzumian [Amb90]. He uses factorization of products of invariant measures to obtain corresponding probability densities, for example, for the affine shape of a tetrad of points in the plane.

12.2.3 POINT PROCESSES

The investigations described so far concerned finite systems of random points. For randomly generated infinite discrete point sets, suitable models are provided by stochastic point processes.

GLOSSARY

Locally finite: $M \subset \mathbb{R}^d$ is locally finite if $\text{card}(M \cap B) < \infty$ for every compact set $B \subset \mathbb{R}^d$.

$\mathcal{M}$: The set of all locally finite subsets of $\mathbb{R}^d$.

$\mathcal{M}$: The smallest σ -algebra on $\mathcal{M}$ for which every function $M \mapsto \text{card}(M \cap B)$ is measurable, where $B \subset \mathbb{R}^d$ is a Borel set.

(Simple) point process X on $\mathbb{R}^d$: A measurable map X from some probability space $(\Omega, \mathcal{A}, P)$ into $(\mathcal{M}, \mathcal{M})$.

Distribution of X : The image measure P_X of P under X .

Intensity measure Λ of X : $\Lambda(B) = \mathbb{E} \text{card}(X \cap B)$, for Borel sets $B \subset \mathbb{R}^d$.

Stationary (or **homogeneous**): X is a stationary point process if the distribution P_X is invariant under translations.

The point process X on $\mathbb{R}^d$, with intensity measure Λ (assumed to be finite on compact sets), is a **Poisson process** if, for any finitely many pairwise disjoint Borel sets $B_1, \dots, B_k$, the random variables $\text{card}(X \cap B_1), \dots, \text{card}(X \cap B_k)$ are independent and Poisson distributed. Thus, a Poisson point process X satisfies

$$\text{Prob}\{\text{card}(X \cap B) = k\} = e^{-\Lambda(B)} \frac{\Lambda(B)^k}{k!}$$

for $k \in \mathbb{N}_0$ and every Borel set B . If it is stationary, then the intensity measure Λ is γ times the Lebesgue measure, and the number γ is called the **intensity** of X . Let X be a stationary Poisson process and $C \subset \mathbb{R}^d$ a compact set, and let $k \in \mathbb{N}_0$. Under the condition that exactly k points of the process fall into C , these points are equivalent to k i.i.d. uniform points in C . This fact clearly illustrates the geometric significance of stationary Poisson point processes, as does the following. Consider n i.i.d. uniform points in the ball rB^d . The Poisson process with intensity measure equal to the Lebesgue measure can be considered as the limit process that is obtained if n and r tend to infinity in such a way that $n/V_d(rB^d) \rightarrow 1$.

A detailed study of geometric properties of stationary Poisson processes in the plane was made by Miles [Mil70].

For much of the theory of point processes, the underlying space $\mathbb{R}^d$ can be replaced by a locally compact topological space Σ with a countable base. Of importance for stochastic geometry are, in particular, the cases where Σ is the space of r -flats in $\mathbb{R}^d$ (see [Section 12.3.3](#)) or the space of convex bodies in $\mathbb{R}^d$.

12.3 RANDOM FLATS

Next to random points, randomly generated r -dimensional flats in $\mathbb{R}^d$ are the objects of study in stochastic geometry that are particularly close to discrete geometry. Like convex hulls of random points, intersections of random halfspaces yield random polytopes in a natural way. Random flats through convex bodies as well as infinite arrangements of random hyperplanes give rise to a variety of questions.

12.3.1 RANDOM HYPERPLANES AND HALFSPACES

Intersections of random halfspaces appear as solution sets of systems of linear inequalities with random coefficients. Therefore, such random polyhedra play a role in the average case analysis of linear programming algorithms (see the book by Borgwardt [Bor87] and its bibliography). Under various assumptions on the distribution of the coefficients, one has information on the expected number of vertices of the solution sets. Extending earlier work of Prékopa, Buchta [Buc87a] obtained several estimates, of which the following is an example.

Let $E(v)$ be the expected number of vertices of the polyhedron given by the inequalities $\sum_{i=1}^n a_{ij}x_j \leq b$ ($i = 1, \dots, m$), $x_j \geq 0$ ($j = 1, \dots, n$). If the coefficients a_{ij} are nonnegative and distributed independently, continuously, and symmetrically with respect to the same number $c > 0$, then

$$E(v) = \frac{1}{2^{m-1}} \binom{n}{m} + \frac{m}{2^{m-1}} \binom{n}{m-1} + O(n^{m-2})$$

for $n \rightarrow \infty$. Buchta [Buc87b] also has formulas and estimates for $E(v)$ in the

case of the polyhedron given by $\sum_{j=1}^n a_{ij}x_j \leq 1$ ($i = 1, \dots, m$), where the points $(a_{i1}, \dots, a_{in})$ ($i = 1, \dots, m$) are i.i.d. uniform on the sphere S^{d-1} .

In a certain duality to convex hulls of random points in a convex body, one may consider intersections of halfspaces containing a convex body. Let $K \subset \mathbb{R}^d$ be a convex body with a boundary of class C^3 and with positive Gauss curvature κ ; suppose that $0 \in \text{int } K$ and let $r > 0$. Call a random closed halfspace $H_{u,t}^- := \{x \in \mathbb{R}^d \mid \langle x, u \rangle \leq t\}$ with $u \in S^{d-1}$ and $t > 0$ “ (K, r) -adapted” if the unit normal vector u is uniform on S^{d-1} and the distance t is independent of u and is, for given u , uniform in the interval for which $H_{u,t}^-$ contains K but not rB^d . Let $\mathbb{E}\tilde{V}_d(K, n)$ be the expected volume of the intersection of rB^d with n i.i.d. (K, r) -adapted random halfspaces. Then Kaltenbach [Kal90] proved that

$$\begin{aligned} \mathbb{E}\tilde{V}_d(K, n) - V_d(K) &= c_1(d) \int_{\partial K} \kappa^{1/(d+1)} dS \left(\frac{n}{V_1(rB^d) - V_1(K)} \right)^{-2/(d+1)} + \\ &\quad + O(n^{-3/(d+1)}) + O(r^d(1 - \epsilon)^n) \end{aligned}$$

for $n \rightarrow \infty$, where $0 < \epsilon < 1$ is fixed.

Let $X_1, \dots, X_n$ be i.i.d. random points on the boundary of a smooth convex body K . Let $K_{(n)}$ be the intersection of the supporting halfspaces of K at $X_1, \dots, X_n$ (intersected with some fixed large cube, to make it bounded), and put $D_{(j)}(K, n) := V_j(K_{(n)}) - V_j(K)$. Under the assumption that the distribution of the X_i has a positive density h and that K and h are sufficiently smooth, Böröczky and Reitzner [Bör02] have obtained asymptotic expansions, as $n \rightarrow \infty$, for $\mathbb{E}D_{(j)}(K, n)$ in the cases $j = d, d-1$, and 1.

Let $(X_i)_{i \in \mathbb{N}}$ be a sequence of i.i.d. random points on ∂K , and let $K_{(n)}$ and h be defined as above. If ∂K is of class C^2 and positive curvature and h is positive and continuous, one may ask whether $n^{2/(d-1)}D_{(j)}(K, n)$ converges almost surely to a positive constant, if $n \rightarrow \infty$. For $d = 2$ and $j = 1, 2$, this was shown by Schneider [Sch88]. Reitzner [Rei02b] was able to prove such a result for $d \geq 2$ and $j = d$. He deduced that random approximation, in this sense, is very close to best approximation.

12.3.2 RANDOM FLATS THROUGH CONVEX BODIES

The notion of a uniform random point in a convex body K in $\mathbb{R}^d$ is extended by that of a uniform random r -flat through K . Let $\mathcal{E}_r^d$ be the space of r -dimensional affine subspaces of $\mathbb{R}^d$ with the usual topology and Borel structure ($r \in \{0, \dots, d-1\}$). A random r -flat is a measurable map from some probability space into $\mathcal{E}_r^d$. It is a **uniform (isotropic uniform)** random r -flat through K if its distribution can be obtained from a translation invariant (resp. rigid-motion invariant) measure on $\mathcal{E}_r^d$, by restricting it to the r -flats meeting K and normalizing to a probability measure. (For details, see [WeW93, Section 2] and [ScW00, Chapter 4].)

A random r -flat E (uniform or not) through K generates the random secant $E \cap K$, which has often been studied, particularly for $r = 1$. References are in [ScW92, Chapter 6] and [ScWi93, Section 7]. Finitely many i.i.d. random flats through K lead to combinatorial questions. Associated random variables, such as the number of intersection points inside K if $d = 2$ and $r = 1$, are hard to attack; for work of Sulanke (1965) and Gates (1984) see [ScWi93]. Of special interest is the case of $i \leq d$ i.i.d. uniform hyperplanes $H_1, \dots, H_i$ through a convex body $K \subset \mathbb{R}^d$.

Let $p_i(K)$ denote the probability that the intersection $H_1 \cap \dots \cap H_i$ also meets K . In some special cases, the maximum of this probability (which depends on K and on the distribution of the hyperplanes) is known, but not in general. References for this and related problems and a conjecture are found in [BaS95]. If $N > d$ i.i.d. uniform hyperplanes through K are given, they give rise to a random cell decomposition of $\text{int } K$. For $k \in \{0, \dots, d\}$, the expected number, $\mathbb{E}\nu_k$, of k -dimensional cells of this decomposition is given by

$$\mathbb{E}\nu_k = \sum_{i=d-k}^d \binom{i}{d-k} \binom{N}{i} p_i(K),$$

with $p_i(K)$ as defined above (Schneider [Sch82]). If the hyperplanes are isotropic uniform, then

$$\mathbb{E}\nu_k = \sum_{i=d-k}^d \binom{i}{d-k} \binom{N}{i} \frac{i! \kappa_i}{2^i} \frac{V_i(K)}{V_1^n(K)}.$$

OPEN PROBLEM

PROBLEM 12.3.1

For $i \leq d$ i.i.d. uniform random hyperplanes through a convex body K , find the sharp upper bound for the probability that their intersection also intersects K .

12.3.3 POISSON FLATS

A suitable model for infinite discrete random arrangements of r -flats in $\mathbb{R}^d$ is provided by a point process in the space $\mathcal{E}_r^d$. Stationary Poisson processes are the simplest and geometrically most interesting examples (stationarity again means translation invariance of the distribution). Basic work was done by Miles [Mil71a] and Matheron [Math75]. In the case $r = d-1$, one speaks of a **stationary Poisson hyperplane process**. For a hyperplane process, an i th intersection density Δ_i can be defined, in such a way that, for a Borel set $A \subset \mathbb{R}^d$, the expectation of the total i -dimensional volume inside A of the intersections of any $d-i$ hyperplanes of the process is given by Δ_i times the Lebesgue measure of A . Given the intensity Δ_{d-1} , the maximal i th intersection density Δ_i (for an $i \in \{0, \dots, d-2\}$) is achieved if the process is isotropic (its distribution is rigid-motion invariant); this result is due to Thomas (1984, see [ScW00, Section 4.5]). (His result and method were carried over to deterministic discrete hyperplane systems by Schneider [Sch95].) Similar questions can be asked for stationary Poisson r -flats with $r < d-1$, for example for $2r \geq d$ and intersections of any two r -flats. Here nonisotropic extremal cases occur, such as in the case $r = 2$, $d = 4$ solved by Mecke [Mec88]. Various other cases have been treated; see Mecke [Mec91], Keutel [Keu91], and the references given there.

12.4 RANDOM CONGRUENT COPIES

The following is a typical question on randomly moving sets. Let $K_0, K \subset \mathbb{R}^d$ be given convex bodies. An isotropic random congruent copy of K meeting K_0 is of

the form gK , where g is a random element of the motion group G_d of $\mathbb{R}^d$, and the distribution of g is obtained from the Haar measure on G_d by restricting it to the set $\{g \in G_d \mid K_0 \cap gK \neq \emptyset\}$ and normalizing. Let $K_1, \dots, K_n$ be convex bodies, let $g_i K_i$ be an isotropic random copy of K_i meeting K_0 , and suppose that $g_1, \dots, g_n$ are stochastically independent. What is the probability that the random bodies $g_1 K_1, \dots, g_n K_n$ have a common point inside K_0 ? This question and similar ones can be given explicit answers by means of integral geometry. We refer to the books of Santaló [San76] and of Schneider and Weil [ScW92].

12.5 RANDOM MOSAICS

By a *tessellation* of $\mathbb{R}^d$, or a *mosaic* in $\mathbb{R}^d$, we understand a collection of d -dimensional polytopes such that their union is $\mathbb{R}^d$, the intersection of any two of the polytopes is either empty or a face of each of them, and any bounded set meets only finitely many of the polytopes. A *random mosaic* can be modeled by a point process in the space of convex polytopes, such that the properties above are satisfied almost surely. General references are [Møl89], [MeSSW90, Chapter 3], [WeW93, Section 7], [StKM95, Chapter 10], and [ScW00, Chapter 6].

NOTATION

X	stationary random mosaic in $\mathbb{R}^d$
$X^{(k)}$	process of its k -dimensional faces
$d_j^{(k)}$	density of the j th intrinsic volume of the polytopes in $X^{(k)}$
$\gamma^{(k)}$	$= d_0^{(k)}$, k -face intensity of X
$Z^{(k)}$	typical k -face of X
n_{jk}	expected number of elements of $X^{(k)}$ that are typically incident with a j -face of X

Under a natural assumption on the stationary random mosaic X , the notions of ‘density’ and ‘typical’ exist with a precise meaning. The density $d_j^{(k)}$ is then the intensity $\gamma^{(k)}$ times the expectation of the j th intrinsic volume of the typical k -face $Z^{(k)}$. Here, we can only convey the intuitive idea that one averages over expanding bounded regions of the mosaic and performs a limit procedure. Exact definitions can be found in [ScW00]; we refer also to Chapter 6 of that book for the results listed below and for all the related references.

12.5.1 GENERAL MOSAICS

For arbitrary stationary random mosaics, there are a number of identities relating averages of combinatorial quantities. Basic examples are:

$$\sum_{k=0}^j (-1)^k n_{jk} = 1, \quad \sum_{k=j}^d (-1)^{d-k} n_{jk} = 1, \quad \gamma^{(j)} n_{jk} = \gamma^{(k)} n_{kj},$$
$$\sum_{i=j}^d (-1)^i d_j^{(i)} = 0, \quad \text{and in particular} \quad \sum_{i=0}^d (-1)^i \gamma^{(i)} = 0.$$

If the random mosaic X is normal, meaning that every k -face is contained in exactly $d - k + 1$ d -polytopes of X ($k = 0, \dots, d - 1$), then

$$(1 - (-1)^k) \gamma^{(k)} = \sum_{j=0}^{k-1} (-1)^j \binom{d+1-j}{k-j} \gamma^{(j)}.$$

Lurking in the background are, of course, the polytopal relations of Euler, Dehn-Sommerville, and Gram; see [Chapters 16](#) and [18](#) of this Handbook.

12.5.2 HYPERPLANE TESSELLATIONS

A random mosaic X is called a stationary hyperplane tessellation if it is induced, in the obvious way, by a stationary hyperplane process (as defined in [Section 12.3.3](#)). Such random mosaics have special properties. Under an assumption of general position (satisfied, for example, by Poisson hyperplane processes) one has, for $0 \leq j \leq k \leq d$,

$$d_j^{(k)} = \binom{d-j}{d-k} d_j^{(j)}, \quad \text{in particular} \quad \gamma^{(k)} = \binom{d}{k} \gamma^{(0)},$$

and

$$n_{kj} = 2^{k-j} \binom{k}{j}.$$

A stationary Poisson hyperplane process, satisfying a suitable assumption of non-degeneracy, induces a stationary random mosaic X in general position, called a **Poisson hyperplane mosaic**. In the isotropic case (where the distributions are invariant under rigid motions), X is completely determined by the intensity, $\hat{\gamma}$, of the underlying Poisson hyperplane process. In this case, one has

$$d_j^{(k)} = \binom{d-j}{d-k} \binom{d}{j} \frac{\kappa_{d-1}^{d-j}}{d^{d-j} \kappa_d^{d-j-1} \kappa_j} \hat{\gamma}^{d-j},$$

in particular,

$$\gamma^{(k)} = \binom{d}{k} \frac{\kappa_{d-1}^d}{d^d \kappa_d^{d-1}} \hat{\gamma}^d, \quad \text{and} \quad \mathbb{E} V_j(Z^{(k)}) = \binom{k}{j} \left(\frac{d \kappa_d}{\kappa_{d-1}} \right)^j \frac{1}{\kappa_j \hat{\gamma}^j}.$$

The almost surely unique d -polytope of X containing 0 is called the Poisson zero-cell and denoted by Z_0 . For a stationary Poisson hyperplane mosaic, the inequalities

$$\mathbb{E} V_d(Z_0) \geq d! \kappa_d \left(\frac{2 \kappa_{d-1}}{d \kappa_d} \hat{\gamma} \right)^{-d}$$

and

$$2^d \leq \mathbb{E} f_0(Z_0) \leq 2^{-d} d! \kappa_d^2$$

are valid. In the isotropic case, equality holds in the first and on the right-hand side of the second inequality.

For the typical cell $Z^{(d)}$, the distribution of the inradius I (radius of the largest contained ball) can be determined; it is given by $\text{Prob}\{I(Z^{(d)}) \leq a\} = 1 - \exp(-2\hat{\gamma}a)$ for $a \geq 0$.

12.5.3 VORONOI AND DELAUNAY MOSAICS

A discrete point set in $\mathbb{R}^d$ induces a Voronoi and a Delaunay mosaic (see [Chapter 23](#) for the definitions). Starting from a stationary Poisson point process $\tilde{X}$ in $\mathbb{R}^d$, one obtains in this way a stationary *Poisson-Voronoi mosaic* and *Poisson-Delaunay mosaic*. Both of these are completely determined by the intensity, $\tilde{\gamma}$, of the underlying Poisson process $\tilde{X}$. For a Poisson-Voronoi mosaic and for $k \in \{0, \dots, d\}$, one has

$$d_k^{(k)} = \frac{2^{d-k+1} \pi^{\frac{d-k}{2}} \Gamma\left(\frac{d^2-kd+k+1}{2}\right) \Gamma\left(1 + \frac{d}{2}\right)^{d-k+\frac{k}{d}} \Gamma\left(d-k + \frac{k}{d}\right)}{d(d-k+1)! \Gamma\left(\frac{d^2-kd+k}{2}\right) \Gamma\left(\frac{d+1}{2}\right)^{d-k} \Gamma\left(\frac{k+1}{2}\right)} \tilde{\gamma}^{\frac{d-k}{d}}.$$

In particular, the vertex density is given by

$$\gamma^{(0)} = \frac{2^{d+1} \pi^{\frac{d-1}{2}} \Gamma\left(\frac{d^2+1}{2}\right)}{d^2(d+1) \Gamma\left(\frac{d^2}{2}\right)} \left[\frac{\Gamma\left(1 + \frac{d}{2}\right)}{\Gamma\left(\frac{d+1}{2}\right)} \right]^d \tilde{\gamma}.$$

For many other parameters, their explicit values in terms of $\tilde{\gamma}$ are known, especially in small dimensions.

For a Poisson-Delaunay mosaic one can, in a certain sense, explicitly determine the distribution of the typical d -cell and the moments of its volume.

12.6 SOURCES AND RELATED MATERIAL

SOURCES FOR STOCHASTIC GEOMETRY IN GENERAL

Stoyan, Kendall, and Mecke [StKM95]: A monograph on theoretical foundations and applications of stochastic geometry.

Matheron [Math75]: A monograph on basic models of stochastic geometry and applications of integral geometry.

Santaló [San76]: The classical work on integral geometry and its applications to geometric probabilities.

Schneider and Weil [ScW00]: An introduction to the mathematical models of stochastic geometry, with emphasis on the application of integral geometry and functionals from convexity.

Kendall and Moran [KeM63]: A collection of problems on geometric probabilities.

Solomon [Sol78]: A selection of topics from geometric probability theory.

Mathai [Mat99]: A comprehensive collection of results on geometric probabilities, in particular of those types where analytic calculations lead to explicit results.

Klain and Rota [KIR97]: An introduction to typical results of integral geometry, their interpretations in terms of geometric probabilities, and counterparts of discrete and combinatorial character.

Ambartzumian [Amb90]: Develops a special approach to stochastic geometry via factorization of measures, with various applications.

Moran [Mor66], [Mor69], Little [Lit74], Baddeley [Bad77]: “Notes on recent research in geometrical probability,” useful surveys with many references.

Baddeley [Bad82]: An introduction and reading list for stochastic geometry.

Baddeley [Bad84]: Connections of stochastic geometry with image analysis.

Weil and Wieacker [WeW93]: A comprehensive handbook article on stochastic geometry.

RELATED CHAPTERS

Several topics are outside the scope of this chapter, although they could be subsumed under probabilistic aspects of discrete geometry. Among these are randomization and average-case analysis of geometric algorithms and the probabilistic analysis of optimization problems in Euclidean spaces. Two classical topics of discrete geometry, namely packing and covering, were also excluded, for the reason that the existing probabilistic results are in a spirit rather far from discrete geometry.

Chapters of this Handbook in which these and related topics are covered are:

[Chapter 1: Finite point configurations](#)

[Chapter 2: Packing and covering](#)

[Chapter 16: Basic properties of convex polytopes](#)

[Chapter 18: Face numbers of polytopes and complexes](#)

[Chapter 23: Voronoi diagrams and Delaunay triangulations](#)

[Chapter 40: Randomization and derandomization](#)

[Chapter 46: Mathematical programming](#)

RELEVANT SURVEYS AND FURTHER SOURCES

Some of the topics treated have been the subjects of earlier surveys. The following sources contain references to the excluded topics as well as to work within the scope of this chapter.

13 GEOMETRIC DISCREPANCY THEORY AND UNIFORM DISTRIBUTION

J. Ralph Alexander, József Beck, and William W.L. Chen

INTRODUCTION

A sequence $s_1, s_2, \dots$ in $\mathbf{U} = [0, 1)$ is said to be *uniformly distributed* if, in the limit, the number of s_j falling in any given subinterval is proportional to its length. Equivalently, $s_1, s_2, \dots$ is uniformly distributed if the sequence of equiweighted atomic probability measures $\mu_N(s_j) = 1/N$, supported by the initial N -segments $s_1, s_2, \dots, s_N$, converges weakly to Lebesgue measure on $\mathbf{U}$. This notion immediately generalizes to any topological space with a corresponding probability measure on the Borel sets.

Uniform distribution, as an area of study, originated from the remarkable paper of Weyl [Wey16], in which he established the fundamental result known nowadays as the Weyl criterion (see [Cas57, KN74]). This reduces a problem on uniform distribution to a study of related exponential sums, and provides a deeper understanding of certain aspects of Diophantine approximation, especially basic results such as Kronecker's density theorem. Indeed, careful analysis of the exponential sums that arise often leads to Erdős-Turán-type upper bounds, which in turn lead to quantitative statements concerning uniform distribution.

Today, the concept of uniform distribution has important applications in a number of branches of mathematics such as number theory (especially Diophantine approximation), combinatorics, ergodic theory, discrete geometry, statistics, numerical analysis, etc. In this chapter, we focus on the geometric aspects of the theory.

13.1 UNIFORM DISTRIBUTION OF SEQUENCES

GLOSSARY

Uniformly distributed: Given a sequence $(s_n)_{n \in \mathbb{N}}$, with $s_n \in \mathbf{U} = [0, 1)$, let $Z_N([a, b)) = |\{j \leq N \mid s_j \in [a, b)\}|$. The sequence is uniformly distributed if, for every $0 \leq a < b \leq 1$, $\lim_{N \rightarrow \infty} N^{-1} Z_N([a, b)) = b - a$.

Fractional part: The fractional part $\{x\}$ of a real number x is $x - \lfloor x \rfloor$.

Kronecker sequence: A sequence of points of the form $(\{N\alpha_1\}, \dots, \{N\alpha_k\})_{N \in \mathbb{N}}$ in $\mathbf{U}^k$, where $1, \alpha_1, \dots, \alpha_k \in \mathbb{R}$ are linearly independent over $\mathbb{Q}$.

Discrepancy, or irregularity of distribution: The discrepancy of a sequence

$(s_n)_{n \in \mathbb{N}}$, with $s_n \in \mathbf{U} = [0, 1)$, in a subinterval $[a, b)$ of $\mathbf{U}$, is

$$\Delta_N([a, b)) = |Z_N([a, b)) - N(b - a)|.$$

More generally, the discrepancy of a sequence $(s_n)_{n \in \mathbb{N}}$, with $s_n \in \mathcal{S}$, a topological probability space, in a measurable subset $A \subset \mathcal{S}$, is $\Delta_N(A) = |Z_N(A) - N\mu(A)|$, where $Z_N(A) = |\{j \leq N \mid s_j \in A\}|$.

Aligned rectangle, aligned triangle: A rectangle (resp. triangle) in $\mathbb{R}^2$ two sides of which are parallel to the coordinate axes.

Hausdorff dimension: A set S in a metric space has Hausdorff dimension m , where $0 \leq m \leq +\infty$, if

- (i) for any $0 < k < m$, $\mu_k(S) > 0$;
- (ii) for any $m < k < +\infty$, $\mu_k(S) < +\infty$.

Here, μ_k is the k -dimensional **Hausdorff measure**, given by

$$\mu_k(S) = 2^{-k} \kappa_k \liminf_{\epsilon \rightarrow 0} \left\{ \sum_{i=1}^{\infty} (\text{diam } S_i)^k \mid S \subset \bigcup_{i=1}^{\infty} S_i, \text{diam } S_i \leq \epsilon \right\},$$

where κ_k is the volume of the unit ball in $\mathbb{E}^k$.

Remark. Throughout this chapter, the symbol c will always represent the generic absolute positive constant, depending only on the indicated parameters. The value generally varies from one appearance to the next.

It is not hard to prove that for any irrational number α , the sequence of fractional parts $\{N\alpha\}$ is everywhere dense in $\mathbf{U}$ (here N is the running index). Suppose that the numbers $1, \alpha_1, \dots, \alpha_k$ are linearly independent over $\mathbb{Q}$. Then Kronecker's theorem states that the k -dimensional Kronecker sequence $(\{N\alpha_1\}, \dots, \{N\alpha_k\})$ is dense in the unit k -cube $\mathbf{U}^k$. It is a simple consequence of the Weyl criterion that any such Kronecker sequence is uniformly distributed in $\mathbf{U}^k$, a far stronger result than the density theorem. For example, letting $k = 1$, we see that $\{N\sqrt{2}\}$ is uniformly distributed in $\mathbf{U}$.

Weyl's work led naturally to the question: How rapidly can a sequence in $\mathbf{U}$ become uniformly distributed as measured by the discrepancy $\Delta_N([a, b))$ of subintervals? Here, $\Delta_N([a, b)) = |Z_N([a, b)) - N(b - a)|$, where $Z_N([a, b))$ counts those $j \leq N$ for which s_j lies in $[a, b)$. Thus we see that Δ_N measures the difference between the actual number of s_j in an interval and the expected number. The sequence is uniformly distributed if and only if $\Delta_N(I) = o(N)$ for all subintervals I . The notion of discrepancy immediately extends to any topological probability space, provided there is at hand a suitable collection of measurable sets $\mathcal{J}$ corresponding to the intervals. If A is in $\mathcal{J}$, set $\Delta_N(A) = |Z_N(A) - N\mu(A)|$.

From the works of Hardy, Littlewood, Ostrowski, and others, it became clear that the smaller the partial quotients in the continued fractions of the irrational number α are, the more uniformly distributed the sequence $\{N\alpha\}$ is. For instance, the partial quotients of quadratic irrationals are characterized by being cyclic, hence bounded. Studying the behavior of $\{N\alpha\}$ for these numbers has proved an excellent indicator of what might be optimal for general sequences in $\mathbf{U}$. Here one has $\Delta_N(I) < c(\alpha) \log N$ for all intervals I and integers $N \geq 2$. Unfortunately, one does not have anything corresponding to continued fractions in higher dimensions, and this has been an obstacle to a similar study of Kronecker sequences (see [Bec94]).

Van der Corput gave an alternative construction of a super uniformly distributed sequence of rationals in $\mathbf{U}$ for which $\Delta_N(I) < c \log N$ for all intervals I and integers $N \geq 2$ (see [KN74, p. 127]). He also asked for the best possible estimate in this direction. In particular, he posed:

PROBLEM 13.1.1 *Van der Corput Problem* [vdC35a] [vdC35b]

Can there exist a sequence for which $\Delta_N(I) < c$ for all N and I ?

He conjectured, in a slightly different formulation, that such a sequence could not exist. This conjecture was affirmed by van Aardenne-Ehrenfest [vA-E45], who later showed that for any sequence in $\mathbf{U}$, $\sup_I \Delta_N(I) > c \log \log N / \log \log \log N$ for infinitely many values of N [vA-E49]. Her pioneering work gave the first nontrivial lower bound on the discrepancy of general sequences in $\mathbf{U}$. It is trivial to construct a sequence for which $\sup_I \Delta_N(I) \leq 1$ for infinitely many values of N .

In a classic paper, Roth showed that for any infinite sequence in $\mathbf{U}$, it must be true that $\sup_I \Delta_N(I) > c(\log N)^{1/2}$ for infinitely many N . Finally, in another classic paper, Schmidt used an entirely new method to prove the following result.

THEOREM 13.1.2 *Schmidt* [Sch72b]

The inequality $\sup_I \Delta_N(I) > c \log N$ holds for infinitely many N .

For a more detailed discussion of work arising from the van der Corput conjecture, see [BC87, pp. 3–6].

In light of van der Corput's sequence, as well as $\{N\sqrt{2}\}$, Schmidt's result is best possible. The following problem, which has been described as “excruciatingly difficult,” is a major remaining open question from the classical theory.

PROBLEM 13.1.3

Extend Schmidt's result to a best possible estimate of the discrepancy for sequences in $\mathbf{U}^k$ for $k > 1$.

For a given sequence, the results above do not imply the existence of a fixed interval I in $\mathbf{U}$ for which $\sup_N \Delta_N(I) = \infty$. Let I_α denote the interval $[0, \alpha)$, where $0 < \alpha \leq 1$. Schmidt [Sch72a] showed that for any fixed sequence in $\mathbf{U}$ there are only countably many values of α for which $\Delta_N(I_\alpha)$ is bounded. The best result in this direction is due to Halász.

THEOREM 13.1.4 *Halász* [Hal81]

For any fixed sequence in $\mathbf{U}$, let A denote the set of values of α for which $\Delta_N(I_\alpha) = o(\log N)$. Then A has Hausdorff dimension 0.

For a more detailed discussion of work arising from this question, see [BC87, pp. 10–11].

The fundamental works of Roth and Schmidt opened the door to the study of discrepancy in higher dimensions, and there were surprises. In his classic paper, Roth [Rot54] transformed the heart of van der Corput's problem to a question concerning the unit square $\mathbf{U}^2$. In this new formulation, Schmidt's “log N theorem” implies that if N points are placed in $\mathbf{U}^2$, there is always an aligned rectangle $I = [\gamma_1, \alpha_1) \times [\gamma_2, \alpha_2)$ having discrepancy exceeding $c \log N$. Roth also showed that it was possible to place N points in the square $\mathbf{U}^2$ so that the discrepancy of no aligned rectangle exceeds $c \log N$. One way is to choose $p_j = ((j-1)/N, \{j\sqrt{2}\})$ for $j \leq N$. Thus, the function $c \log N$ describes the *minimax discrepancy* for aligned

rectangles. However, Schmidt showed that there is always an aligned right triangle (the part of an aligned rectangle above, or below, a diagonal) with discrepancy exceeding $cN^{1/4-\epsilon}$! Later work has shown that $cN^{1/4}$ exactly describes the minimax discrepancy of aligned right triangles. This paradoxical behavior is not isolated.

Generally, if one studies a collection $\mathcal{J}$ of “nice” sets such as disks, aligned boxes, rotated cubes, etc., in $\mathbf{U}^k$ or some other convex region, it turns out that the minimax discrepancy is either bounded above by $c(\log N)^r$ or bounded below by cN^s , with nothing halfway. In $\mathbf{U}^k$, typically $s = (k-1)/2k$. Thus, there tends to be a logarithmic version of the Vapnik-Chervonenkis principle in operation (see [Chapter 36](#) of this Handbook for a related discussion). Later, we shall see how certain geometric properties place $\mathcal{J}$ in one or the other of these two classes.

13.2 THE GENERAL FREE PLACEMENT PROBLEM FOR N POINTS

One can ask for bounds on the discrepancy of N variable points $\mathcal{P} = \{p_1, p_2, \dots, p_N\}$ that are freely placed in a domain $\mathbf{K}$ in Euclidean t -space $\mathbb{E}^t$. By contrast, when one considers the discrepancy of a *sequence* in $\mathbf{K}$, the initial n -segment of $p_1, \dots, p_n, \dots, p_N$ remains fixed for $n \leq N$ as new points appear with increasing N . For a given $\mathbf{K}$, as the unit interval $\mathbf{U}$ demonstrates, estimates for these two problems are quite different as functions of N . The freely placed points in $\mathbf{U}$ need never have discrepancy exceeding 1.

With Roth’s reformulation (discussed in Section 13.1), the classical problem is easier to state and, more importantly, it generalizes in a natural manner to a wide class of problems. The bulk of geometric discrepancy problems are now posed as free placement problems. In practically all situations, the domain $\mathbf{K}$ has a very simple description as a cube, disk, sphere, etc., and standard notation is used in the specific situations.

PROBABILITY MEASURES AND DISCREPANCY

In a free placement problem there are two probability measures in play. First, there is the atomic measure μ^+ that assigns weight $1/N$ to each p_j . Second, there is a probability measure μ^- on the Borel sets of $\mathbf{K}$. The measure μ^- is generally the restriction of a natural uniform measure, such as scaled Lebesgue measure. An example would be given by $\mu^- = \sigma/4\pi$ on the unit sphere $\mathbf{S}^2$, where σ is the usual surface measure. It is convenient to define the signed measure $\mu = \mu^+ - \mu^-$ (in the previous section μ^- was denoted by μ). The discrepancy of a Borel set A is, as before, given by $\Delta(A) = |Z(A) - N\mu^-(A)| = N|\mu(A)|$.

The function Δ is always restricted to a very special collection $\mathcal{J}$ of sets, and the challenge lies in obtaining estimates concerning the restricted Δ . It is the central importance of the collection $\mathcal{J}$ that gives the study of discrepancy its distinct character. In a given problem it is sometimes possible to reduce the size of $\mathcal{J}$. Taking the unit interval $\mathbf{U}$ as an example, letting $\mathcal{J}$ be the collection of intervals $[\gamma, \alpha)$ seems to be the obvious choice. But a moment’s reflection shows that only intervals of the form $I_\alpha = [0, \alpha)$ need be considered for estimates of discrepancy. At most a factor of 2 is introduced in any estimate of bounds.

NOTIONS OF DISCREPANCY

In most interesting problems $\mathcal{J}$ itself carries a measure ν in the sense of integral geometry, and this adds much more structure. While there is artistic latitude in the choice of ν , more often than not there is a natural measure on $\mathcal{J}$. In the example of $\mathbf{U}$, by identifying $I_\alpha = [0, \alpha)$ with its right endpoint, it is clear that Lebesgue measure on $\mathbf{U}$ is the natural choice for ν .

Given that the measure ν exists, for $1 \leq W < \infty$ define

$$\|\Delta(\mathcal{P}, \mathcal{J})\|_W = \left(\int_{\mathcal{J}} (\Delta(A))^W d\nu \right)^{1/W} \quad \text{and} \quad \|\Delta(\mathcal{P}, \mathcal{J})\|_\infty = \sup_{\mathcal{J}} \Delta(A),$$

and for $1 \leq W \leq \infty$ define

$$D(\mathbf{K}, \mathcal{J}, W, N) = \inf_{|\mathcal{P}|=N} \{\|\Delta(\mathcal{P}, \mathcal{J})\|_W\}.$$

The determination of the “minimax” $D(\mathbf{K}, \mathcal{J}, \infty, N)$ is generally the most important as well as the most difficult problem in the study. It should be noted that the function $D(\mathbf{K}, \mathcal{J}, \infty, N)$ is defined even if the measure ν is not. The term $D(\mathbf{K}, \mathcal{J}, 2, N)$ has been shown to be intimately related to problems in numerical integration in some special cases, and is of increasing importance. These various functions $D(\mathbf{K}, \mathcal{J}, W, N)$ measure how well the continuous distribution μ^- can be approximated by N freely placed atoms.

The inequality

$$\nu(\mathcal{J})^{-1/W} \|\Delta(\mathcal{P}, \mathcal{J})\|_W \leq \|\Delta(\mathcal{P}, \mathcal{J})\|_\infty \quad (13.2.1)$$

provides a general approach for obtaining a lower bound for $D(\mathbf{K}, \mathcal{J}, \infty, N)$. The choice $W = 2$ has been especially fruitful, but good estimates of $D(\mathbf{K}, \mathcal{J}, W, N)$ for any W are of independent interest.

An upper bound on $D(\mathbf{K}, \mathcal{J}, \infty, N)$ generally is obtained by showing the existence of a favorable example. This may be done either by a direct construction, often extremely difficult to verify, or by a probabilistic argument showing such an example does exist without giving it explicitly. These comments would apply as well to upper bounds for any $D(\mathbf{K}, \mathcal{J}, W, N)$.

13.3 ALIGNED RECTANGLES IN THE UNIT SQUARE

The unit square $\mathbf{U}^2 = [0, 1) \times [0, 1)$ is by far the most thoroughly studied 2-dimensional object. The main reason for this is Roth’s reformulation of the van der Corput problem. Many of the interesting questions that arose have been answered, and we give a summary of the highlights.

For $\mathbf{U}^2$ one wishes to study the discrepancy of rectangles of the type $I = [\gamma_1, \alpha_1) \times [\gamma_2, \alpha_2)$. It is a trivial observation that only those I for which $\gamma_1 = \gamma_2 = 0$ need be considered, and this restricted family, denoted by $\mathcal{B}^2$, is the choice for $\mathcal{J}$. By considering this smaller collection one introduces at most a factor of 4 on bounds. There is a natural measure ν on $\mathcal{B}^2$, which may be identified with Lebesgue measure on $\mathbf{U}^2$ via the upper right corner points (α_1, α_2) . In the same spirit, let $\mathcal{B}^1$ denote the previously introduced collection of intervals $I_\alpha = [0, \alpha)$ in $\mathbf{U}$.

THEOREM 13.3.1 *Roth's Equivalence* [Rot54] [BC87, pp. 6–7]

Let f be a positive increasing function tending to infinity. Then the following two statements are equivalent:

- (i) There is an absolute positive constant c_1 such that for any finite sequence $s_1, s_2, \dots, s_N$ in $\mathbf{U}$, there always exists a positive integer $n \leq N$ such that $\|\Delta(\mathcal{P}_n, \mathcal{B}^1)\|_\infty > c_1 f(N)$. Here, $\mathcal{P}_n$ is the initial n -segment.
- (ii) There is an absolute positive constant c_2 such that for all positive integers N , $D(\mathbf{U}^2, \mathcal{B}^2, \infty, N) > c_2 f(N)$.

The equivalence shows that the central question of bounds for the van der Corput problem can be replaced by an elegant problem concerning the free placement of N points in the unit square $\mathbf{U}^2$. The mapping $s_j \rightarrow ((j-1)/N, s_j)$ plays a role in the proof of this equivalence. If one takes as $\mathcal{P}_N$ the image in $\mathbf{U}^2$ under the mapping of the initial N -segment of the van der Corput sequence, the following upper bound theorem may be proved.

THEOREM 13.3.2 *Lerch* [BC87, Theorem 4, $K = 2$]

For $N \geq 2$,

$$D(\mathbf{U}^2, \mathcal{B}^2, \infty, N) < c \log N. \quad (13.3.1)$$

The corresponding lower bound is established by the important “log N theorem” of Schmidt.

THEOREM 13.3.3 *Schmidt* [Sch72b] [BC87, Theorem 3B]

One has

$$D(\mathbf{U}^2, \mathcal{B}^2, \infty, N) > c \log N. \quad (13.3.2)$$

By an explicit lattice construction, Davenport [Dav56] gave the best possible upper bound estimate for $W = 2$. His analysis shows that if the irrational number α has continued fractions with bounded partial quotients, then the $N = 2M$ points in $\mathbf{U}^2$ given by

$$p_j^\pm = ((j-1)/M, \{\pm j\alpha\}), \quad j \leq M,$$

can be taken as $\mathcal{P}$ in proving the following theorem. Other proofs have been given by Vilenkin [Vil67], Halton and Zaremba [HZ69], and Roth [Rot76].

THEOREM 13.3.4 *Davenport* [Dav56] [BC87, Theorem 2A]

For $N \geq 2$,

$$D(\mathbf{U}^2, \mathcal{B}^2, 2, N) < c(\log N)^{1/2}. \quad (13.3.3)$$

This complements the following lower bound obtained by Roth in his classic paper.

THEOREM 13.3.5 *Roth* [Rot54] [BC87, Theorem 1A, $K = 2$]

One has

$$D(\mathbf{U}^2, \mathcal{B}^2, 2, N) > c(\log N)^{1/2}. \quad (13.3.4)$$

For $W = 1$, an upper bound $D(\mathbf{U}^2, \mathcal{B}^2, 1, N) < c(\log N)^{1/2}$ follows at once from Davenport's bound (13.3.3) by the monotonicity of $D(\mathbf{U}^2, \mathcal{B}^2, W, N)$ as a function of W . The corresponding lower bound was obtained by Halász more recently.

THEOREM 13.3.6 *Halász* [Hal81] [BC87, Theorem 1C, $K = 2$]

One has

$$D(\mathbf{U}^2, \mathcal{B}^2, 1, N) > c(\log N)^{1/2}. \quad (13.3.5)$$

Halász (see [BC87, Theorem 3C]) deduced that there is always an aligned square of discrepancy larger than $c \log N$. Of course, the square generally will not be a member of the special collection $\mathcal{B}^2$. Ruzsa [Ruz93] has given a clever elementary proof that the existence of such a square follows directly from inequality (13.3.2) above.

The ideas developed in the study of discrepancy can be applied to approximations of integrals. We briefly mention two examples, both restricted to 2 dimensions for the sake of simplicity.

A function ψ is termed ***M-simple*** if $\psi(x) = \sum_{j=1}^M m_j \chi_{B_j}(x)$, where χ_{B_j} is the characteristic function of the aligned rectangle B_j . In this theorem, the lower bounds are nontrivial because of the logarithmic factors coming from discrepancy theory on $\mathbf{U}^2$.

THEOREM 13.3.7 *Chen* [Che85] [Che87] [BC87, Theorems 5A, 5C]

Let the function f be defined on $\mathbf{U}^2$ by $f(x) = C + \int_{B(x)} g(y) dy$ where C is a constant, g is nonzero on a set of positive measure in $\mathbf{U}^2$, and $B(x_1, x_2) = [0, x_1) \times [0, x_2)$. Then, for any M -simple function ψ ,

$$\begin{aligned} \|f - \psi\|_W &> c(f, W) M^{-1} (\log M)^{1/2}, \quad 1 \leq W < \infty; \\ \|f - \psi\|_\infty &> c(f) M^{-1} \log M. \end{aligned}$$

Let $\mathcal{C}$ be the class of all continuous real valued functions on $\mathbf{U}^2$, endowed with the Wiener sheet measure ω . For every function $f \in \mathcal{C}$ and every set $\mathcal{P}$ of N points in $\mathbf{U}^2$, let

$$I(f) = \int_{\mathbf{U}^2} f(x) dx \quad \text{and} \quad U(\mathcal{P}, f) = \frac{1}{N} \sum_{p \in \mathcal{P}} f(p).$$

THEOREM 13.3.8 *Woźniakowski* [Woz91]

One has

$$\inf_{|\mathcal{P}|=N} \left(\int_{\mathcal{C}} |U(\mathcal{P}, f) - I(f)|^2 d\omega \right)^{1/2} = \frac{D(\mathbf{U}^2, \mathcal{B}^2, 2, N)}{N}.$$

13.4 ALIGNED BOXES IN A UNIT k -CUBE

The van der Corput problem led to the study of $D(\mathbf{U}^2, \mathcal{B}^2, W, N)$, which in turn led to the study of $D(\mathbf{U}^k, \mathcal{B}^k, W, N)$ for general positive integers k and real $W \geq 1$. Here, $\mathcal{B}^k$ denotes the collection of boxes $I = [0, \alpha_1) \times \dots \times [0, \alpha_k)$, and the measure ν is identified with Lebesgue measure on $\mathbf{U}^k$ via the corner points $(\alpha_1, \dots, \alpha_k)$.

The principle of Roth's equivalence extends so that the discrepancy problem for sequences in $\mathbf{U}^k$ reformulates as a free placement problem in $\mathbf{U}^{k+1}$, so that we discuss only the latter version. Inequalities (13.3.1)–(13.3.5) give the exact order of magnitude of $D(\mathbf{U}^2, \mathcal{B}^2, W, N)$ for the most natural values of W , namely

$1 \leq W \leq 2$ and $W = \infty$, with the latter being top prize. While much is known, knowledge of $D(\mathbf{U}^k, \mathcal{B}^k, W, N)$ is incomplete, especially for $W = \infty$, while there is ongoing work on the case $W = 1$ which may lead to its complete solution. It should be remarked that if k and N are fixed, then $D(\mathbf{U}^k, \mathcal{B}^k, W, N)$ is a nondecreasing function of W for $1 \leq W \leq \infty$.

As was indicated earlier, upper bound methods generally fall into two classes, explicit constructions and probabilistic existence arguments. In practice, careful constructions are made prior to a probabilistic averaging process. Chen's proof of the following upper bound theorem involved extensive combinatorial and number-theoretic constructions as well as probabilistic considerations.

THEOREM 13.4.1 *Chen* [Che80] [BC87, Theorem 2D]

For W satisfying $1 \leq W < \infty$, and integers $k \geq 2$ and $N \geq 2$,

$$D(\mathbf{U}^k, \mathcal{B}^k, W, N) < c(W, k)(\log N)^{(k-1)/2}. \quad (13.4.1)$$

A second proof was given by Chen [Che83] (see also [BC87, Section 3.5]). Earlier, Roth [Rot80] (see also [BC87, Theorem 2C]) treated the case $W = 2$. The inequality (13.4.1) highlights one of the truly baffling aspects of the theory, namely the apparent jump discontinuity in the asymptotic behavior of $D(\mathbf{U}^k, \mathcal{B}^k, W, N)$ at $W = \infty$. This discontinuity is most dramatically established for $k = 2$, but is known to occur for any $k \geq 3$ (see (13.4.3) below).

Explicit multidimensional sequences greatly generalizing the van der Corput sequence also have been used to obtain upper bounds for $D(\mathbf{U}^k, \mathcal{B}^k, \infty, N)$. Halton constructed explicit point sets in $\mathbf{U}^k$ in order to prove the next theorem. Faure (see [BC87, Section 3.2]) gave a different proof of the same result. If $k = 2$ is a guide, Halton's result may in fact be the best possible.

THEOREM 13.4.2 *Halton* [Hal60] [BC87, Theorem 4]

For integers $k \geq 2$ and $N \geq 2$,

$$D(\mathbf{U}^k, \mathcal{B}^k, \infty, N) < c(k)(\log N)^{k-1}. \quad (13.4.2)$$

In order to prove (13.3.3), Davenport used properties of special lattices; but only very recently has there been further success with lattices in higher dimensions. Skriganov has established some most interesting results, which imply the following theorem. Given a region, a lattice is termed **admissible** if the region contains no member of the lattice except possibly the origin (see [Cas59]). Examples for the following theorem are given by lattices arising from algebraic integers in totally real algebraic number fields.

THEOREM 13.4.3 *Skriganov* [Skr94]

Suppose Γ is a fixed k -dimensional lattice admissible for the region $|x_1 x_2 \dots x_k| < 1$.

- (i) *Halton's upper bound inequality (13.4.2) holds if the N points are obtained by intersecting $\mathbf{U}^k$ with $t\Gamma$, where $t > 0$ is a suitably chosen real scalar.*
- (ii) *With the same choice of t as in part (i), there exists $x \in \mathbb{E}^k$ such that Chen's upper bound inequality (13.4.1) holds if the N points are obtained by intersecting $\mathbf{U}^k$ with $t\Gamma + x$.*

Recently, using p -adic Fourier-Walsh analysis together with ideas originating from coding theory, Chen and Skriganov [CS02] have obtained explicit constructions that give (13.4.1) in the special case $W = 2$, with an explicitly given constant $c(2, k)$.

Moving to lower bound estimates, the following theorem of Schmidt is complemented by Chen's result (13.4.1). For $W \geq 2$ this lower bound is due to Roth, since D is monotone in W .

THEOREM 13.4.4 *Schmidt* [Sch77a] [BC87, Theorem 1B]

For $W > 1$ and integers $k \geq 2$,

$$D(\mathbf{U}^k, \mathcal{B}^k, W, N) > c(W, k)(\log N)^{(k-1)/2}.$$

Concerning $W = 1$, there is the result of Halász, which is probably not optimal. It is reasonably conjectured that $(k-1)/2$ is the correct exponent. There is ongoing work which may lead to its complete solution.

THEOREM 13.4.5 *Halász* [Hal81] [BC87, Theorem 1C]

For integers $k \geq 2$,

$$D(\mathbf{U}^k, \mathcal{B}^k, 1, N) > c(k)(\log N)^{1/2}.$$

The next lower bound estimate belongs to Baker. Although probably not best possible, it firmly establishes a discontinuity in asymptotic behavior at $W = \infty$ for all $k \geq 3$.

THEOREM 13.4.6 *Baker* [Bak99]

For integers $k \geq 3$ and $N > 20$,

$$D(\mathbf{U}^k, \mathcal{B}^k, \infty, N) > c(k)(\log N)^{(k-1)/2}(\log \log N)^{c_k}. \quad (13.4.3)$$

In fact, the exponent c_3 can be taken to be any positive real number less than $1/4$. Earlier, Beck [Bec89] had established a slightly weaker lower bound for the case $k = 3$, where c_3 can be taken to be any positive real number less than $1/8$. The work of Beck and Baker represents the first improvement of Roth's lower bound

$$D(\mathbf{U}^k, \mathcal{B}^k, \infty, N) > c(k)(\log N)^{(k-1)/2},$$

established over 30 years ago.

Can the factor $1/2$ be removed from the exponent? This is the "great open problem." However, Beck has refined Roth's estimate in a geometric direction.

THEOREM 13.4.7 *Beck* [BC87, Theorem 19A]

Let $\mathcal{J}$ be the collection of aligned cubes contained in $\mathbf{U}^k$. Then

$$D(\mathbf{U}^k, \mathcal{J}, \infty, N) > c(k)(\log N)^{(k-1)/2}. \quad (13.4.4)$$

Actually, Beck's method shows $D(\mathbf{U}^k, \mathcal{J}, 2, N) > c(k)(\log N)^{(k-1)/2}$, with respect to a natural measure ν on sets of aligned cubes. This improves Roth's inequality $D(\mathbf{U}^k, \mathcal{B}^k, 2, N) > c(k)(\log N)^{(k-1)/2}$. So far, it has not been possible to extend Ruzsa's ideas to higher dimensions in order to show that the previous theorem follows directly from Roth's estimate. However, more recently, Drmota [Drm96] has published a new proof that $D(\mathbf{U}^k, \mathcal{J}, 2, N) > c(k)D(\mathbf{U}^k, \mathcal{B}^k, 2, N)$, and this does imply (13.4.4).

13.5 MOTION-INVARIANT PROBLEMS

In this section and the next three, we discuss collections $\mathcal{J}$ of convex sets having the property that any set in $\mathcal{J}$ may be moved by a direct (orientation preserving) motion of $\mathbb{E}^k$ and yet remain in $\mathcal{J}$. Motion-invariant problems were first extensively studied by Schmidt, and many of his estimates, obtained by a difficult technique using integral equations, were close to best possible. The book [BC87] contains an account of Schmidt's methods. But more recently, the Fourier transform method of Beck has achieved results that in general surpass those obtained by Schmidt. For a broad class of problems, Beck's Fourier method gives nearly best possible estimates for $D(\mathbf{K}, \mathcal{J}, 2, N)$.

The pleasant surprise is that if $\mathcal{J}$ is motion-invariant, then the bounds on $D(\mathbf{K}, \mathcal{J}, \infty, N)$ turn out to be very close to those for $D(\mathbf{K}, \mathcal{J}, 2, N)$. This is shown by a probabilistic upper bound method, which generally pins $D(\mathbf{K}, \mathcal{J}, \infty, N)$ between bounds differing at most by a factor of $c(k)(\log N)^{1/2}$.

The simplest motion-invariant example is given by letting $\mathcal{J}$ be the collection of all directly congruent copies of a given convex set A . In this situation, $\mathcal{J}$ carries a natural measure ν , which may be identified with Haar measure on the motion group on $\mathbb{E}^k$. A broader choice would be to let $\mathcal{J}$ be all sets in $\mathbb{E}^k$ directly similar to A . Again, there is a natural measure ν on $\mathcal{J}$. However, for the results stated in the next two sections, the various measures ν on the choices for $\mathcal{J}$ will not be discussed in great detail. In most situations, such measures do play an active role in the proofs through inequality (13.2.1) with $W = 2$. A complete exposition of integration in the context of integral geometry, Haar measure, etc., may be found in the book by Santaló [San76].

For any domain $\mathbf{K}$ in $\mathbb{E}^t$ and each collection $\mathcal{J}$, it is helpful to define three auxiliary collections:

Definition:

- (i) $\mathcal{J}_{tor}$ consists of those subsets of $\mathbf{K}$ obtained by reducing elements of $\mathcal{J}$ modulo $\mathbb{Z}^k$. To avoid messiness, let us always suppose that $\mathcal{J}$ has been restricted so that this reduction is 1-1 on each member of $\mathcal{J}$. For example, one might consider only those members of $\mathcal{J}$ having diameter less than 1.
- (ii) $\mathcal{J}_c$ consists of those subsets of $\mathbf{K}$ that are members of $\mathcal{J}$.
- (iii) $\mathcal{J}_i$ consists of those subsets of $\mathbf{K}$ obtained by intersecting $\mathbf{K}$ with members of $\mathcal{J}$.

Note that $\mathcal{J}_c$ and $\mathcal{J}_i$ are well defined for any domain $\mathbf{K}$. However, $\mathcal{J}_{tor}$ essentially applies only to $\mathbf{U}^k$. If viewed as a flat torus, then $\mathbf{U}^k$ is the proper domain for Kronecker sequences and Weyl's exponential sums. There are several general inequalities for discrepancy results involving $\mathcal{J}_{tor}$, $\mathcal{J}_c$, and $\mathcal{J}_i$. For example, we have $D(\mathbf{U}^k, \mathcal{J}_c, \infty, N) \leq D(\mathbf{U}^k, \mathcal{J}_{tor}, \infty, N)$ because $\mathcal{J}_c$ is contained in $\mathcal{J}_{tor}$. Also, if the members of $\mathcal{J}$ have diameters less than 1, then we have $D(\mathbf{U}^k, \mathcal{J}_{tor}, \infty, N) \leq 2^k D(\mathbf{U}^k, \mathcal{J}_i, \infty, N)$, since any set in $\mathcal{J}_{tor}$ is the union of at most 2^k sets in $\mathcal{J}_i$.

13.6 SIMILAR OBJECTS IN THE UNIT k -CUBE

GLOSSARY

If A is a compact convex set in $\mathbb{E}^k$, let $d(A)$ denote the diameter of A , $r(A)$ denote the radius of the largest k -ball contained in A , and $\sigma(\partial A)$ denote the surface content of ∂A . The collection $\mathcal{J}$ is said to be **ds-generated** by A if $\mathcal{J}$ consists of all directly similar images of A having diameters not exceeding $d(A)$.

We state two pivotal theorems of Beck. As usual, if $\mathcal{S}$ is a discrete set, $Z(B)$ denotes the cardinality of $B \cap \mathcal{S}$.

THEOREM 13.6.1 *Beck* [Bec87] [BC87, Theorem 17A]

Let $\mathcal{S}$ be an arbitrary infinite discrete set in $\mathbb{E}^k$, A be a compact convex set with $r(A) \geq 1$, and $\mathcal{J}$ be ds-generated by A . Then there is a set B in $\mathcal{J}$ such that

$$|Z(B) - \text{vol } B| > c(k)(\sigma(\partial A))^{1/2}. \quad (13.6.1)$$

COROLLARY 13.6.2 *Beck* [BC87, Corollary 17B]

Let A be a compact convex body in $\mathbb{E}^k$ with $r(A) \geq N^{-1/k}$, and let $\mathcal{J}$ be ds-generated by A . Then

$$D(\mathbf{U}^k, \mathcal{J}_{\text{tor}}, \infty, N) > c(A)N^{(k-1)/2k}. \quad (13.6.2)$$

The deduction of Corollary 13.6.2 from Theorem 13.6.1 involves a simple rescaling argument. Another important aspect of Beck's work is the introduction of upper bound methods based on probabilistic considerations. The following result shows that Theorem 13.6.1 is very nearly best possible.

THEOREM 13.6.3 *Beck* [BC87, Theorem 18A]

Let A be a compact convex body in $\mathbb{E}^k$ with $r(A) \geq 1$, and let $\mathcal{J}$ be ds-generated by A . Then there exists an infinite discrete set $\mathcal{S}_0$ such that for every set B in $\mathcal{J}$,

$$|Z(B) - \text{vol } B| < c(k)(\sigma(\partial A))^{1/2}(\log \sigma(\partial A))^{1/2}. \quad (13.6.3)$$

COROLLARY 13.6.4 *Beck* [BC87, Corollary 18C]

Let A be a compact convex body in $\mathbb{E}^k$, and $\mathcal{J}$ be ds-generated by A . Then

$$D(\mathbf{U}^k, \mathcal{J}_{\text{tor}}, \infty, N) < c(A)N^{(k-1)/2k}(\log N)^{1/2}. \quad (13.6.4)$$

Beck (see [BC87, pp. 129–130]) deduced several related corollaries from Theorem 13.6.3. The example sets $\mathcal{P}_N$ for Corollary 13.6.4 can be taken as the initial segments of a certain fixed sequence whose choice definitely depends on A . If $d(A) = \lambda$ and A is either a disk (solid sphere) or a cube, then the right side of (13.6.2) takes the form $c(k)(\lambda^k N)^{(k-1)/2k}$. Montgomery [Mon89] has obtained a similar lower bound for cubes and disks.

The problem of estimating discrepancy for $\mathcal{J}_c$ is even more challenging because of “boundary effects.” We state, as an example, a theorem for disks. The right inequality follows from (13.6.4).

THEOREM 13.6.5 *Beck* [Bec87] [BC87, Theorem 16A]

Let $\mathcal{J}$ be ds -generated by a k -disk. Then

$$c_1(k, \epsilon)N^{(k-1)/2k-\epsilon} < D(\mathbf{U}^k, \mathcal{J}_\epsilon, \infty, N) < c_2(k)N^{(k-1)/2k}(\log N)^{1/2}. \quad (13.6.5)$$

Because all the lower bounds above come from $\mathbf{L}^2$ estimates, these various results (13.6.1)–(13.6.5) allow us to make the general statement that for W in the range $2 \leq W \leq \infty$, the magnitude of $D(\mathbf{U}^k, \mathcal{J}, W, N)$ is controlled by $N^{(k-1)/2k}$. Thus there is no extreme discontinuity in asymptotic behavior at $W = \infty$. However, recent work by Beck and Chen proves that there is a discontinuity at some W satisfying $1 \leq W \leq 2$, and the following results indicate that $W = 1$ is a likely candidate.

THEOREM 13.6.6 *Beck, Chen* [BC93b]

Let $\mathcal{J}$ be ds -generated by a convex polygon A with $d(A) < 1$. Then

$$\begin{aligned} D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, W, N) &< c(A, W)N^{(W-1)/2W}, & 1 < W \leq 2; \\ D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, 1, N) &< c(A)(\log N)^2. \end{aligned} \quad (13.6.6)$$

In fact, Theorem 13.6.6 is motivated by the study of discrepancy with respect to halfplanes, and is established by ideas used to establish Theorem 13.9.8 below. Note the similarities of the inequalities (13.6.6) and (13.9.5). After all, a convex polygon is the intersection of a finite number of halfplanes, and so the proof of Theorem 13.6.6 involves carrying out the idea of the proof of Theorem 13.9.8 a finite number of times.

The next theorem shows that powers of N other than $N^{(k-1)/2k}$ may appear for $2 \leq W \leq \infty$. It deals with what has been termed the **isotropic discrepancy** in $\mathbf{U}^k$.

THEOREM 13.6.7 *Schmidt* [Sch75] [BC87, Theorem 15]

Let $\mathcal{J}$ be the collection of all convex sets in $\mathbb{E}^k$. Then

$$D(\mathbf{U}^k, \mathcal{J}_i, \infty, N) > c(k)N^{(k-1)/(k+1)}. \quad (13.6.7)$$

The function $N^{(k-1)/(k+1)}$ dominates $N^{(k-1)/2k}$, so that this largest possible choice for $\mathcal{J}$ does in fact yield a larger discrepancy. Beck has shown by probabilistic techniques that the inequality (13.6.7), excepting a possible logarithmic factor, is best possible for $k = 2$.

The following result of Larcher [Lar91] shows that for certain rotation-invariant $\mathcal{J}$ the discrepancy of Kronecker sequences (defined in Section 13.1) will not behave as $cN^{(k-1)/2k}$, but as the square of this quantity.

THEOREM 13.6.8 *Larcher*

Let the sequence of point sets $\mathcal{P}_N$ be the initial segments of a Kronecker sequence in $\mathbf{U}^k$, and let $\mathcal{J}$ be ds -generated by a cube of edge length $\lambda < 1$. Then, for each N ,

$$\|\Delta(\mathcal{P}_N, \mathcal{J}_i)\|_\infty > c(k)\lambda^{k-1}N^{(k-1)/k}.$$

Furthermore, the exponent $(k-1)/k$ cannot be increased.

13.7 CONGRUENT OBJECTS IN THE UNIT k -CUBE

GLOSSARY

If $\mathcal{J}$ consists of all directly congruent copies of a convex set A , we say that A **dm-generates** $\mathcal{J}$. Simple examples are given by the collection of all k -disks of a fixed radius r or by the collection of all k -cubes of a fixed edge length λ .

Given a convex set A , there is some evidence for the conjecture that the discrepancy for the dm-generated collection will be essentially as large as that for the ds-generated collection. However, this is generally very difficult to establish, even in very specific situations. There are the following results in this direction. The upper bound inequalities all come from Corollary 13.6.4 above.

THEOREM 13.7.1 *Beck* [BC87, Theorem 22A]

Let $\mathcal{J}$ be dm-generated by a square of edge length λ . Then

$$c_1(\lambda)N^{1/8} < D(\mathbf{U}^2, \mathcal{J}_{tor}, \infty, N) < c_2(\lambda)N^{1/4}(\log N)^{1/2}.$$

It is felt that $N^{1/4}$ gives the proper lower bound, and for $\mathcal{J}_i$ this is definitely true. The lower bound in the next result follows at once from the work of Alexander [Ale91] described in Section 13.9.

THEOREM 13.7.2 *Alexander, Beck*

Let $\mathcal{J}$ be dm-generated by a k -cube of edge length λ . Then

$$c_1(\lambda, k)N^{(k-1)/2k} < D(\mathbf{U}^k, \mathcal{J}_i, \infty, N) < c_2(\lambda, k)N^{(k-1)/2k}(\log N)^{1/2}.$$

A similar result probably holds for k -disks, but this has been established only for $k = 2$.

THEOREM 13.7.3 *Beck* [BC87, Theorem 22B]

Let $\mathcal{J}$ be dm-generated by a 2-disk of radius r . Then

$$c_1(r)N^{1/4} < D(\mathbf{U}^2, \mathcal{J}_i, \infty, N) < c_2(r)N^{1/4}(\log N)^{1/2}.$$

13.8 WORK OF MONTGOMERY

It should be reported that Montgomery [Mon89] has independently developed a lower bound method which, as does Beck's method, uses techniques from harmonic analysis. Montgomery's method, especially in dimension 2, obtains for a number of special classes $\mathcal{J}$ estimates comparable to those obtained by Beck's method. In particular, Montgomery has considered $\mathcal{J}$ that are ds-generated by a region whose boundary is a piecewise smooth simple closed curve.

13.9 HALFSPACES AND RELATED OBJECTS

GLOSSARY

Segment: Given a compact subset $\mathbf{K}$ and a closed halfspace H in $\mathbb{E}^k$, $K \cap H$ is called a segment of $\mathbf{K}$.

Slab: The region between two parallel hyperplanes.

Spherical slice: The intersection of two open hemispheres on a sphere.

Let H be a closed halfspace in $\mathbb{E}^k$. Then the collection $\mathcal{H}^k$ of all closed halfspaces is dm-generated by H , and if we associate H with the oriented hyperplane ∂H , there is a well known invariant measure ν on $\mathcal{H}^k$. Further information concerning this and related measures may be found in [Chapter 12](#) of Santaló [San76]. For a compact domain $\mathbf{K}$ in $\mathbb{E}^k$, it is clear that only the collection $\mathcal{H}_i^k$, the *segments* of $\mathbf{K}$, are proper for study, since $\mathcal{H}_c^k$ is empty and $\mathcal{H}_{tor}^k$ is unsuitable.

In this section, it is necessary for the domain $\mathbf{K}$ to be somewhat more general; hence we make only the following broad assumptions:

- (i) $\mathbf{K}$ lies on the boundary of a fixed convex set $\mathbf{M}$ in $\mathbb{E}^{k+1}$;
- (ii) $\sigma(\mathbf{K}) = 1$, where σ is the usual k -measure on $\partial \mathbf{M}$.

Since $\mathbb{E}^k$ is the boundary of a convex body in $\mathbb{E}^{k+1}$, any set in $\mathbb{E}^k$ of unit Lebesgue k -measure satisfies these assumptions. The normalization of assumption (ii) is for convenience, and, by rescaling, the inequalities of this section may be applied to any uniform probability measure on a domain $\mathbf{K}$ in $\mathbb{E}^{k+1}$. Such rescaling only affects dimensional constants; for standard domains, such as the unit k -sphere $\mathbf{S}^k$ and the unit k -disk $\mathbf{D}^k$, this will be done without comment.

Although in applications $\mathbf{K}$ will have a simple geometric description, the next theorem treats the general situation and obtains the essentially exact magnitude of $D(\mathbf{K}, \mathcal{H}_i^{k+1}, 2, N)$. If $\mathbf{K}$ lies in $\mathbb{E}^k$, then $\mathcal{H}^{k+1}$ may be replaced by $\mathcal{H}^k$. If ν is properly normalized, this change invokes no rescaling.

THEOREM 13.9.1 *Alexander* [Ale91]

Let $\mathcal{K}$ be the collection of all $\mathbf{K}$ satisfying assumptions (i) and (ii) above. Then

$$c_1(k)N^{(k-1)/2k} < \inf_{\mathbf{K} \in \mathcal{K}} D(\mathbf{K}, \mathcal{H}_i^{k+1}, 2, N) < c_2(\mathbf{M})N^{(k-1)/2k}. \quad (13.9.1)$$

The upper bound of (13.9.1) can be proved by an indirect probabilistic method introduced by Alexander [Ale72] for $\mathbf{K} = \mathbf{S}^2$, but the method of Beck and Chen [BC90] also may be applied for standard choices of $\mathbf{K}$ such as $\mathbf{U}^k$ and $\mathbf{D}^k$. When $\mathbf{M} = \mathbf{K} = \mathbf{S}^k$, the segments are the spherical caps. For this important special case the upper bound is due to Stolarsky [Sto73], while the lower bound is due to Beck [Bec84] (see also [BC87, Theorem 24B]).

Since the ν -measure of the halfspaces that separate $\mathbf{M}$ is less than $c(k)d(\mathbf{M})$, inequality (13.2.1) may be applied to obtain a lower bound for $D(\mathbf{K}, \mathcal{H}_i^{k+1}, \infty, N)$. The upper bound in the following theorem should be taken in the context of actual

applications such as $\mathbf{M}$ being a k -sphere $\mathbf{S}^k$, a compact convex body in $\mathbb{E}^k$, or more generally, a compact convex hypersurface in $\mathbb{E}^{k+1}$.

THEOREM 13.9.2 *Alexander, Beck*

Let $\mathcal{K}$ be the collection of $\mathbf{K}$ satisfying assumptions (i) and (ii) above. Furthermore, suppose that $\mathbf{M}$ is of finite diameter. Then

$$c_3(k)(d(\mathbf{M}))^{-1/2}N^{(k-1)/2k} < \inf_{\mathbf{K} \in \mathcal{K}} D(\mathbf{K}, \mathcal{H}_i^{k+1}, \infty, N) < c_4(\mathbf{M})N^{(k-1)/2k}(\log N)^{1/2}. \quad (13.9.2)$$

For $\mathbf{M} = \mathbf{K} = \mathbf{S}^k$, inequalities (13.9.2) are due to Beck, improving a slightly weaker lower bound by Schmidt [Sch69]. Consideration of $\mathbf{K} = \mathbf{U}^2$ makes it obvious that there exists an aligned right triangle with discrepancy at least $cN^{1/4}$, as stated in Section 13.1. For the case $\mathbf{M} = \mathbf{K} = \mathbf{D}^2$, a unit 2-disk (Roth's *disk-segment problem*), Beck [Bec83] (see also [BC87, Theorem 23A]) obtained inequalities (13.9.2), excepting a factor $(\log N)^{-7/2}$ in the lower bound. Later, Alexander [Ale90] improved the lower bound, and Matoušek [Mat95] obtained essentially the same upper bound. Matoušek's work on $\mathbf{D}^2$ makes it seem likely that Beck's factor $(\log N)^{1/2}$ in his general upper bound theorem might be removable in many specific situations, but this is very challenging.

THEOREM 13.9.3 *Alexander, Matoušek*

For Roth's disk-segment problem,

$$c_1N^{1/4} < D(\mathbf{D}^2, \mathcal{H}_i^2, \infty, N) < c_2N^{1/4}. \quad (13.9.3)$$

Alexander's lower bound method, by the nature of the convolutions employed, gives information on the discrepancy of slabs. This is especially apparent in the recent work of Chazelle, Matoušek, and Sharir, who have developed a more direct and geometrically transparent version of Alexander's method. The following theorem on the discrepancy of thin slabs is a corollary to their technique. It is clear that if a slab has discrepancy Δ , then one of the two bounding halfspaces has discrepancy at least $\Delta/2$.

THEOREM 13.9.4 *Chazelle, Matoušek, Sharir* [CMS95]

Let N points lie in the unit cube $\mathbf{U}^k$. Then there exists a slab $\mathbf{T}$ of width $c_1(k)N^{-1/k}$ such that $\Delta(\mathbf{T}) > c_2(k)N^{(k-1)/2k}$.

Alexander [Ale94] has investigated the effect of the dimension k on the discrepancy of halfspaces, and obtained somewhat complicated inequalities that imply the following result.

THEOREM 13.9.5 *Alexander*

For the lower bounds in inequalities (13.9.1) and (13.9.2) above, there is an absolute positive constant c such that one may choose $c_1(k) > ck^{-3/4}$ and $c_3(k) > ck^{-1}$.

Schmidt [Sch69] studied the discrepancy of spherical slices (the intersection of two open hemispheres) on $\mathbf{S}^k$. Associating a hemisphere with its pole, Schmidt identified ν with the normalized product measure on $\mathbf{S}^k \times \mathbf{S}^k$. Blümlinger [Blü91] demonstrated a surprising relationship between halfspace (spherical cap) and slice discrepancy for $\mathbf{S}^k$. However, his definition for ν in terms of Haar measure on $SO(k+1)$ differed somewhat from Schmidt's.

THEOREM 13.9.6 *Blümlinger*

Let S^k be the collection of slices of $\mathbf{S}^k$. Then

$$c(k)D(\mathbf{S}^k, \mathcal{H}_i^{k+1}, 2, N) < D(\mathbf{S}^k, S^k, 2, N). \quad (13.9.4)$$

For the next result, the left inequality follows from inequalities (13.2.1), (13.9.1), and (13.9.4). Blümlinger uses a version of Beck's probabilistic method to establish the right inequality.

THEOREM 13.9.7 *Blümlinger*

For slice discrepancy on $\mathbf{S}^k$,

$$c_1(k)N^{(k-1)/2k} < D(\mathbf{S}^k, S^k, \infty, N) < c_2(k)N^{(k-1)/2k}(\log N)^{1/2}.$$

Grabner [Gra91] has given an Erdős-Turán type upper bound on spherical cap discrepancy in terms of spherical harmonics. This adds to the considerable body of results extending inequalities for exponential sums to other sets of orthonormal functions, and thereby extends the Weyl theory.

All of the results so far in this section treat $2 \leq W \leq \infty$. For W in the range $1 \leq W < 2$ there is mystery, but we do have the following result, related to inequality (13.6.6), showing that a dramatic change in asymptotic behavior occurs in the range $1 \leq W \leq 2$. For $\mathbf{U}^2$, Beck and Chen show that regular grid points will work for the upper bound example for $W = 1$, and they are able to modify their method to apply to any bounded convex domain in $\mathbb{E}^2$.

THEOREM 13.9.8 *Beck, Chen* [BC93a]

Let $\mathbf{K}$ be a bounded convex domain in $\mathbb{E}^2$. Then

$$\begin{aligned} D(\mathbf{K}, \mathcal{H}_i^2, W, N) &< c(\mathbf{K}, W)N^{(W-1)/2W}, & 1 < W \leq 2; \\ D(\mathbf{K}, \mathcal{H}_i^2, 1, N) &< c(\mathbf{K})(\log N)^2. \end{aligned} \quad (13.9.5)$$

13.10 BOUNDARIES OF GENERATORS FOR HOMOTHEMICALLY INVARIANT J

We have already noted several factors that play a role in determining whether $D(\mathbf{K}, \mathcal{J}, W, N)$ behaves like N^r as opposed to $(\log N)^s$. Beck's work shows that if $\mathcal{J}$ is dm-generated, $D(\mathbf{K}, \mathcal{J}, \infty, N)$ behaves as N^r . However, the work of Beck and Chen clearly shows that if W is sufficiently small, then even for motion-invariant $\mathcal{J}$, it may be that $D(\mathbf{K}, \mathcal{J}, W, N)$ is bounded above by $(\log N)^s$.

Beck [Bec88] has extensively studied $D(\mathbf{U}^2, \mathcal{J}_{tor}, \infty, N)$ under the assumption that $\mathcal{J}$ is homothetically invariant, and in this section we shall record some of the results obtained.

It turns out that the boundary shape of a generator is the critical element in determining to which, if either, class $\mathcal{J}$ belongs. Remarkably, for the "typical" homothetically invariant class $\mathcal{J}$, $D(\mathbf{U}^2, \mathcal{J}_{tor}, \infty, N)$ oscillates infinitely often to be larger than $N^{1/4-\epsilon}$ and smaller than $(\log N)^{4+\epsilon}$.

GLOSSARY

The convex set A ***h-generates*** $\mathcal{J}$ if $\mathcal{J}$ consists of all homothetic images B of A with $d(B) \leq d(A)$.

Blaschke-Hausdorff metric: The metric on the space $\text{CONV}(2)$ of all compact convex sets in $\mathbb{E}^2$ in which the distance between two sets is the minimum distance from any point of one set to the other.

A set is of ***first category*** if it is a countable union of nowhere dense sets.

If one considers the two examples of $\mathcal{J}$ being h-generated by an aligned square and by a disk, previously stated results make it very likely that shape strongly affects discrepancy for homothetically invariant $\mathcal{J}$. The first two theorems quantify this phenomenon for two very standard boundary shapes, first polygons, then smooth closed curves.

THEOREM 13.10.1 *Beck* [Bec88] [BC87, Corollary 20D]

Let $\mathcal{J}$ be h-generated by a convex polygon A . Then, for any $\epsilon > 0$,

$$D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N) = o((\log N)^{4+\epsilon}). \quad (13.10.1)$$

Beck and Chen [BC89] have given a less complicated argument that obtains $o((\log N)^{5+\epsilon})$ on the right side of (13.10.1).

THEOREM 13.10.2 *Beck* [Bec88] [BC87, Corollary 19F]

Let A be a compact convex set in $\mathbb{E}^2$ with a twice continuously differentiable boundary curve having strictly positive curvature. If A h-generates $\mathcal{J}$, then for $N \geq 2$,

$$D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N) > c(A)N^{1/4}(\log N)^{-1/2}. \quad (13.10.2)$$

Recently, for sufficiently smooth positively curved bodies, Drmota [Drm93] has extended (13.10.2) into higher dimensions and also removed the logarithmic factor. Thus, he obtains a lower bound of the form $c(A)N^{(k-1)/2k}$, along with the standard upper bound obtained by Beck's probabilistic method.

Let $\text{CONV}(2)$ denote the usual locally compact space of all compact convex sets in $\mathbb{E}^2$ endowed with the Blaschke-Hausdorff metric. There is the following surprising result, which quantifies the oscillatory behavior mentioned above.

THEOREM 13.10.3 *Beck* [BC87, Theorem 21]

Let $\epsilon > 0$ be given. For all A in $\text{CONV}(2)$, excepting a set of first category, if $\mathcal{J}$ is h-generated by A , then each of the following two inequalities is satisfied infinitely often:

- (i) $D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N) < (\log N)^{4+\epsilon}$.
- (ii) $D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N) > N^{1/4}(\log N)^{-(1+\epsilon)/2}$.

In fact, the final theorem of this section will say more about the rationale of such estimates.

The next theorem gives the best lower bound estimate known if it is assumed only that the generator A has nonempty interior, certainly a minimal hypothesis.

THEOREM 13.10.4 Beck [Bec88] [BC87, Corollary 19G]

If $\mathcal{J}$ is h -generated by a compact convex set A having positive area, then

$$D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N) > c(A)(\log N)^{1/2}.$$

Possibly the right side should be $c(A) \log N$, which would be best possible as the example of aligned squares demonstrates. Lastly, we discuss the important theorem underlying most of these results about h -generated $\mathcal{J}$. Let A be a member of $\text{CONV}(2)$ with nonempty interior, and for each integer $l \geq 3$ let A_l be an inscribed l -gon of maximal area. The N th **approximability number** $\xi_N(A)$ is defined as the smallest integer l such that the area of $A \setminus A_l$ is less than l^2/N .

THEOREM 13.10.5 Beck [Bec88] [BC87, Corollary 19H, Theorem 20C]

Let A be a member of $\text{CONV}(2)$ with nonempty interior. Then if $\mathcal{J}$ is h -generated by A , we have

$$c_1(A)(\xi_N(A))^{1/2}(\log N)^{-1/4} < D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N) < c_2(A, \epsilon)\xi_N(A)(\log N)^{4+\epsilon}. \quad (13.10.3)$$

The proof of the preceding fundamental theorem, which is in fact the join of two major theorems, is long, but the import is clear; namely, that for h -generated $\mathcal{J}$, if one understands $\xi_N(A)$, then one essentially understands $D(\mathbf{U}^2, \mathcal{J}_{\text{tor}}, \infty, N)$. If $\xi_N(A)$ remains nearly constant for long intervals, then A acts like a polygon and D will drift below $(\log N)^{4+2\epsilon}$. If, at some stage, ∂A behaves as if it consists of circular arcs, then $\xi_N(A)$ will begin to grow as $cN^{1/2}$.

For still more information concerning the material in this section, along with the proofs, see [BC87, Chapter 7]. Károlyi [Kár95a, Kár95b] has extended the idea of approximability number to higher dimensions and obtained upper bounds analogous to those in (13.10.3).

13.11 $D(\mathbf{K}, \mathcal{J}, 2, N)$ IN LIGHT OF DISTANCE GEOMETRY

Although knowledge of $D(\mathbf{K}, \mathcal{J}, \infty, N)$ is our highest aim, in the great majority of problems this is achieved by first obtaining bounds on $D(\mathbf{K}, \mathcal{J}, 2, N)$. In this section, we briefly show how this function fits nicely into the theory of metric spaces of negative type. In our situation, the distance between points will be given by a Crofton formula with respect to the measure ν on $\mathcal{J}$. This approach evolved from a paper written in 1971 by Alexander and Stolarsky investigating extremal problems in distance geometry, and has been developed in a number of subsequent papers by both authors studying special cases. However, we reverse history and leap immediately to a formulation suitable for our present purposes. We avoid mention of certain technical assumptions concerning $\mathcal{J}$ and ν which cause no difficulty in practice.

Assume that $\mathbf{K}$ is a compact convex set in $\mathbb{E}^k$ and that $\mathcal{J} = \mathcal{J}_c$. This latter assumption causes no loss of generality since one can always just redefine $\mathcal{J}$. Let ν , as usual, be a measure on $\mathcal{J}$, with the further assumption that $\nu(\mathcal{J}) < \infty$.

Definition: If p and q are points in $\mathbf{K}$, the set A in $\mathcal{J}$ is said to **separate** p and q if A contains exactly one of these two points. The **distance function** ρ on $\mathbf{K}$ is

defined by the Crofton formula $\rho(p, q) = (1/2) \nu\{J \mid J \text{ separates } p \text{ and } q\}$, and if μ is any signed measure on $\mathbf{K}$ having finite positive and negative parts, one defines the functional $\mathbf{I}(\mu)$ by

$$\mathbf{I}(\mu) = \iint \rho(p, q) d\mu(p) d\mu(q).$$

With these definitions one obtains the following representation for $\mathbf{I}(\mu)$.

THEOREM 13.11.1 *Alexander* [Ale91]

One has

$$\mathbf{I}(\mu) = \int_{\mathcal{J}} \mu(A) \mu(\mathbf{K} \setminus A) d\nu(A). \quad (13.11.1)$$

For μ satisfying the condition of total mass zero, $\int_{\mathbf{K}} d\mu = 0$, the integrand in (13.11.1) becomes $-(\mu(A))^2$. The signed measures $\mu = \mu^+ - \mu^-$ that we are considering, with μ^- being a uniform probability measure on $\mathbf{K}$ and μ^+ consisting of N atoms of equal weight $1/N$, certainly have total mass zero. Here one has $\Delta(A) = N\mu(A)$. Hence there is the following corollary.

COROLLARY 13.11.2

For the signed measures μ presently considered, if $\mathcal{P}$ denotes the N points supporting μ^+ , then

$$-N^2 \mathbf{I}(\mu) = \int_{\mathcal{J}} (\Delta(A))^2 d\nu(A) = (\|\Delta(\mathcal{P}, \mathcal{J})\|_2)^2. \quad (13.11.2)$$

Thus if one studies the metric ρ , it may be possible to prove that $-\mathbf{I}(\mu) > f(N)$, whence it follows that $(D(\mathbf{K}, \mathcal{J}, 2, N))^2 > N^2 f(N)$. If $\mathcal{J}$ consists of the halfspaces of $\mathbb{E}^k$, then ρ is the Euclidean metric. In this important special case, Alexander [Ale91] was able to make good estimates. Chazelle, Matoušek, and Sharir [CMS95] and A.D. Rogers [Rog94] contributed still more techniques for treating the halfspace problem.

If μ_1 and μ_2 are any two signed measures of total mass 1 on $\mathbf{K}$, then one can define the **relative discrepancy** $\Delta(A) = N(\mu_1(A) - \mu_2(A))$. The first equality of (13.11.2) still holds if $\mu = \mu_1 - \mu_2$. A signed measure μ_0 of total mass 1 is termed **optimal** if it solves the integral equation $\int_{\mathbf{K}} \rho(x, y) d\mu(y) = \lambda$ for some positive number λ . If an optimal measure μ_0 exists, then $\mathbf{I}(\mu_0) = \lambda$ maximizes $\mathbf{I}$ on the class of all signed Borel measures of total mass 1 on $\mathbf{K}$. In the presence of an optimal measure, one has the following very pretty identity.

THEOREM 13.11.3 *Generalized Stolarsky Identity*

Suppose that the measure μ_0 is optimal on $\mathbf{K}$, and that μ is any signed measure of total mass 1 on $\mathbf{K}$. If Δ is the relative discrepancy with respect to μ_0 and μ , then

$$N^2 \mathbf{I}(\mu) + \int_{\mathcal{J}} (\Delta(A))^2 d\nu(A) = N^2 \mathbf{I}(\mu_0). \quad (13.11.3)$$

The first important example of this formula is due to Stolarsky [Sto73] where he treated the sphere $\mathbf{S}^k$, taking as μ the uniform atomic measure supported by N variable points. For $\mathbf{S}^k$ it is clear that the uniform probability measure μ_0 is optimal. His integrals involving the spherical caps are equivalent, up to a scale factor, to integrals with respect to the measure on the halfspaces of $\mathbb{E}^k$ for which

ρ is the Euclidean metric. Stolarsky's tying of a geometric extremal problem to Schmidt's work on the discrepancy of spherical caps was a major step forward in the study of discrepancy and of distance geometry.

Very little has been done to investigate the deeper nature of the individual metrics ρ determined by classes $\mathcal{J}$ other than halfspaces. They are all metrics of *negative type*, which essentially means that $\mathbf{I}(\mu) \leq 0$ if μ has total mass 0. There is a certain amount of general theory, begun by Schoenberg and developed by a number of others, but it does not apply directly to the problem of estimating discrepancy.

13.12 UNIFORM PLACEMENT OF POINTS ON SPHERES

As demonstrated by Stolarsky, formula (13.11.3) shows that if one places N points on $\mathbf{S}^k$ so that the sum of all distances is maximized, then $D(\mathbf{S}^k, \mathcal{H}_i^k, 2, N)$ is achieved by this arrangement. Berman and Hanes [BH77] have given a pretty algorithm that searches for optimal configurations. For $k = 2$, while the exact configurations are not known for $N \geq 5$, this algorithm appears to be successful for $N \leq 50$. For such an N surprisingly few rival configurations will be found. Lubotsky, Phillips, and Sarnak [LPS86] have given an algorithm, based on iterations of a specially chosen element in $SO(3)$, which can be used to place many thousands of reasonably well distributed points on $\mathbf{S}^2$. Difficult analysis shows that these points are well placed, but not optimally placed, relative to $\mathcal{H}_i^2$. On the other hand, it is shown that these points are essentially optimally placed with respect to a nongeometric operator discrepancy. Data concerning applications to numerical integration are also included in the paper. More recently, Rakhmanov, Saff, and Zhou [RSZ94] have studied the problem of placing points uniformly on a sphere relative to optimizing certain functionals, and they state a number of interesting conjectures.

In yet another theoretical direction, the existence of very well distributed point sets on $\mathbf{S}^k$ allows the sphere, after difficult analysis, to be closely approximated by equi-edged zonotopes (sums of line segments). The recent papers of Wagner [Wag93] and of Bourgain and Lindenstrauss [BL93] treat this problem.

13.13 COMBINATORIAL DISCREPANCY

GLOSSARY

A **2-coloring** of $\mathbf{X}$ is a mapping $\chi : \mathbf{X} \rightarrow \{-1, 1\}$. For each such χ there is a natural integer-valued set function μ_χ on the finite subsets of $\mathbf{X}$ defined by $\mu_\chi(A) = \sum_{x \in A} \chi(x)$, and if $\mathcal{J}$ is a given family of finite subsets of $\mathbf{X}$ we define

$$D(\mathbf{X}, \mathcal{J}) = \min_{\chi} \max_{A \in \mathcal{J}} |\mu_\chi(A)|.$$

Degree: If $\mathcal{J}$ is a collection of subsets of a finite set X , $\deg \mathcal{J} = \max\{|\mathcal{J}(x)| \mid x \in \mathbf{X}\}$, where $\mathcal{J}(x)$ is the subcollection consisting of those members of $\mathcal{J}$ that contain x .

The collection $\mathcal{J}$ **shatters** a set $S \subset X$ if, for any given subset $B \subset S$, there exists A in $\mathcal{J}$ such that $B = A \cap S$. The **VC-dimension** of $\mathcal{J}$ is defined by $\dim_{vc} \mathcal{J} = \max\{|S| \mid S \subset X, \mathcal{J} \text{ shatters } S\}$. For $m \leq |X|$, the **primal shatter function** $\pi_{\mathcal{J}}$ is defined by

$$\pi_{\mathcal{J}}(m) = \max_{\substack{Y \subset X \\ |Y| \leq m}} |\{Y \cap A \mid A \in \mathcal{J}\}|.$$

The **dual shatter function** is defined by $\pi_{\mathcal{J}}^*(m) = \pi_{\mathcal{J}^*}(m)$, where $X^* = \mathcal{J}$, and $\mathcal{J}^* = \{\mathcal{J}(x) \mid x \in X\}$.

Techniques in combinatorial discrepancy theory have proved very powerful in this geometric setting. Here one 2-colors a discrete set and studies the discrepancy of a special class $\mathcal{J}$ of subsets as measured by $|\#\text{red} - \#\text{blue}|$. If one 2-colors the first N positive integers, then the beautiful “1/4 theorem” of Roth [Rot64] says that there will always be an arithmetic progression having discrepancy at least $cN^{1/4}$. This result should be compared to van der Waerden’s theorem, which says that there is a long monochromatic progression, whose discrepancy obviously will be its length. However, it is known that this length need not be more than $\log N$, and the minimax might be as small as $\log \log \dots \log N$ (here the number of iterated logarithms may be arbitrarily large). Moreover, general results concerning combinatorial discrepancy, for example, those that use the Vapnik-Chervonenkis dimension, are very useful in computational geometry; cf. [Chapter 44](#).

Combinatorial discrepancy theory involves discrepancy estimates arising from 2-colorings of a set X . Upper bound estimates of combinatorial discrepancy have proved to be very helpful in obtaining upper bound estimates of geometric discrepancy. In this final section we briefly discuss various properties of the collection $\mathcal{J}$ that lead to useful upper bound estimates of combinatorial discrepancy.

The simplest property of the collection $\mathcal{J}$ is its cardinality $|\mathcal{J}|$. Here, Spencer obtained a fine result.

THEOREM 13.13.1 *Spencer* [AS93]

Let X be a finite set. If $|\mathcal{J}| \geq |X|$, then

$$D(X, \mathcal{J}) \leq c \left(|X| \log \left(1 + \frac{|\mathcal{J}|}{|X|} \right) \right)^{1/2}.$$

Applications and extensions of the following theorem may be found in [BC87, [Chapter 8](#)].

THEOREM 13.13.2 *Beck, Fiala* [BF81] [BC87, Lemma 8.5.]

Let X be a finite set. Then

$$D(X, \mathcal{J}) \leq 2 \deg \mathcal{J} - 1.$$

Since $\pi_{\mathcal{J}}(m) = 2^m$ if and only if $\dim_{vc} \mathcal{J} \geq m$, the function $\pi_{\mathcal{J}}$ contains much more information than does VC-dimension alone. If $\dim_{vc} \mathcal{J} = d$, then $\pi_{\mathcal{J}}(m)$ is polynomially bounded by cm^d . However, in many geometric situations this bound on the shatter function can be improved, leading to better discrepancy bounds. Detailed discussions may be found in the papers by Haussler and Welzl [HW87] and by Chazelle and Welzl [CW89].

Dual objects are defined in the usual manner (see [Glossary](#)). We state several recent results.

THEOREM 13.13.3 *Matoušek, Welzl, Wernisch* [MW93]

Suppose that $(\mathbf{X}, \mathcal{J})$ is a finite set system with $|\mathbf{X}| = n$. If $\pi_{\mathcal{J}}(m) \leq c_1 m^d$ for $m \leq n$, then

$$\begin{aligned} D(\mathbf{X}, \mathcal{J}) &\leq c_2 n^{(d-1)/2d} (\log n)^{1+1/2d}, & d > 1, \\ D(\mathbf{X}, \mathcal{J}) &\leq c_3 (\log n)^{5/2}, & d = 1. \end{aligned} \quad (13.13.1)$$

If $\pi_{\mathcal{J}}^*(m) \leq c_4 m^d$ for $m \leq |\mathcal{J}|$, then

$$\begin{aligned} D(\mathbf{X}, \mathcal{J}) &\leq c_5 n^{(d-1)/2d} \log n, & d > 1, \\ D(\mathbf{X}, \mathcal{J}) &\leq c_6 (\log n)^{3/2}, & d = 1. \end{aligned} \quad (13.13.2)$$

More recently, Matoušek [Mat95] has shown that the factor $(\log n)^{1+1/2d}$ may be dropped from inequality (13.13.1) for $d > 1$, and has applied this result to half-spaces with great effect (see inequality (13.9.3)). One part of Matoušek's argument depends on combinatorial results of Haussler [Hau95].

14 TOPOLOGICAL METHODS

Rade T. Živaljević

INTRODUCTION

A problem is solved or some other goal achieved by “topological methods” if in our arguments we appeal to the “form,” the “shape,” or the “global” rather than “local” structure of the object or configuration space associated with the phenomenon we are interested in. This configuration space is typically a manifold or a simplicial complex. The global properties of the configuration space are usually expressed in terms of its homology and homotopy groups, which capture the idea of the higher (dis)connectivity of a geometric object and to some extent provide “an analysis properly geometric or linear that expresses location directly as algebra expresses magnitude.”¹

Thesis: *Any global effect that depends on the object as a whole and that cannot be localized is of homological nature, and should be amenable to topological methods.*

WHERE HAS TOPOLOGY BEEN APPLIED IN COMPUTER SCIENCE?

The references [Car03] and [BEA+99] provide a broad overview of many current applications of algebraic topology in computer science and vice versa as well as an insight into promising new developments. The field is undergoing a rapid expansion and the following list should be understood as a sample of some of the main themes or aspects of potential future research.

- (a) Algebraic topology (AT) is viewed as a useful tool in solving combinatorial or discrete geometric problems of relevance to computing and the analysis of algorithms, [Mat02, Mat03, Živ98].
- (b) *Computational topology* emerges [BEA+99] as a separate branch of computational geometry unifying topological questions in computer applications such as image processing, cartography, computer graphics, solid modeling, mesh generation, and molecular modeling [BEA+99, DEG99].
- (c) Effective algebraic topology deals with algorithmic and computational aspects of topology including the recognition problem (3-manifolds), effective computations of topological invariants (homology, homotopy groups, knot invariants), etc. [Dun, Ser].
- (d) Combinatorial proofs of statements originally obtained by nonconstructive topological methods were discovered [Mat, Zie02].
- (e) The methods of AT can provide qualitative and shape information unavailable by the use of other methods. For example AT provides a tool for visualization

¹A dream of G.W. Leibniz expressed in a letter to C. Huygens dated 1697; see [Bre93, Chap. 7].

and feature identification in highly complex empirical data, e.g., in biogeometry [BioG].

- (f) AT provides a useful framework for analyzing problems in distributed and concurrent computing [HR95, HR00].

HOW IS TOPOLOGY APPLIED IN DISCRETE GEOMETRIC PROBLEMS?

In this chapter we put some emphasis on the role of (equivariant) topological methods in solving combinatorial or discrete geometric problems that have proven to be of relevance for computational geometry and computational mathematics in general. The versatile *configuration space/test map* scheme was developed in numerous research papers over the years and formally codified in [Živ98]. Its essential features are the following two steps:

Step 1: The problem is rephrased in topological terms.

The problem should give us a clue how to define a “natural” *configuration space* X and how to rephrase the question in terms of zeros or coincidences of the associated *test maps*. Alternatively the problem may be divided into several subproblems, in which case one is often led to the question of when the subsets of X corresponding to the various subproblems have *nonempty intersection*.

Step 2: Standard topological techniques are used to solve the rephrased problem.

The topological technique that is most frequently used in discrete geometric problems is based on the technique of *intersecting homology classes* and on *generalized Borsuk-Ulam theorems*.

14.1 THE CONFIGURATION SPACE/TEST MAP PARADIGM

GLOSSARY

Configuration space/test map scheme (CS/TM): A very useful and general scheme for proving combinatorial or geometric facts. The problem is reduced to the question of showing that there does not exist a G -equivariant map $f : X \rightarrow V \setminus Z$ (Section 14.5) where X is the configuration space, V the test space, and Z the test subspace associated with the problem, while G is a naturally arising group of symmetries.

Configuration space: In general, any topological space X that parameterizes a class of configurations of geometric objects (e.g., arrangements of points, lines, fans, flags, etc.) or combinatorial structures (trees, graphs, partitions, etc.). Given a problem $\mathcal{P}$, an associated configuration or **candidate space** $X_{\mathcal{P}}$ collects all geometric configurations that are (reasonable) candidates for a solution of $\mathcal{P}$.

Test map and test space : A map $t : X_{\mathcal{P}} \rightarrow V$ from the configuration space $X_{\mathcal{P}}$ into the so-called test space V that tests the validity of a candidate $p \in X_{\mathcal{P}}$ as

a solution of $\mathcal{P}$. The final ingredient is the **test subspace** $Z \subset V$, where $p \in X$ is a solution to the problem if and only if $t(p) \in Z$. Usually $V \cong \mathbb{R}^d$ while Z is just the origin $\{0\} \subset V$ or more generally a linear subspace arrangement in V .

Equivariant map: The final ingredient in the CS/TM-scheme is a group G of symmetries that acts on both the configuration space $X_{\mathcal{P}}$ and the test space V (keeping the test subspace Z invariant). The test map t is always assumed G -equivariant, i.e., $t(g \cdot x) = g \cdot t(x)$ for each $g \in G$ and $x \in X_{\mathcal{P}}$. Some of the methods and tools of equivariant topology are outlined in Section 14.5.

EXAMPLE 14.1.1 (Y. Soibelman [Soi02])

Suppose that ρ is a metric on $\mathbb{R}^2$ that induces the same topology as the usual Euclidean metric. In other words we assume that for each sequence of points $(x_n)_{n \geq 0}$, $\rho(x_n, x_0) \rightarrow 0$ if and only if $|x_n - x_0| \rightarrow 0$. Then there exists a ρ -equilateral triangle, i.e., a triple (a, b, c) of distinct points in $\mathbb{R}^2$ such that $\rho(a, b) = \rho(b, c) = \rho(c, a)$.

This is our first example that illustrates the CS/TM-scheme. The configuration space X should collect all candidates for the solution, so a first, “naive” choice is the space of all (ordered) triples $(x, y, z) \in \mathbb{R}^2$. Of course we can immediately rule out some obvious nonsolutions, e.g., degenerate triangles (x, y, z) such that at least one of numbers $\rho(x, y), \rho(y, z), \rho(z, x)$ is zero. (This illustrates the fact that in general there may be several possible choices for a configuration space associated to the initial problem.) Our choice is $X := (\mathbb{R}^2)^3 \setminus \Delta$ where $\Delta := \{(x, x, x) \mid x \in \mathbb{R}^2\}$. A “triangle” $(x, y, z) \in X$ is ρ -equilateral if and only if $(\rho(x, y), \rho(y, z), \rho(z, x)) \in Z$, where $Z := \{(u, u, u) \in \mathbb{R}^3 \mid u \in \mathbb{R}\}$. Hence a test map $t : X \rightarrow \mathbb{R}^3$ is defined by $t(x, y, z) = (\rho(x, y), \rho(y, z), \rho(z, x))$, the test space is $V = \mathbb{R}^3$, and $Z \subset \mathbb{R}^3$ is the associated test subspace. A triangle $\{x, y, z\}$, viewed as a set of vertices, is in general labeled by six different triples in the configuration space X . This redundancy is a motivation for introducing the group of symmetries $G = S_3$, which acts on both the configuration space X and the test space V . The test map t is clearly S_3 -equivariant. If the image of t is disjoint from Z , there arises an S_3 -equivariant map from X to $V \setminus Z$. If S^1 is the unit circle in a 2-plane in $V = \mathbb{R}^3$ orthogonal to $Z \cong \mathbb{R}^1$, then projection and normalization give an S_3 -equivariant map $\alpha : V \setminus Z \rightarrow S^1$. The unit 3-sphere S^3 in a 4-plane orthogonal to Δ is S_3 -invariant, hence the inclusion map $\beta : S^3 \rightarrow X$ is S_3 -equivariant. Finally, the composition $f := \alpha \circ t \circ \beta : S^3 \rightarrow S^1$ is also S_3 -equivariant, hence $\mathbb{Z}_3$ -equivariant, which leads to a contradiction. One way to prove this is to use Theorem 14.5.1, since the sphere S^3 is clearly 1-connected and the action of $\mathbb{Z}_3$ on S^3 is free.

Here is another example of how topology comes into play and proves useful in geometric and combinatorial problems. The *configuration space* associated to the next problem is a 2-dimensional torus $T^2 \cong S^1 \times S^1$. This time, however, the test map is not explicitly given. Instead, the problem is reduced to counting intersection points of two “test subspaces” in T^2 .

EXAMPLE 14.1.2 A watch with two equal hands

A watch was manufactured with a defect so that both hands (minute and hour) are identical. Otherwise the watch works well and the question is to determine the number of ambiguous positions, i.e., the positions for which it is not possible to determine the exact time.

FIGURE 14.1.1

The configuration space of the two hands is a torus.

First of all we observe that every position of a hand is determined by an angle $\omega \in [0, 2\pi]$, so that the configuration space of all possible positions of a hand is homeomorphic to the unit circle S^1 . Two independent hands have the 2-dimensional torus $T^2 \cong S^1 \times S^1$ as their configuration space, i.e., the space representing all allowed states or positions of the system. A usual model of a torus is a square or a rectangle (see Figure 14.1.1) with the opposite sides glued together. If θ corresponds to the minute hand and ω is the coordinate of the hour hand, then the fact that the first hand is twelve times faster is recorded by the equation $\theta = 12\omega$. This equation describes a curve Γ_1 on the torus T^2 , which is just a circle winding 12 times in the direction of the θ axis while it winds only once in the direction of the ω axis. The curve Γ_1 is represented in our picture as the union of 12 line segments, seven of them indicated in Figure 14.1.1. If the hands change places then the corresponding curve Γ_2 has equation $\omega = 12\theta$. The ambiguous positions are exactly the intersection points of these two curves (except those that belong to the diagonal $\Delta := \{(\theta, \omega) \mid \theta = \omega\}$, when it is still possible to tell the exact time without knowing which hand is for hours and which for minutes). The reader can now easily find the number of these intersection points and compute that there are 143 of them in the intersection $\Gamma_1 \cap \Gamma_2$, and 11 in the intersection $\Gamma_1 \cap \Gamma_2 \cap \Delta$, which shows that there are all together 132 ambiguous positions.

REMARK 14.1.3

Let us note that the “watch with equal hands” problem reduces to counting points or 0-dimensional manifolds in the intersection of two circles, viewed as 1-dimensional submanifolds of the 2-dimensional manifold T^2 . More generally, one may be interested in how many points there are in the intersection of two or more submanifolds of a higher-dimensional ambient manifold. Topology gives us a versatile tool for computing this and much more, in terms of the so-called *intersection product* $\alpha \frown \beta$ of *homology classes* α and β in a manifold M . This intersection product is, via Poincaré duality, equivalent to the “cup” product, and has the usual properties [Mun84]. In our Example 14.1.2, keeping in mind that $a \frown b = -b \frown a$ for all 1-dimensional classes, and in particular that $a \frown a = 0$ if $\dim(a) = 1$, we have $[\Gamma_1] \frown [\Gamma_2] = ([\theta] + 12[\omega]) \frown ([\omega] + 12[\theta]) = [\theta] \frown [\omega] + 12[\omega] \frown [\omega] + 12[\theta] \frown [\theta] + 144[\omega] \frown [\theta] = 143[\omega] \frown [\theta]$ and, taking the orientation into account, we conclude that the number of intersection points is 143.

14.2 PARTITIONS OF MASS DISTRIBUTIONS

Problems of partitioning mass distributions in the plane, 3-space, or spaces of higher dimension form the first circle of discrete geometric problems where topological methods have traditionally been applied with great success.

An (open) ham sandwich is a collection of three measurable sets in $\mathbb{R}^3$, representing a slice of bread, a slice of ham, and a slice of cheese. It turns out that there always exists a plane simultaneously halving all three measurable sets or, in other words, that a ham sandwich can be cut fairly into two pieces by a single straight cut. Suppose, on the other hand, that you want to split an irregularly shaped slice of pizza with a hungry friend who is supposed to divide the pizza into two pieces by a straight knife-cut, but who can cut anywhere he likes. You are allowed to mark your piece in advance by specifying a single point that will lie in your piece. Then, if you are very careful about marking your piece, you can count on at least one third of the pizza. These two results are instances of *the ham sandwich theorem* and *the center point theorem* which, together with their relatives, often require topological methods in their proofs.

GLOSSARY

Measure: An abstract function μ defined on a class of sets that has all the formal properties (additivity, positivity) of the usual *volume* or *area* functions.

Measurable set: Any set in the domain of the function μ .

Mass distribution and density function: A density function is an integrable function $f : \mathbb{R}^d \rightarrow [0, +\infty)$ representing the density of a “mass distribution” (measure) on $\mathbb{R}^d$. The measure μ arising this way is defined by $\mu(A) := \int_A f \, dx$.

Halving hyperplane: A hyperplane that simultaneously bisects a family of measurable sets.

Grassmann and Stiefel manifolds: The Grassmann manifold $G_k(\mathbb{R}^n)$ of all k -dimensional linear subspaces of $\mathbb{R}^n$ and the Stiefel manifold $V_k(\mathbb{R}^n)$ of all orthonormal k -frames in $\mathbb{R}^n$ are frequently used in the construction of configuration spaces associated to measure partitioning problems.

14.2.1 THE HAM SANDWICH THEOREM

Given a collection of d measurable sets (mass distributions, finite sets) in $\mathbb{R}^d$, the problem is to simultaneously bisect all of them by a single hyperplane. Often a measurable set is a geometric object $A \subset \mathbb{R}^d$, say a polytope, whose measure is simply its volume $\text{vol } A$. More generally, a measurable set A is an arbitrary subset of $\mathbb{R}^d$ if it is clear from the context what we mean by its “measure” $\mu(A)$. Typically, A is a Lebesgue-measurable set and $\mu(A) = m(A)$ its Lebesgue measure which, in the usual cases, reduces to the measure vol described above. More generally, if $f : \mathbb{R}^d \rightarrow \mathbb{R}^+$ is an integrable density function, then $\mu(A) := \int_A f \, dm = \int_{\mathbb{R}^d} f \phi_A \, dm$ is the measure or the mass distribution associated with the function f , where ϕ_A is the characteristic function of A (1 on A , 0 otherwise). An important special

case arises if $f = \phi_B$ for a Lebesgue-measurable set B , where $\mu(A) = m(A \cap B)$. Finally, if $S \subset \mathbb{R}^d$ is a finite set, then $\mu(A) := |A \cap S|$ is the so-called **counting measure** induced by the set S . All of these examples are subsumed by the case of a positive, σ -additive Borel measure μ . This means that μ is defined on a σ -algebra $\mathcal{F}$ of subsets of $\mathbb{R}^d$ that includes all closed halfspaces and other sets that arise naturally in geometric problems. The reader should, in principle, not have any difficulty reformulating any of the following results for whatever special class of measures she may be interested in.

THEOREM 14.2.1 *Ham Sandwich Theorem* [Bor33]

Let $\mu_1, \mu_2, \dots, \mu_d$ be a collection of measures (mass distributions, measurable sets, finite sets) in the sense above. Then there exists a hyperplane H such that for all $i = 1, \dots, d$, $\mu_i(H^+) \geq 1/2 \mu_i(\mathbb{R}^d)$ and $\mu_i(H^-) \geq 1/2 \mu_i(\mathbb{R}^d)$, where H^+ and H^- are the closed halfspaces associated with the hyperplane H .

In the special case where $\mu(H) = 0$, i.e., where the hyperplane itself has measure zero, H is called a **halving hyperplane** since $\mu_i(H^+) = \mu_i(H^-) = 1/2 \mu_i(\mathbb{R}^d)$ for all i . A halving hyperplane H is also called a “ham sandwich cut,” for the reasons noted above.

TOPOLOGICAL BACKGROUND

The topological result lying behind the ham sandwich theorem is the Borsuk-Ulam theorem, [Ste85, Mat03]. The proof of the ham sandwich theorem historically marks one of the first applications of the CS/TM-scheme, with the $(d-1)$ -sphere as the configuration space, $\mathbb{R}^d$ as the test space, and $G = \mathbb{Z}_2$ as the group of symmetries associated to the problem. Given a collection $\{A_i\}_{i=1}^d$ of d measurable sets, the test map $t : S^{d-1} \rightarrow \mathbb{R}^d$ is defined by $t(e) = (\alpha_1, \dots, \alpha_d)$, with α_i determined by the condition that $H_i := \{x \in \mathbb{R}^d \mid \langle x, e \rangle = \alpha_i\}$ is a median halving hyperplane for the measurable set A_i . (The median halving hyperplane in any direction is the mid-hyperplane between the two extreme halving hyperplanes in that direction.) The test space is the diagonal $Z := \{(\alpha, \dots, \alpha) \in \mathbb{R}^d \mid \alpha \in \mathbb{R}\}$. The test map t is obviously “odd,” or $\mathbb{Z}_2$ -equivariant, in the sense that $t(-e) = -t(e)$.

THEOREM 14.2.2 *Borsuk-Ulam Theorem* [Bor33]

For every continuous map $f : S^n \rightarrow \mathbb{R}^n$ from an n -dimensional sphere into n -dimensional Euclidean space, there exists a point $x \in S^n$ such that $f(x) = f(-x)$.

An important special case of the Borsuk-Ulam theorem arises if f is an odd map. The conclusion is that a continuous odd map must have a zero on the sphere, i.e., $f(x) = 0$ for some $x \in S^d$. This is precisely the reason why the test map t for the ham sandwich theorem has the property $t(e) \in Z$ for some $e \in S^{d-1}$. Note that the general Borsuk-Ulam theorem follows from the special case if the latter is applied to the map $\phi : S^d \rightarrow \mathbb{R}^d$ given by $\phi(x) := f(x) - f(-x)$.

There is a different topological approach to the ham sandwich theorem closer to the earlier example about a watch with two indistinguishable hands. Here we mention only that the role of the torus T^2 is played by a manifold M representing all hyperplanes in $\mathbb{R}^d$ (the configuration space), while the curves Γ_1 and Γ_2 are replaced by suitable submanifolds N_i of M , one for each of the measures μ_i , $i = 1, \dots, d$. N_i is defined as the space of all halving hyperplanes for the measurable set A_i .

APPLICATIONS AND RELATED RESULTS

Let $S_1, \dots, S_d$ be a collection of finite sets, called “colors,” in $\mathbb{R}^d$. Assume that the size of each of these sets is n and that the points are all in general position. Then, according to Akiyama and Alon [AA89], the ham sandwich theorem implies that there exists a partition of $S := \bigcup_{i=1}^d S_i$ into n nonempty, pairwise disjoint sets $D_1, \dots, D_n$ that are multicolored in the sense that $|D_i \cap S_j| = 1$ for all i and j , such that the simplices $\text{conv } D_1, \dots, \text{conv } D_n$ are pairwise disjoint.

14.2.2 THE CENTER POINT THEOREM

THEOREM 14.2.3 *Center Point Theorem* [Rad46]

Let $A \subset \mathbb{R}^d$ be a Lebesgue-measurable subset of $\mathbb{R}^d$ or, more generally, one of the measures μ described prior to Theorem 14.2.1. Then there exists a point $x \in \mathbb{R}^d$ such that for every closed halfspace $P \subset \mathbb{R}^d$, if $x \in P$ then

$$\text{vol}(P \cap A) \geq \frac{\text{vol}(A)}{d+1}.$$

When formulated for a more general measure μ , the result guarantees that $\mu(P) \geq \mu(\mathbb{R}^d)/(d+1)$ for every closed halfspace $P \ni x$.

TOPOLOGICAL BACKGROUND

If the Borsuk-Ulam theorem is responsible for the ham sandwich theorem, then R. Rado’s center point theorem can be seen as a consequence of another well-known topological result, Brouwer’s fixed point theorem. Note that the usual formulation about self-maps $f : K \rightarrow K$ generalizes easily to the following formulation.

THEOREM 14.2.4 *Brouwer’s Fixed Point Theorem* [Bro75, Kak41]

Let K be a compact, convex body in $\mathbb{R}^n$. Suppose $f : K \rightarrow \mathbb{R}^n$ is a continuous map such that for each $x \in K$ the image $f(x)$ belongs to the supporting cone of K at x , $\text{cone}_x(K) := \bigcup_{\lambda \geq 0} (x + \lambda(K - x))$. Then $f(x) = x$ for some $x \in K$.

Very often it is more convenient to use Kakutani’s theorem, which is a generalization of Brouwer’s theorem to “multivalued functions” $f : B \rightarrow \mathbb{R}^n$.

The center point theorem is deduced from Brouwer’s theorem roughly as follows. Let $x \in B$, where B is a “large” ball containing the set A . If x is not a center point, then there is a vector $e \in S^{d-1}$ pointing in a direction in which x can be moved to make it closer to being one. In this way we define a function $x \mapsto f(x)$, and a fixed point, i.e., a point that doesn’t need to be moved, is a center point.

Recall that the center point theorem was originally deduced (by R. Rado) from Helly’s theorem about intersecting families of convex sets, which also has several topological relatives. For this reason, it is often viewed as a measure-theoretic equivalent of Helly’s theorem.

APPLICATIONS AND RELATED RESULTS

As noted by Miller and Thurston (see [MTTV97, MTTV98]), the center point theorem and the Koebe theorem on the disk representation of planar graphs can be used to prove the existence of a small separator for a planar graph, a result proved originally (by Lipton and Tarjan) by different methods.

The **regression depth** $\text{rd}_{\mathcal{P}}(H)$ of a hyperplane H relative to a collection $\mathcal{P}$ of n points in $\mathbb{R}^d$ is the minimum number of points that H must pass through in moving to the vertical position. Dually, given an arrangement $\mathcal{H}$ of n hyperplanes in $\mathbb{R}^d$, the regression depth $\text{rd}_{\mathcal{H}}(x)$ of a point x relative to $\mathcal{H}$ is the smallest k such that x cannot escape to infinity without crossing (or moving parallel to) at least k hyperplanes. The problem of finding a point (resp. hyperplane) with maximum regression depth relative to $\mathcal{H}$ (resp. $\mathcal{P}$) is shown in [AET00] to be intimately connected with the problem of finding center points. The main result (confirming a conjecture of Rousseeuw and Hubert) is that there always exists a point with regression depth $\lceil n/(d+1) \rceil$; cf. [Chapter 57](#) of this Handbook.

14.2.3 CENTER TRANSVERSAL THEOREM

THEOREM 14.2.5 *Center Transversal Theorem* [ZV90]

Let $A_0, A_1, \dots, A_k$, $0 \leq k \leq d-1$, be a collection of Lebesgue-measurable sets in $\mathbb{R}^d$ or, more generally, let $\mu_0, \mu_1, \dots, \mu_k$ be a sequence of measures. Then there exists a k -dimensional affine subspace $D \subset \mathbb{R}^d$ such that for every closed halfspace $H(v, \alpha) := \{x \in \mathbb{R}^d \mid \langle x, v \rangle \leq \alpha\}$ and every $i \in \{0, 1, \dots, k\}$,

$$D \subset H(v, \alpha) \implies m(A_i \cap H(v, \alpha)) \geq \frac{m(A_i)}{d - k + 1}.$$

If formulated for a sequence $\mu_0, \dots, \mu_k$ of more general measures, the result guarantees that $\mu_i(H(v, \alpha)) \geq \mu_i(\mathbb{R}^d)/(d - k + 1)$ for all i and all $H(v, \alpha) \supseteq D$.

TOPOLOGICAL BACKGROUND

The center transversal theorem contains the ham sandwich and center point theorems as two boundary cases [ZV90]. The topological principle that is at the root of this result should be strong enough for this purpose. This result has several incarnations. One of them, in the language of the CS/TM-scheme, is a theorem of E. Fadell and S. Husseini [FH88] that claims the nonexistence of a $\mathbb{Z}_2^{\oplus k}$ -equivariant map $f: V_{n,k} \rightarrow (\mathbb{R}^k)^{n-k} \setminus \{0\}$ from the Stiefel manifold of all orthonormal k -frames in $\mathbb{R}^n$ to the sum of $n - k$ copies of $\mathbb{R}^k$. The group $\mathbb{Z}_2^{\oplus k}$ can be identified with the group of all diagonal matrices in $SO(k)$ and its action on $\mathbb{R}^k$ is induced by the obvious action of $SO(k)$. A related result [FH88, ZV90] is that the vector bundle $\xi_k^{\oplus(n-k)}$ does not admit a nonzero, continuous cross-section, where ξ_k is the tautological k -plane bundle over the Grassmann manifold $G_k(\mathbb{R}^n)$.

APPLICATIONS AND RELATED RESULTS

The following Helly-type transversal theorem, due to Dol'nikov, is a consequence of the same topological principle that is at the root of the center transversal theorem. Moreover, the center transversal theorem is related to Dol'nikov's result in the same way that the center point theorem is related to Helly's theorem.

THEOREM 14.2.6 [Dol'93]

Let $K_0, \dots, K_k$ be families of compact convex sets. Suppose that for every i , and for each k -dimensional subspace $V \subset \mathbb{R}^d$, there exists a translate V_i of V intersecting every set in K_i . Then there exists a common k -dimensional transversal of the family $\mathcal{K} := \bigcup_{i=0}^k K_i$, i.e., there exists an affine k -dimensional subspace of $\mathbb{R}^d$ intersecting all the sets in $\mathcal{K}$.

Let $\mathcal{K} = \{K_0, \dots, K_k\}$ be a family of convex bodies in $\mathbb{R}^n$, $1 \leq k \leq n-1$. Then an affine l -plane $A \subset \mathbb{R}^n$ is called a **common maximal l -transversal** of $\mathcal{K}$ if $m(K_i \cap A) \geq m(K_i \cap (A + x))$ for each $i \in \{0, \dots, k\}$ and each $x \in \mathbb{R}^n$, where m is l -dimensional Lebesgue measure in A and $A + x$, respectively. It was shown in [MVZ01] that, given a family $\mathcal{K} = \{K_i\}_{i=0}^k$ of convex bodies in $\mathbb{R}^n$ ($k < l$), the set $C_l(\mathcal{K})$ of all common maximal l -transversals of $\mathcal{K}$ has to be “large” from both the measure-theoretic and the topological point of view. Here again one uses the same topological principle responsible for all results in this section together with some integral geometry calculations to show that a cohomologically “big” subspace of the Grassmann manifold $G_k(\mathbb{R}^n)$ has to be large also in a measure-theoretic sense.

14.2.4 EQUIPARTITION OF MASSES BY HYPERPLANES

Every measurable set $A \subset \mathbb{R}^3$ can be partitioned by three planes into 8 pieces of equal measure. This is an instance of the general problem of characterizing all triples (d, j, k) such that for any j mass distributions (measurable sets) in $\mathbb{R}^d$, there exist k hyperplanes, $k \leq d$, such that each of the 2^k “orthants” contains the fraction $1/2^k$ of each of the masses. Such a triple (d, j, k) will be called *admissible*. For example, the ham sandwich theorem implies that $(d, d, 1)$ is admissible. It is known (E. Ramos, [Ram96]) that $d \geq j(2^k - 1)/k$ is a necessary condition and $d \geq j2^{k-1}$ a sufficient one for a triple (d, j, k) to be admissible. Ramos's method yields many interesting results in lower dimensions, including the admissibility of the triples $(9, 3, 3)$, $(9, 5, 2)$, and $(5, 1, 4)$. The most interesting special case that still seems to be out of reach is the triple $(4, 1, 4)$. The key idea in these proofs is to use, for this purpose, a specially designed, generalized form of the Borsuk-Ulam theorem for continuous, “even-odd” maps of the form $f : S^{d-1} \times \dots \times S^{d-1} \rightarrow \mathbb{R}^l$.

APPLICATIONS AND RELATED RESULTS

According to [Mat03], an early interest of computer scientists in partitioning mass distributions by hyperplanes was stimulated in part by *geometric range searching*; cf. Chapter 36 of this Handbook. As noted by Matoušek, the classical mass partitioning results were eventually superseded by random sampling and related results. However, one still wonders about the possible impact of a positive answer to the

following conjecture (a special case of the conjecture that $(4, 1, 4)$ is admissible) to the construction and complexity of geometric algorithms.

CONJECTURE 14.2.7

For each collection of 16 distinct points $A_1, \dots, A_{16}$ in $\mathbb{R}^4$, there exist 4 hyperplanes $H_1, \dots, H_4$ such that each of the associated 16 open orthants contains at most one of the given points.

It is known that the answer to the conjecture is positive if the points are distributed along a **convex curve** in $\mathbb{R}^4$ (a curve in $\mathbb{R}^m$ is convex if, like the moment curve, it intersects each hyperplane in at most m distinct points). This special case of the conjecture follows [Ram96] from the existence of uniform Gray codes on 4-dimensional cubes [Knu]. Recall that a uniform Gray code on a k -dimensional cube is a Hamiltonian circuit on the graph of all edges of the cube that is balanced in the sense that it uses the same number of edges from each of k parallel classes.

14.2.5 RADIAL PARTITIONS BY POLYHEDRAL FANS

An old result of R. Buck and E. Buck [BB49] says that for each continuous mass distribution in the plane, there exist three concurrent lines $l_1, l_2, l_3 \subset \mathbb{R}^2$ that partition $\mathbb{R}^2$ into six sectors of equal measure. It is natural to search for higher dimensional analogs of this result.

Suppose that $Q \subset \mathbb{R}^d$ is a convex polytope and assume that the origin $O \in \mathbb{R}^d$ belongs to the interior $\text{int}(Q)$ of Q . Let $\{F_i\}_{i=1}^k$ be the collection of all facets of Q . Let $\mathcal{F} := \text{fan}(Q)$ be the associated **fan**, i.e., $\mathcal{F} = \{C_1, \dots, C_k\}$ where $C_i = \text{cone}(F_i)$ is the convex closed cone with vertex O generated by F_i .

THEOREM 14.2.8 [Mak01]

Let Q be a regular dodecahedron with the origin $O \in \mathbb{R}^3$ as its barycenter. Then for any centrally symmetric, continuous mass distribution μ on $\mathbb{R}^3$, there exists a linear map $L \in GL(3, \mathbb{R})$ such that

$$\mu(L(C_1)) = \mu(L(C_2)) = \dots = \mu(L(C_k)).$$

Makeev actually shows in [Mak01] that L can be found in the set of all matrices of the form $a \cdot t$, where t is an upper triangular matrix and $a \in GL(3, \mathbb{R})$ is a matrix given in advance. In an earlier paper (see [Mak98]) he showed that a radial partition by a fan determined by the facets of a cube always exists for an arbitrary measure in $\mathbb{R}^3$. Moreover, he shows in [Mak01] that a result analogous to Theorem 14.2.8 also holds for rhombic dodecahedra. Recall that the rhombic dodecahedron U_3 is the polytope bounded by twelve planes, each containing an edge of a cube and parallel to one of the great diagonal planes. A higher dimensional analogue of the rhombic dodecahedron is the polytope U_n in $\mathbb{R}^n$ described as the dual of the difference body of a regular simplex.

PROBLEM 14.2.9

Let $T \subset \mathbb{R}^n$ be a regular simplex and $Q := T - T$ the associated “difference polytope.” Let $U_n := Q^\circ$ be the polytope polar to Q . Clearly U_n is a centrally symmetric polytope with $n^2 + n$ facets F_i , $i = 1, \dots, n^2 + n$. Let $\{K_i\}_{i=1}^{n^2+n}$ be the associated conical dissection of $\mathbb{R}^n$, where $K_i := \text{cone}(F_i)$. Is it true that for any continuous

mass distribution μ on $\mathbb{R}^n$ there exists a nondegenerate affine map $A : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that

$$\mu(A(K_1)) = \mu(A(K_2)) = \dots = \mu(A(K_{n^2+n}))?$$

The following result of Vrećica and Živaljević is an example of a radial partition result for a single measure in $\mathbb{R}^n$ with ratios prescribed by a positive vector α .

THEOREM 14.2.10 [VZ01]

Let $\Delta \subset \mathbb{R}^n$ be a nondegenerate simplex with $O \in \text{int}(\Delta)$. Suppose that μ is a continuous mass distribution on $\mathbb{R}^n$, and let $\alpha = (\alpha_0, \dots, \alpha_n)$ be a given positive vector such that $\alpha_0 + \dots + \alpha_n = 1$. Then there exists a vector $v \in \mathbb{R}^n$ such that $\mu(v + K_i) = \alpha_i \mu(\mathbb{R}^n)$ for each $i = 0, \dots, n$, where $\mathcal{F} = \text{fan}(\Delta) = \{K_i\}_{i=0}^n$ is the radial fan associated to Δ .

14.2.6 EQUIPARTITIONS BY WEDGELIKE CONES

The center transversal theorem is a common generalization of the ham sandwich theorem and the center point theorem. There is another general statement extending the ham sandwich theorem that, as a special boundary case, includes the equipartition case of Theorem 14.2.10.

Definition: Let $\Delta := \text{conv}(\{a_i\}_{i=0}^m)$ be a regular simplex of dimension $m \leq d$ and let $P := \text{aff } \Delta$ be its affine hull. Then $\mathcal{D}(\Delta) = \{D_i\}_{i=0}^m$ represents the dissection of $\mathbb{R}^d$ into $m + 1$ wedgelike cones, where $D_i := P^\perp \oplus \text{cone}(\text{conv}(\{a_j\}_{j \neq i}))$.

CONJECTURE 14.2.11

Let $\mu_0, \dots, \mu_k$ be a family of continuous mass distributions (measures), $0 \leq k \leq d - 1$, defined on $\mathbb{R}^d$. Then there exists a $(d - k)$ -dimensional regular simplex Δ such that for the corresponding dissection, $\mathcal{D}(\Delta)$, for some $x \in \mathbb{R}^d$, and for all i, j ,

$$\mu_i(x + D_j) \geq \frac{\mu_i(\mathbb{R}^d)}{d - k + 1}.$$

This conjecture is denoted in [VZ92] by $B(d, k)$. Theorem 14.2.10 implies $B(d, 0)$, and the ham sandwich theorem is $B(d, d - 1)$. The conjecture is also confirmed in the case $B(d, d - 2)$ for all d . Moreover, there exists a natural topological conjecture implying $B(d, k)$ that is closely related to the analogous statement needed for the center transversal theorem. This statement, denoted in [VZ92] by $C(d, k)$, in the spirit of the CS/TM-scheme, essentially claims that there is no $\mathbb{Z}_{k+1}$ -equivariant map from the Stiefel manifold $V_k(\mathbb{R}^n)$ to the unit sphere $S(V)$ in an appropriate $\mathbb{Z}_{k+1}$ -representation V .

14.2.7 PARTITIONS BY CONVEX SETS

CONJECTURE 14.2.12

Let n and d be integers with $n, d \geq 2$. Assume that $\mu_1, \dots, \mu_d$ are continuous mass distributions such that $\mu_1(\mathbb{R}^d) = \dots = \mu_d(\mathbb{R}^d) = n$. Then there exists a partition of

$\mathbb{R}^d$ into n sets $C_1, \dots, C_n$ such that the interiors $\text{int}(C_i)$ are convex sets and that $\mu_i(C_i) = 1$ for each $i = 1, \dots, n$.

This conjecture was formulated in [KK99] by A. Kaneko and M. Kano for the case $d = 2$. Kaneko and Kano originally formulated the conjecture for finite sets rather than for continuous mass distributions, but this is not essential. Note that the case $n = 2$ is true by the ham sandwich theorem. The case $d = 2$ was independently established by S. Bespamyatnikh, D. Kirkpatrick, and J. Snoeyink, by T. Sakai, and by H. Ito, H. Uehara, and M. Yokoyama; see [BM01] for additional information.

14.2.8 PARTITIONS BY k -FANS IN PRESCRIBED RATIOS

The conjecture of Kaneko and Kano (the case $d = 2, n = 3$) motivated I. Bárány and J. Matoušek in [BM01, BM02] to study general conical partitions of planar or spherical measures in prescribed ratios. We assume, in the following statements, that all measures are continuous mass distributions.

An arrangement of k semilines in the Euclidean (projective) plane or on the 2-sphere is called a k -fan if all semilines start from the same point. A k -fan is an α -partition for a probability measure μ if $\mu(\sigma_i) = \alpha_i$ for each $i = 1, \dots, k$, where $\{\sigma_i\}_{i=1}^k$ are conical sectors associated with the k -fan and $\alpha = (\alpha_1, \dots, \alpha_k)$ is a given vector. The set of all $\alpha = (\alpha_1, \dots, \alpha_m)$ such that for any collection of probability measures $\mu_1, \dots, \mu_m$ there exists a common α -partition by a k -fan is denoted by $\mathcal{A}_{m,k}$. It was shown in [BM01] that the interesting cases of the problem of existence of α -partitions are $(k, m) = (2, 3), (3, 2), (4, 2)$.

CONJECTURE 14.2.13

Suppose that (k, m) is equal to $(2, 3), (3, 2)$ or $(4, 2)$. Then $\alpha \in \mathcal{A}_{k,m}$ if and only if

$$\alpha_1 + \dots + \alpha_m = 1 \quad \text{and} \quad \alpha_i > 0 \quad \text{for each} \quad i = 1, \dots, m.$$

The only known elements in $\mathcal{A}_{4,2}$ are, up to a permutation of coordinates, $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ and $(\frac{1}{5}, \frac{1}{5}, \frac{1}{5}, \frac{2}{5})$. They were discovered by Bárány and Matoušek by an ingenious application of the CS/TM scheme [BM01, BM02]. From this Bárány and Matoušek deduced that $\{(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}), (\frac{1}{2}, \frac{1}{4}, \frac{1}{4})\} \cup \{(\frac{p}{5}, \frac{q}{5}, \frac{r}{5}) \mid p, q, r \in \mathbb{N}^+, p + q + r = 5\} \subset \mathcal{A}_{3,2}$.

14.2.9 OTHER EQUIPARTITIONS

There are other types of partitions of mass distributions. A “cobweb partition theorem” of Schulman [Sch93] guarantees an equipartition of a plane mass distribution into 8 pieces by an arrangement of lines resembling a cobweb.

A result of Paterson (see [Mat03]) is an interesting example of a ham-sandwich-type theorem that deals with partitions of lines rather than of points. It says that for every set of lines in $\mathbb{R}^3$, there exist 3 mutually perpendicular planes such that the interior of each of the resulting octants is intersected by no more than half of the lines.

14.3 THE PROBLEMS OF BORSUK AND KNASTER

The topological methods used in proofs of measure partition results are actually applicable to a much wider class of combinatorial and geometric problems. In fact quite different problems, which on the surface have very little in common (say one of them may be discrete and the other not), may actually lead to the same or closely related configuration spaces and test maps. This in turn implies that such problems both follow from the same general topological principle and that they could, despite appearances, be classified as “relatives.”

14.3.1 BORSUK'S PROBLEM

Borsuk's well-known problem [Bor33] about covering sets in $\mathbb{R}^n$ with sets of smaller diameter was solved in the negative by J. Kahn and G. Kalai [KK93] who proved that the size of a minimal cover is exponential in n ; see [Chapters 1](#) and [2](#) of this Handbook. This, however, gave a new impetus to the study of “Borsuk numbers” after the old exponential upper bounds suddenly became more plausible. This may be one of the reasons why results about “universal covers,” originally used for these estimates, have received new attention in the last few years.

The following result was proved originally by V. Makeev; see also [HMS02, Kup99]. Recall the rhombic dodecahedron U_3 , the polytope bounded by twelve rhombic facets, which appeared in Section 14.2.5.

THEOREM 14.3.1 [Mak98]

A rhombic dodecahedron of width 1 is a universal cover for all sets $S \subset \mathbb{R}^3$ of diameter 1. In other words, each set of diameter 1 in 3-space can be covered by a rhombic dodecahedron whose opposite faces are 1 unit apart.

Let $\Sigma \subset \mathbb{R}^n$ be a regular simplex of edge-length 1, with vertices $v_1, \dots, v_{n+1}$. Then the intersection of $n(n+1)/2$ parallel strips S_{ij} of width 1, where S_{ij} is bounded by the $(n-1)$ -planes orthogonal to the segment $[v_i, v_j]$ passing through the vertices v_i and v_j ($i < j$), is a higher dimensional analog of the rhombic dodecahedron. It is easy to see that this is just another description of the polytope U_n that we encountered in Problem 14.2.9.

CONJECTURE 14.3.2 *Makeev's conjecture* [Mak94]

The polytope U_n is a universal cover in $\mathbb{R}^n$. In other words, for each set $S \subset \mathbb{R}^n$ of diameter 1, there exists an isometry $I : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $S \subset I(U_n)$.

The relevance of the Makeev conjecture for the general Borsuk problem is obvious since in low dimensions, $d = 2$ and $d = 3$, the solutions were based on the construction of suitable universal covers. (Note that the case $d = 4$ of the Borsuk partition problem is still open!) The following stronger conjecture is yet another example of a topological statement with potentially interesting consequences in discrete and computational geometry.

CONJECTURE 14.3.3 [HMS02]

Let $f : S^{n-1} \rightarrow \mathbb{R}$ be an odd function, and let $\Sigma_n \subset \mathbb{R}^n$ be a regular simplex of

edge-length 1, with vertices $v_1, \dots, v_{n+1}$. Then there exists an orthogonal linear map $A \in SO(n)$ such that the $n(n+1)/2$ hyperplanes H_{ij} , $1 \leq i < j \leq n+1$, are concurrent, where

$$H_{ij} := \{x \in \mathbb{R}^n \mid \langle x, A(v_j - v_i) \rangle = f(A(v_j - v_i))\}.$$

G. Kuperberg showed in [Kup99] that, unlike the cases $n = 2$ and $n = 3$, for $n \geq 4$ there is homologically an even number of isometries $I : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $S \subset I(U_n)$ for a given set S of constant width. Kuperberg showed that the Makeev conjecture can be reduced (essentially in the spirit of the CS/TM-scheme) to the question of the existence of a Γ -equivariant map $f : SO(n) \rightarrow V \setminus \{0\}$, where Γ is a group of symmetries of the root system of type A_n and the test space V is an $n(n-1)/2$ -dimensional representation of Γ . The fact that such a map exists if and only if $n \geq 4$ may be an indication that the Makeev conjecture is false in higher dimensions.

14.3.2 KNASTER'S PROBLEM

Knaster's problem is one of the old conjectures of discrete geometry with a distinct topological flavor. The conjecture is now known to be false in general, but the problem remains open in many interesting special cases.

PROBLEM 14.3.4 *Knaster's problem* [Kna47]

Given a finite subset $S = \{s_1, \dots, s_k\} \subset S^n$ of the n -sphere, determine the conditions on k and n so that for each continuous map $f : S^n \rightarrow \mathbb{R}^m$ there will exist an isometry $O \in SO(n+1)$ with

$$f(O(s_1)) = f(O(s_2)) = \dots = f(O(s_k)).$$

Knaster originally conjectured that such an isometry O always exists if $k \leq n - m + 2$. Just as in the case of the Borsuk problem, the first counterexamples took a long time to appear. V. Makeev [Mak86, Mak90], and somewhat later K. Babenko and S. Bogatyĭ [BB89], showed that the condition $k \leq n - m + 2$ is not sufficient if the original set S is sufficiently "flat." In [Che98], W. Chen constructed new counterexamples confirming that the (original) Knaster conjecture is false for all $n > m > 2$.

The fact that Knaster's conjecture is false in general does not rule out the possibility that for some special configurations $S \subset S^n$ the answer is still positive. The case where S is the set of vertices of a "big" regular simplex in S^n is of special interest since it directly generalizes the Borsuk-Ulam theorem.

Questions closely related to Knaster's conjecture are the problems of inscribing or circumscribing polyhedra to convex bodies in $\mathbb{R}^n$; see [HMS02, Kup99]. G. Kuperberg observed that both the circumscription problem for constant-width bodies and Knaster's problem are special cases of the following problem.

PROBLEM 14.3.5 [Kup99]

Given a finite set T of points on S^{d-1} and a linear subspace L of the space of all functions from T to $\mathbb{R}^n$, decide if, for each continuous function $f : S^{d-1} \rightarrow \mathbb{R}^n$, there is an isometry O such that the restriction of $f \circ O$ to T is an element of L .

14.4 TVERBERG-TYPE THEOREMS AND THEIR APPLICATIONS

Every collection of seven points in the plane can be partitioned into three nonempty, disjoint subsets so that the corresponding convex hulls have a nonempty intersection. If we add two more points and color all the points with three colors so that each color is equally represented, then there exists a partition of this set of nine colored points into three multicolored three-point sets such that the corresponding multicolored triangles have a nonempty intersection. Something similar is possible in 3-space, but this time we need five points of each color in order to guarantee a partition of this kind. In short, given a constellation of five blue, five red, and five yellow stars in space, it is always possible to form three vertex-disjoint multicolored triangles with nonempty intersection. These are the simplest nontrivial cases of the Tverberg-type theorems, which, together with their consequences and most important applications, are shown in Figure 14.4.1.

FIGURE 14.4.1
Tverberg-type theorems.

GLOSSARY

Tverberg-type problem: A problem in which a finite set $A \subset \mathbb{R}^d$ is to be partitioned into nonempty, disjoint pieces $A_1, \dots, A_p$, possibly subject to some constraints, so that the corresponding convex hulls $\{\text{conv}(A_i)\}_{i=1}^p$ intersect.

Colors: A set of $k+1$ colors is a collection $\mathcal{C} = \{C_0, \dots, C_k\}$ of disjoint subsets of $\mathbb{R}^d$, $d \geq k$. A set $B \subset \mathbb{R}^d$ is **multicolored** if it contains a point from each of the sets C_i ; in this case $\text{conv } B$ is called a **rainbow simplex** (possibly degenerate).

Type A and Type B: Colored Tverberg problems are of type A or type B depending on whether $k = d$ or $k < d$ (resp.), where $k+1$ is the number of colors.

Tverberg numbers $T(r, d)$, $T(r, k, d)$: $T(r, k, d)$ is the minimal size of each of the colors C_i , $i = 0, \dots, k$, that guarantees that there always exist r intersecting rainbow simplices. $T(r, d) := T(r, d, d)$.

14.4.1 MONOCHROMATIC TVERBERG THEOREMS

THEOREM 14.4.1 *Affine Tverberg Theorem* [Tve66]

Every set $K = \{a_j\}_{j=0}^{(q-1)(d+1)} \subset \mathbb{R}^d$ with $(d+1)(q-1)+1$ elements can be partitioned into q nonempty, disjoint subsets $K_1, \dots, K_q$ so that the corresponding convex hulls have nonempty intersection:

$$\bigcap_{i=1}^q \text{conv}(K_i) \neq \emptyset.$$

(The special case $q = 2$ is Radon's theorem; see [Chapter 4](#).)

THEOREM 14.4.2 *Continuous Tverberg Theorem* [BSS81]

Let Δ^m be an m -dimensional simplex and assume that q is a prime integer. Then for every continuous map $f : \Delta^{(q-1)(d+1)} \rightarrow \mathbb{R}^d$ there exist vertex-disjoint faces $\Delta^{t_1}, \dots, \Delta^{t_q} \subset \Delta^{(q-1)(d+1)}$ such that $\bigcap_{i=1}^q f(\Delta^{t_i}) \neq \emptyset$.

APPLICATIONS AND RELATED RESULTS

The affine Tverberg theorem was proved by Helge Tverberg in 1966. The continuous Tverberg theorem, proved by Bárány, Shlosman, and Szűcs, reduces to the affine version if f is an affine (simplicial) map. It is not known if this result remains true for arbitrary q , although several authors have independently confirmed this if q is a prime power: see [Živ98] for a historical account. Some of the relevant references for these two theorems and their applications are [Bár93, Bjö95, Sar92, Eck93, Vol96, Živ98, Mat02, Mat03].

The following “necklace-splitting theorem” of Noga Alon is a very nice application of the continuous Tverberg theorem.

THEOREM 14.4.3 [Alo87]

Assume that an open necklace has ka_i beads of color i , $1 \leq i \leq t$, $k \geq 2$. Then it is possible to cut this necklace at $t(k-1)$ places and assemble the resulting intervals into k collections, each containing exactly a_i beads of color i .

REMARK 14.4.4

The proof of the necklace-splitting theorem provides a very nice example of an application of the CS/TM scheme (Section 14.1). A continuous model of a necklace is an interval $[0, 1]$ together with k measurable subsets $A_1, \dots, A_k$ representing “beads” of different colors. It is well known that the configuration space of all sequences $0 \leq x_1 \leq \dots \leq x_m \leq 1$ is the m -dimensional simplex, hence the totality of all m -cuts of a necklace is identified with an m -dimensional simplex Σ . Given a cut $c \in \Sigma$, the assembling of the resulting subintervals $I_0(c), \dots, I_m(c)$ of $[0, 1]$ into k collections is determined by a function $f : [m+1] \rightarrow [k]$. Hence, a configuration space associated to the necklace-splitting problem is obtained by gluing together m -simplices Σ_f , one for each function $f \in \text{Fun}([m+1], [k])$. The complex $\mathcal{C}_{m,k}$ obtained by this construction turns out, in fact, to be a very important example

of a complex obtained from a simplex by a *deleted join operation*. The reader is referred to [Mat03] and [Živ98] for details about the role of (deleted) joins in combinatorics.

An interesting connection has emerged recently between ham-sandwich- and Tverberg-type problems. An example of this is the so-called Tverberg-Vrećica conjecture, which incorporates both the center transversal theorem (Theorem 14.2.5) and the (affine) Tverberg theorem in a single general statement.

CONJECTURE 14.4.5 [TV93]

Assume that $0 \leq k \leq d-1$ and let $S_0, S_1, \dots, S_k$ be a collection of finite sets in $\mathbb{R}^d$ of given cardinalities $|S_i| = (r_i - 1)(d - k + 1) + 1$, $i = 0, 1, \dots, k$. Then S_i can be split into r_i nonempty sets, $S_i^1, \dots, S_i^{r_i}$, so that for some k -dimensional affine subspace $D \subset \mathbb{R}^d$, $D \cap \text{conv}(S_i^j) \neq \emptyset$ for all i and j , $0 \leq i \leq k$, $1 \leq j \leq r_i$.

This conjecture was confirmed in [Živ99] for the case where both d and k are odd integers and $r_i = q$ for each i , where q is an odd prime number. Recently S. Vrećica confirmed this conjecture also in the case $r_1 = \dots = r_k = 2$ [Vre03].

The expository article [Kal01] is recommended as a source of additional information about Tverberg-type theorems not covered here. From among Kalai's deep conjectures, beautiful visions, and unexpected possible connections (e.g., with the 4-color theorem), we select the following conjecture.

CONJECTURE 14.4.6 *G. Kalai* (1974)

Given a set $A \subset \mathbb{R}^d$, let $T_r(A)$ be the set of all points in $\mathbb{R}^d$ that belong to the convex hull of r pairwise disjoint subsets of A . By convention let $\dim(\emptyset) = -1$. Then

$$\sum_{r=1}^{|A|} \dim(T_r(A)) \geq 0.$$

14.4.2 COLORED TVERBERG THEOREMS

Let $T(r, k, d)$ be the minimal number t so that for every collection of colors $\mathcal{C} = \{C_0, \dots, C_k\}$ with the property $|C_i| \geq t$ for all $i = 0, \dots, k$, there exist r multicolored sets $A_i = \{a_j^i\}_{j=0}^k$, $i = 1, \dots, r$, that are pairwise disjoint but where the corresponding rainbow simplices $\sigma_i := \text{conv } A_i$ have a nonempty intersection, $\bigcap_{i=1}^r \sigma_i \neq \emptyset$.

The colored Tverberg problem is to establish the existence of, and then to evaluate or estimate, the integer $T = T(r, k, d)$. The cases $k = d$ and $k < d$ are related, but there is also an essential difference. In the case $k = d$, provided t is large enough, the number of intersecting rainbow simplices can be arbitrarily large. In the case $k < d$, for dimension reasons, one cannot expect more than $r \leq d/(d-k)$ intersecting k -dimensional rainbow simplices. This is the reason why colored Tverberg theorems are classified as type A or type B, depending on whether $k = d$ or $k < d$.

In the type A case, where $T(r, d, d)$ is abbreviated simply as $T(r, d)$, it is easy to see that a lower bound for this function is r . It is conjectured that this lower bound is attained:

CONJECTURE 14.4.7 (Type A) [BL92]

$T(r, d) = r$ for all r and d .

This conjecture has been confirmed for $r = 2$ and for $d \leq 2$ [BL92].

The colored Tverberg problem (type A) was originally conjectured and designed as a tool for solving important problems of computational geometry (see [Section 14.4.3](#)). The weak form of the conjecture, $T(r, d) < +\infty$ [BFL90], is already far from obvious.

The following theorem of Živaljević and Vrećica (see [Bár93, Mat03, Živ98]) provides the best bounds known in the general case. It implies that $T(r, d) \leq 4r - 3$ for all r and d .

THEOREM 14.4.8 (Type A) [ZV92]

For every integer r and every collection of $d+1$ disjoint sets (“colors”) $C_0, C_1, \dots, C_d$ in $\mathbb{R}^d$, each of cardinality at least $4r - 3$, there exist r disjoint, multicolored subsets $S_i \subset \bigcup_{i=0}^d C_i$ such that

$$\bigcap_{i=1}^r \text{conv } S_i \neq \emptyset.$$

If r is a power of a prime number then it suffices to assume that the size of each of the colors is at least $2r - 1$. In other words, $T(r, d) \leq 2r - 1$ if r is a prime power and $T(r, d) \leq 4r - 3$ in the general case.

In the type B case, let us assume that $r \leq d/(d - k)$, which is a necessary condition for a colored Tverberg theorem of type B.

CONJECTURE 14.4.9 (Type B)

$T(r, k, d) = 2r - 1$.

There exist examples showing that $T(r, k, d) \geq 2r - 1$.

The following theorem [VZ94, Živ98] confirms Conjecture 14.4.9 above for the case of a prime power r .

THEOREM 14.4.10 (Type B)

Let $C_0, \dots, C_k$ be a collection of $k + 1$ disjoint finite sets (“colors”) in $\mathbb{R}^d$. Let r be a prime power such that $r \leq d/(d - k)$ and let $|C_i| = t \geq 2r - 1$. Then there exist r multicolored k -dimensional simplices S_i , $i = 1, \dots, r$, that are pairwise vertex-disjoint such that

$$\bigcap_{i=1}^r \text{conv } S_i \neq \emptyset.$$

The usual price for using topological (equivariant) methods is the extra assumption that r is a prime or a power of a prime number. On the other hand, the results obtained by these methods hold in greater generality and include nonlinear versions of Theorems 14.4.8 and 14.4.10; see [Živ98] for details and examples.

EXAMPLE 14.4.11

The simplest instance of Theorem 14.4.10 is the case $d = 2$, $k = 1$, and $r = 2$. Then, in the nonlinear version of this theorem, we recognize the well-known fact that the complete bipartite graph $K_{3,3}$ is not planar. This is one of the earliest results in topology, already known to Euler, who formulated it as a problem about three houses and three wells.

14.4.3 APPLICATIONS OF COLORED TVERBERG THEOREMS

Theorem 14.4.8 provided a general bound of the form $T(d+1, d) \leq 4d+1$, which opened the possibility of proving many interesting results in discrete and computational geometry.

HALVING HYPERPLANES AND THE k -SET PROBLEM

The number $h_d(n)$ of halving hyperplanes of a set of size n in $\mathbb{R}^d$, i.e., the number of essentially distinct placements of a hyperplane that split the set in half, according to Bárány, Füredi, and Lovász [BFL90], satisfies

$$h_d(n) = O(n^{d-\epsilon_d}), \quad \text{where } \epsilon_d = T(d+1, d)^{-(d+1)}.$$

POINT SELECTIONS AND WEAK ϵ -NETS

The equivalence of the following statements was established in [ABFK92] before Theorem 14.4.8 was proved. Considerable progress has since been made in this area [Mat02], and different combinatorial techniques for proving these statements have emerged in the meantime.

- Weak colored Tverberg theorem: $T(d+1, d)$ is finite.
- Point selection theorem: There exists a constant $s = s_d$, whose value depends on the bound for $T(d+1, d)$, such that any family $\mathcal{H}$ of $(d+1)$ -element subsets of a set $X \subset \mathbb{R}^d$ of size $|\mathcal{H}| = p^{\binom{|X|}{d+1}}$ contains a pierceable subfamily $\mathcal{H}'$ such that $|\mathcal{H}'| \gg p^s \binom{|X|}{d+1}$. ($\mathcal{H}'$ is **pierceable** if $\bigcap_{S \in \mathcal{H}'} \text{conv } S \neq \emptyset$. $A \gg_d B$ if $A \geq c_1(d)B + c_2(d)$, where $c_1(d) > 0$ and $c_2(d)$ are constants depending only on the dimension d .)
- Weak ϵ -net theorem: For any $X \subset \mathbb{R}^d$ there exists a weak ϵ -net F for convex sets with $|F| \ll_d \epsilon^{(d+1)(1-1/s)}$, where $s = s_d$ is as above. (See Chapter 36 for the notion of ϵ -net; a *weak* ϵ -net is similar, except that it need not be part of X .)
- Hitting set theorem: For every $\eta > 0$ and every $X \subset \mathbb{R}^d$ there exists a set $E \subset \mathbb{R}^d$ that misses at most $\eta \binom{|X|}{d+1}$ simplices of X and has size $|E| \ll_d \eta^{1-s_d}$, where s_d is as above.

OTHER RELATED RESULTS

A topological configuration space that arises via the CS/TM-scheme in proofs of Theorems 14.4.8 and 14.4.10 is the so-called **chessboard complex** $\Delta_{r,t}$, which owes its name to the fact that it can be described as the complex of all nontaking rook placements on an $r \times t$ chessboard. This is an interesting combinatorial object that arises independently as the coset complex of the symmetric group, as the complex of partial matchings in a complete bipartite graph, and as the complex of all partial injective functions. In light of the fact that the high connectivity of a configuration space is a property of central importance for applications (cf. Theorem 14.5.1), chessboard complexes have been studied from this point of view in numerous papers; see [Ath] and [Wac] for recent advances and references.

14.5 TOOLS FROM EQUIVARIANT TOPOLOGY

The method of equivariant maps is a versatile tool for proving results in discrete geometry and combinatorics. For many results these are the only proofs available. Equivariant maps are typically encountered at the final stage of application of the CS/TM-scheme (Section 14.1).

GLOSSARY

G-space X , G -action: A group G acts on a space X if each element of G is a continuous transformation of X and multiplication in G corresponds to composition of transformations. Formally, a G -action α is a continuous map $\alpha : G \times X \rightarrow X$ such that $\alpha(g, \alpha(h, x)) = \alpha(gh, x)$. Then X is called a G -space and $\alpha(g, x)$ is often abbreviated as $g \cdot x$ or gx .

Free G -action: An action is free if $g \cdot x = x$ for some $x \in X$ implies $g = e$, where e is the unit element in G .

G -equivariant map: A map $f : X \rightarrow Y$ of two G -spaces X and Y is equivariant if for all $g \in G$ and $x \in X$, $f(g \cdot x) = g \cdot f(x)$.

Borsuk-Ulam-type theorem: Any theorem establishing the nonexistence of a G -equivariant map between two G -spaces X and Y .

n -connected space: A path-connected and simply connected space with trivial homology in dimensions $1, 2, \dots, n$. A path-connected space X is simply connected or 1-connected if every closed loop $\omega : S^1 \rightarrow X$ can be deformed to a point.

The following generalization of the Borsuk-Ulam theorem is the key result used in proofs of many Tverberg-type statements. Note that if $X = S^n$, $Y = S^{n-1}$, and $G = \mathbb{Z}_2$, it specializes to the “odd” form of the Borsuk-Ulam theorem given in Section 14.2 (following Theorem 14.2.2).

THEOREM 14.5.1 [Dol83]

Suppose X and Y are simplicial (more generally CW) complexes equipped with the free action of a finite group G , and that X is m -connected, where $m = \dim Y$. Then there does not exist a G -equivariant map $f : X \rightarrow Y$.

Theorem 14.5.1 is strong enough for the majority of applications. Nevertheless, in some cases more sophisticated tools are needed. A *topological index theory* is a complexity theory for G -spaces that allows us to conclude that there does not exist a G -equivariant map $f : X \rightarrow Y$ if the G -space Y is of *larger complexity* than the G -space X . A measure of complexity of a given G -space is the so-called *equivariant index* $\text{Ind}_G(X)$. In general, an index function is defined on a class of G -spaces, say all finite G -CW complexes, and takes values in a suitable partially ordered set Ω . For example, if $G = \mathbb{Z}_2$, an index function $\text{Ind}_{\mathbb{Z}_2}(X)$ is defined as the minimum integer n such that there exists a $\mathbb{Z}_2$ -equivariant map $f : X \rightarrow S^n$. In this case $\Omega := \mathbb{N}$ is the poset of nonnegative integers. Note that the Borsuk-Ulam theorem simply states that $\text{Ind}_{\mathbb{Z}_2}(S^n) = n$.

PROPOSITION 14.5.2 [Mat03, Živ98]

For each nontrivial finite group G , there exists an integer-valued index function $\text{Ind}_G(\cdot)$ defined on the class of finite, G -simplicial complexes such that

- (i) If $\text{Ind}_G(Y) > \text{Ind}_G(X)$, then a G -equivariant map $f : X \rightarrow Y$ does not exist.
- (ii) If X is $(n-1)$ -connected then $\text{Ind}_G(X) \geq n$.
- (iii) If X is an n -dimensional, free G -complex then $\text{Ind}_G(X) \leq n$.
- (iv) $\text{Ind}_G(X * Y) \leq \text{Ind}_G(X) + \text{Ind}_G(Y) + 1$, where $X * Y$ is the join of spaces.

It is clear that the computation or good estimates of the complexity indices $\text{Ind}_G(X)$ are essential for applications. Occasionally this can be done even if the details of construction of the index function are not known. Such a tool for finding the lower bounds for an index function described in Proposition 14.5.2 is provided by the following inequality.

PROPOSITION 14.5.3 *Sarkaria inequality* [Mat03, Živ98]

Let L be a free G -complex and $L_0 \subset L$ a G -invariant, simplicial subcomplex. Let $\Delta(L \setminus L_0)$ be the order complex (cf. [Chapter 21](#)) of the complementary poset $L \setminus L_0$. Then

$$\text{Ind}_G(L_0) \geq \text{Ind}_G(L) - \text{Ind}_G(\Delta(L \setminus L_0)) - 1.$$

In some applications it is more natural, and sometimes essential, to use more sophisticated partially ordered sets of G -degrees of complexity. A notable example is the *ideal valued index theory* of S. Husseini and E. Fadell [FH88], which proved useful in establishing the existence of equilibrium points in incomplete markets (mathematical economics).

15 POLYOMINOES

Solomon W. Golomb and David A. Klarner¹

INTRODUCTION

A *polyomino* is a finite, connected subgraph of the square-grid graph consisting of infinitely many unit cells matched edge-to-edge, with pairs of adjacent cells forming edges of the graph. Polyominoes have a long history, going back to the start of the 20th century, but they were popularized in the present era initially by Solomon Golomb, then by Martin Gardner in his *Scientific American* columns “Mathematical Games.” They now constitute one of the most popular subjects in mathematical recreations, and have found interest among mathematicians, physicists, biologists, and computer scientists as well.

15.1 BASIC CONCEPTS

GLOSSARY

Cell: A unit square in the Cartesian plane with its sides parallel to the coordinate axes and with its center at an integer point (u, v) . This cell is denoted $[u, v]$ and identified with the corresponding member of $\mathbb{Z}^2$.

Adjacent cells: Two cells, $[u, v]$ and $[r, s]$, with $|u - r| + |v - s| = 1$.

Square-grid graph: The graph with vertex set $\mathbb{Z}^2$ and an edge for each pair of adjacent cells.

Polyomino: A finite set S of cells such that the induced subgraph of the square-grid graph with vertex set S is connected. A polyomino with exactly n cells is called an *n -omino*. Polyominoes are also known as *animals*.

FIGURE 15.1.1

Two sets of cells: the set on the left is a polyomino, the one on the right is not.

¹This is a revision, by S.W. Golomb, of the chapter of the same title originally written for the first edition by the late D.A. Klarner.

15.2 EQUIVALENCE OF POLYOMINOES

Notions of equivalence for polyominoes are defined in terms of groups of affine maps that act on the set $\mathbb{Z}^2$ of cells in the plane.

GLOSSARY

Translation by (r, s) : The mapping from $\mathbb{Z}^2$ to itself that maps $[u, v]$ to $[u + r, v + s]$; it sends any subset $S \subset \mathbb{Z}^2$ to its *translate* $S + (r, s) = \{[u + r, v + s] : [u, v] \in S\}$.

Translation-equivalent: Sets S, S' of cells such that S' is a translate of S .

Fixed polyomino: A translation-equivalence class of polyominoes; $t(n)$ denotes the number of fixed n -ominoes.

Representatives of the six fixed 3-ominoes are shown in Figure 15.2.1.

FIGURE 15.2.1

The six fixed 3-ominoes.

Lexicographically minimum cell: The unique member $[u, v]$ of a finite set $S \subset \mathbb{Z}^2$ with $v = \min\{v' : [u', v'] \in S\}$, $u = \min\{u' : [u', v] \in S\}$.

Standard position: The translate $S - (u, v)$ of S , where $[u, v]$ is the lexicographically minimum cell in S .

Rotation-translation group: The group $\mathcal{R}$ of mappings of $\mathbb{Z}^2$ to itself of the form $[u, v] \mapsto [u, v] \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}^k + (r, s)$. (The matrix $\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$, which is denoted by R , maps $[u, v]$ to $[v, -u]$ by right multiplication, hence represents a clockwise rotation of 90° .)

Rotationally equivalent: Sets S, S' of cells with $S' = \rho S$ for some $\rho \in \mathcal{R}$.

Chiral polyomino, or handed polyomino: A rotational-equivalence class of polyominoes; $r(n)$ denotes the number of chiral n -ominoes.

The top row of 5-ominoes in Figure 15.2.2 consists of the set of cells $F = \{[0, -1], [-1, 0], [0, 0], [0, 1], [1, 1]\}$, together with FR , FR^2 , and FR^3 . All four of these 5-ominoes are rotationally equivalent. The bottom row in Figure 15.2.2 shows these same four 5-ominoes reflected about the x -axis. These four 5-ominoes are rotationally equivalent as well, but none of them is rotationally equivalent to any of the 5-ominoes shown in the top row. Representatives of the seven chiral 4-ominoes are shown in Figure 15.2.3.

FIGURE 15.2.2

The 5-ominoes in the top row are rotationally equivalent, and so are their reflections in the bottom row, but the two sets are rotationally distinct.

FIGURE 15.2.3

The seven chiral 4-ominoes.

Congruence group: The group $\mathcal{S}$ of motions generated by the matrix $M = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$ (reflection in the x -axis) and the rotation-translation group $\mathcal{R}$. (A typical element of $\mathcal{S}$ has the form $[u, v] \mapsto [u, v]R^k M^i + (r, s)$, for some $k = 0, 1, 2$, or 3, some $i = 0$ or 1, and some $r, s \in \mathbb{Z}$.)

Congruent: Sets S, S' of cells such that $S' = \sigma(S)$ for some $\sigma \in \mathcal{S}$.

Free polyomino: A congruence class of polyominoes; $s(n)$ denotes the number of free n -ominoes.

The twelve free 5-ominoes are shown in Figure 15.2.4.

FIGURE 15.2.4

The twelve free 5-ominoes.

Standard position: A finite set $S \subset \mathbb{Z}^2$ is in standard position if and only if $[0, 0] \in S$, $0 \leq v$ for all $[u, v] \in S$, and $0 \leq u$ for all $[u, 0] \in S$.

THEOREM 15.2.1 *Embedding Theorem*

For each n , let U_n consist of the $n^2 - n + 1$ cells of the form $[u, v]$, where $\begin{cases} 0 \leq u \leq n, & \text{for } v = 0 \\ |u| + v \leq n, & \text{for } v > 0 \end{cases}$. (See Figure 15.2.5 for the case $n = 5$.) Then every n -omino in standard position is a subset of U_n .

FIGURE 15.2.5

A set of $n^2 - n + 1$ cells that contains every n -omino in standard position.

COROLLARY 15.2.2

The number of fixed n -ominoes is finite for each n .

15.3 HOW MANY n -OMINOES ARE THERE?

Table 15.3.1, calculated by Redelmeier [Red81], indicates the values of $t(n)$, $r(n)$, and $s(n)$ for $n = 1, \dots, 24$.

The values seem to be growing exponentially, and indeed they have exponential bounds. It is easy to see that for each n ,

$$\frac{t(n)}{8} \leq s(n) \leq r(n) \leq t(n),$$

and results of Klarner and Rivest [KR73], and of Klarner and Satterfield [KS], using automata theory and building on earlier work of Eden, Klarner, and Read, have shown:

THEOREM 15.3.1

$\lim_{n \rightarrow \infty} (t(n))^{1/n} = \theta$ exists, and $3.9 < \theta < 4.65$.

Jensen and Guttmann [JG00], using an improved algorithm, have extended the enumeration of polyominoes to $n = 46$, but without publishing an extension of Table 15.3.1. They proved $\theta > 3.90318$, and obtained the estimate $\theta \approx 4.062570 \dots$

TABLE 15.3.1 The number of fixed, chiral, and free n -ominoes for $n \leq 24$.

n	$t(n)$	$r(n)$	$s(n)$
1	1	1	1
2	2	1	1
3	6	2	2
4	19	7	5
5	63	18	12
6	216	60	35

23	1344372335524	336093325058	168047007728
24	5239988770268	1309998125640	654999700403

A related, slightly earlier paper by Guttmann, Jensen, et al. [GJW00] describes a method for enumerating “punctured” polyominoes (i.e., those containing holes).

ALGORITHMS

Considerable effort has been expended to find a formula for the number of fixed n -ominoes (say), with no success. Redelmeier’s algorithm, which produced the entries in Table 15.3.1 (and took over ten months of computer time to run), generates the fixed n -ominoes one by one and counts them. Although the running time is (necessarily) exponential, the algorithm takes only $O(n)$ space. Improved algorithms have since been found [JG00], but none has subexponential running time.

UNSOLVED PROBLEMS

PROBLEM 15.3.2

Can $t(n)$ be computed by a polynomial-time algorithm?

A related problem concerns the constant θ defined above:

PROBLEM 15.3.3

Is there a polynomial algorithm to find, for each n , an approximation θ_n of θ satisfying

$$10^{-n} < |\theta_n - \theta| < 10^{-n+1} ?$$

The lower-bound method of [KS1] gives an algorithm for approximating θ from below that has exponential complexity; no such method is known for approximating θ from above.

PROBLEM 15.3.4

Define some decreasing sequence $\beta = (\beta_1, \beta_2, \dots)$ that tends to θ , and give an algorithm to compute β_n for every n .

It is known that $(t(n))^{1/n} \leq \theta$ for all n , and it seems that the ratios $\tau(n) = t(n+1)/t(n)$ increase for all n . If the latter is true, $\tau(n)$ would approach θ from below. This gives two more unsolved problems:

PROBLEM 15.3.5

Show that $(t(n))^{1/n} < (t(n+1))^{1/(n+1)}$ for all n .

PROBLEM 15.3.6

Show that $\tau(n) < \tau(n+1)$ for all n .

15.4 GENERATING POLYOMINOES

The algorithm we describe to generate all n -ominoes, which is essentially due to Redelmeier [Red81], also provides a way of encoding n -ominoes. Starting with all n -ominoes in standard position, with each cell and each neighboring cell numbered, it constructs all numbered $(n+1)$ -ominoes in standard position.

GLOSSARY

Border cell of an n -omino S : A cell $[u, v]$, with $v \geq 0$ or with $v = 0$ and $u \geq 0$, adjacent to some cell of S . The set of all border cells, which is denoted by $B(S)$, can be shown by induction to have no more than $2n$ elements.

The **lexicographic cell ordering** $\prec$ on $\mathbb{Z}^2$ is defined by: $[r, s] \prec [u, v]$ if $s < v$, or if $s = v$ and $r < u$.

The algorithm, illustrated in Figure 15.4.1 for $n = 1, 2$, and 3 , begins with cell 1 in position $[0, 0]$, with its border cells marked 2 and 3, and then adds these—one at a time—each time numbering *new* border cells in their lexicographic order. Whenever a number used for a border cell is not larger than the largest internal number, it is circled, and the corresponding cell is *not* added at the next stage.

Figure 15.4.2 shows all the 4-ominoes produced in this way, with their border cells marked for the next step of the algorithm.

FIGURE 15.4.1

FIGURE 15.4.2

This process assigns a unique set of positive integers to each n -omino S , also illustrated in Figure 15.4.2. The *set character functions* for these integer sets, in turn, truncated after their final 1's, provide a binary codeword $\chi(S)$ for each n -omino S . For example, the code words for the first three 4-ominoes in Figure 15.4.2 would be 1111, 11101, and 111001.

PROBLEM 15.4.1

Which binary strings arise as codewords for n -ominoes?

The following is easy to see:

THEOREM 15.4.2

$t(n+1) = \sum n + |B(S)| - |\chi(S)|$, where the sum extends over all n -ominoes S in standard position, and $|\chi(S)|$ is the number of bits in the codeword of S .

PROBLEM 15.4.3

Is the generating function $T(z) = \sum_{n=1}^{\infty} t(n)z^n$ a rational function? Is $T(z)$ even algebraic?

15.5 SPECIAL TYPES OF POLYOMINOES

Particular kinds of polyominoes arise in various contexts. We will look at several of the most interesting ones.

GLOSSARY

A **composition** of n with k parts is an ordered k -tuple $(p_1, \dots, p_k)$ of positive integers with $p_1 + \dots + p_k = n$.

A polyomino is called **row-convex** if every (horizontal) row consists of a single strip of cells. It is **row-column-convex** if this holds for every column as well.

Simply connected polyomino: A polyomino without holes. (Golomb calls these nonholey polyominoes **profane**.)

A **width- k** polyomino: One each of whose vertical cross sections fits in a $k \times 1$ strip of cells.

A **directed** polyomino is defined recursively as follows: Any single cell is a directed polyomino. An $(n+1)$ -omino is directed if it can be obtained by adding a new cell immediately above, or to the right of, a cell belonging to some directed n -omino.

COMPOSITIONS AND ROW-CONVEX POLYOMINOES

There is a natural 1-1 correspondence between compositions of n and a certain class of n -ominoes in standard position, as indicated in Figure 15.5.1 for the case $n = 4$.

FIGURE 15.5.1
Compositions of 4 corresponding to certain 4-ominoes.

Let us, instead, assign to each composition $(a_1, \dots, a_k)$ of n an n -omino with a *horizontal* strip of a_i cells in row i . This can be done in many ways, and the results are all the row-convex n -ominoes. Since there are $m + n - 1$ ways to form an $(m+n)$ -omino by placing a strip of n cells atop a strip of m cells, it follows that for each composition $(a_1, \dots, a_k)$ of n into positive parts, there are

$$(a_1 + a_2 - 1)(a_2 + a_3 - 1) \cdots (a_{k-1} + a_k - 1)$$

n ominoes having a strip of a_i cells in the i th row for each i (see Figure 15.5.2 for an example arising from the composition $6 = 3 + 1 + 2$).

FIGURE 15.5.2

The 6 row-convex 6-ominoes corresponding to the composition $(3, 1, 2)$ of 6.

It follows that if $b(n)$ is the number of row-convex n -ominoes, then

$$b(n) = \sum (a_1 + a_2 - 1)(a_2 + a_3 - 1) \cdots (a_{k-1} + a_k - 1),$$

where the sum extends over all compositions $(a_1, \dots, a_k)$ of n into k parts, for all k . $b(n)$, and the generating function $B(z) = \sum_{n=1}^{\infty} b(n)z^n$, are given by

THEOREM 15.5.1 [Kla67]

$$b(n+3) = 5b(n+2) - 7b(n+1) + 4b(n), \text{ and } B(z) = \frac{z(1-z)^3}{1-5z+7z^2-4z^3}.$$

COROLLARY 15.5.2

$\lim_{n \rightarrow \infty} (b(n))^{1/n} = \beta$, where β is the largest real root of $z^3 - 5z^2 + 7z - 4 = 0$; $3.20 < \beta < 3.21$.

ROW-COLUMN-CONVEX POLYOMINOES

FIGURE 15.5.3

A typical row-column-convex polyomino.

The problem of finding the number, $c(n)$, of row-column-convex polyominoes was

first posed by D. Knuth [Knu72]. The existence of a generating function for $c(n)$ with special properties, proved in [KR74], enabled Bender to prove the following asymptotic formula:

THEOREM 15.5.3 [Ben74]

$c(n) \sim cg^n$, where $c = 2.67564\dots$ and $g = 2.30914\dots$

The following problem concerns polyominoes radically different from row-column-convex ones.

PROBLEM 15.5.4

Find the smallest natural number n such that there exists an n -omino with no row or column consisting of just a single strip of cells. (An example of a 21-omino with this property is shown in Figure 15.5.4.)

FIGURE 15.5.4

A 21-omino with no row or column a single strip of cells.

SIMPLY CONNECTED POLYOMINOES

Let $t^*(n)$, $s^*(n)$, and $r^*(n)$ denote the numbers of profane fixed, free, and chiral n -ominoes, respectively. Not much is known about their values.

PROBLEM 15.5.5

Compute $t^*(n)$, $s^*(n)$, and $r^*(n)$ for as many values of n as possible.

It is easy to see that $(t^*(n))^{1/n}$, $(s^*(n))^{1/n}$, and $(r^*(n))^{1/n}$ all approach the same limit, θ^* , as $n \rightarrow \infty$, and that $\theta^* \leq \theta$ ($= \lim_{n \rightarrow \infty} (t(n))^{1/n}$ as defined in Section 15.3).

PROBLEM 15.5.6 [Gol]

Does $\theta^* = \theta$?

We conjecture that the answer is “no.”

WIDTH- k POLYOMINOES

A typical width-3 polyomino is shown in Figure 15.5.5.

THEOREM 15.5.7 [Rea62, KS]

Let $t(n, k)$ be the number of fixed width- k n -ominoes, and $T_k(z) = \sum_{n=1}^{\infty} t(n, k)z^n$. Then $T_k(z) = P_k(z)/Q_k(z)$ for some polynomials $P_k(z), Q_k(z)$ with integer coefficients, no common zeroes, and $Q_k(0) = 1$. Equivalently, the sequence $t(n, k)$, $n = 1, 2, \dots$, satisfies a linear, homogeneous difference equation with constant coef-

FIGURE 15.5.5
A width-3 polyomino.

ficients for each fixed k ; the order of the equation is roughly 3^k . Furthermore, the sequence $(t(n, k))^{1/n}$ converges to a limit τ_k as $n \rightarrow \infty$, and $\lim_{k \rightarrow \infty} \tau_k = \theta$ (see [Section 15.3](#)).

For example, for the fixed width-2 n -ominoes (shown in Figure 15.5.6 for small n), we have

$$T_2(z) = \frac{z}{1 - 2z - z^2} = z + 2z^2 + 5z^3 + 12z^4 + \dots,$$

and $t(n + 2, 2) = 2t(n + 1, 2) + t(n, 2)$ for $n \geq 1$.

FIGURE 15.5.6
Width-2 n -ominoes for $n = 1, 2, 3, 4$.

DIRECTED POLYOMINOES

A portion of the family tree for directed polyominoes, constructed similarly to the one in [Figure 15.4.1](#), is shown in [Figure 15.5.7](#). As in [Section 4](#), codewords can be defined for directed polyominoes, and converted into binary words. Let $\mathcal{V}$ be the language formed by all of these.

PROBLEM 15.5.8

Characterize the words in $\mathcal{V}$. In particular, is $\mathcal{V}$ an unambiguous context-free language?

THEOREM 15.5.9 [Bou94]

If $d(n)$ is the number of directed n -ominoes in standard position, and $D(z) = \sum d(n)z^n$, then

$$D(z) = \frac{1}{2} \left(\sqrt{\frac{1+z}{1-3z}} - 1 \right).$$

FIGURE 15.5.7

A family tree for fixed directed polyominoes.

COROLLARY 15.5.10

$$d(n) = \frac{1}{2} \sum_{k=0}^n \binom{1/2}{k} \binom{-1/2}{n-k} (-3)^{n-k}$$

and $d(n)$ satisfies the recurrence relation

$$d(n) = 3^{n-1} - \sum_{k=1}^{n-1} d(k)d(n-k).$$

D. Kaiser [Kai95] used the corollary to generate [Table 15.5.1](#).

15.6 TILING WITH POLYOMINOES

We consider the special case of the tiling problem (see [Chapter 3](#)) in which the space we wish to tile is a set S of cells in the plane and the tiles are polyominoes. Usually S will be a rectangular set.

GLOSSARY

π -type: If S is a finite set of cells, $\mathcal{C}$ a collection of subsets of S , $\pi = (S_1, \dots, S_k)$

TABLE 15.5.1 The first 30 values of $d(n)$, the number of directed n -ominoes in standard position.

n	$d(n)$	n	$d(n)$	n	$d(n)$
1	1	11	17303	21	741365049
2	2	12	49721	22	2173243128
3	5	13	143365	23	6377181825
4	13	14	414584	24	17830782252
5	35	15	1201917	25	55062568341
6	96	16	3492117	26	161995031226
7	267	17	10165779	27	476941691177
8	750	18	29643870	28	1405155255055
9	2123	19	86574831	29	4142457992363
10	6046	20	253188111	30	12219350698880

a partition (or cover) of S , and $T \subset S$, the π -type of T is defined as

$$\tau(\pi, T) = (|S_1 \cap T|, \dots, |S_k \cap T|).$$

Basis: If every rectangle in a set R can be tiled with translates of rectangles belonging to a finite subset $B \subset R$, and if B is minimal with this property, B is called a basis of R .

THEOREM 15.6.1 [Kla70]

Suppose S is a finite set and $\mathcal{C}$ a collection of subsets of S . Then $\mathcal{C}$ tiles S if and only if, for every partition (or cover) π of S , $\tau(\pi, S)$ is a nonnegative integer combination of the types $\tau(\pi, T)$ where T ranges over $\mathcal{C}$.

For example, one can use this to show that a 13×17 rectangular array of squares cannot be tiled with 2×2 and 3×3 squares: Let π be the partition of the 13×17 array S into “black” and “white” cells shown in Figure 15.6.1, and $\mathcal{C}$ the set of all 2×2 and 3×3 squares in S .

FIGURE 15.6.1

A coloring of the 13×17 rectangle.

Then each 2×2 square in $\mathcal{C}$ has type $(2, 2)$, while the 3×3 squares have types $(6, 3)$ and $(3, 6)$. If a tiling were possible, with x 2×2 squares, and with y_1 and y_2 3×3 squares of types $(6, 3)$ and $(3, 6)$ (respectively), then we would have

$$(9 \cdot 13, 8 \cdot 13) = x(2, 2) + y_1(6, 3) + y_2(3, 6),$$

which gives $13 = 3(y_1 - y_2)$, a contradiction.

THEOREM 15.6.2

Let $\mathcal{C}$ be a finite union of translation classes of polyominoes, and let w be a fixed positive integer. Then one can construct a finite automaton that generates all $\mathcal{C}$ -tilings of $w \times n$ rectangles for all possible values of n .

COROLLARY 15.6.3

If w is fixed and $\mathcal{C}$ is given, then it is possible to decide whether there exists some n for which $\mathcal{C}$ tiles a $w \times n$ rectangle.

For example, if we want to tile a $3 \times n$ rectangle with copies of the L -tetromino shown in Figure 15.6.2 in all eight possible orientations, the automaton of Figure 15.6.2 shows that it is necessary and sufficient for n to be a multiple of 8.

FIGURE 15.6.2

An automaton for tiling a $3 \times n$ rectangle with L -tetrominoes.

THEOREM 15.6.4 [KG69, dBK75]

Let R be an infinite set of oriented rectangles with integer dimensions. Then R has a finite basis.

(This theorem, which was originally conjectured by F. Göbel, extends to higher dimensions as well [dBK75].)

For example, let R be the set of all rectangles that can be tiled with the L -tetromino of Figure 15.6.2, and let $B = \{2 \times 4, 4 \times 2, 3 \times 8, 8 \times 3\} \subset R$. Then the following three facts are related:

- (a) R is the set of all $a \times b$ rectangles with $a, b > 1$ and $8|ab$;
- (b) B is a basis of R ;
- (c) Each member of B is tilable with the L -tetromino.

PROBLEM 15.6.5

The smallest rectangle that can be tiled with the Y -pentomino (shown in Figure 15.6.3) is 5×10 . Find a basis B for the set R of all rectangles that can be tiled with Y -pentominoes.

FIGURE 15.6.3

A 5×10 rectangle tiled with Y -pentominoes.

15.7 RECTANGLES OF POLYOMINOES

Here we consider the question of which polyomino shapes have the property that some finite number of copies, allowing all rotations and reflections, can be assembled to form a rectangle. No *a priori* limit can be established, given an arbitrary n -omino, on the minimum number of copies that *may* be required to form a rectangle. (See, e.g., [Ber66].) Fortunately, in any *specific* case, there is a high likelihood of answering the question. But there can be no procedure that can be routinely applied to indicate whether a given polyomino shape will tile some (possibly huge) rectangle.

In 1968, D.A. Klarner [Kla69] defined the **order** of a polyomino P as the minimum number of congruent copies of P that can be assembled (allowing translation, rotation, and reflection) to form a rectangle. For those polyominoes that will not tile any rectangle, the order is undefined. (A polyomino has order 1 if and only if it is itself a rectangle.)

A polyomino has order 2 if and only if it is “half a rectangle”, since two identical copies of it must form a rectangle. This necessarily means that the two copies will be 180° rotations of each other when forming a rectangle. Some examples are shown in Figure 15.7.1.

FIGURE 15.7.1

Some polyominoes of order 2.

There are no polyominoes of order 3. (This was proved in [SW92] by Ian Stewart.) In fact, the only way any rectangle can be divided up into three identical copies of a “well-behaved” geometric figure is to partition it into three *rectangles* (see Figure 15.7.2), and by definition a rectangle has order 1.

FIGURE 15.7.2

How three identical rectangles can form a rectangle.

There are various ways in which four identical polyominoes can be combined to form a rectangle. One way, illustrated in Figure 15.7.3, is to have four 90° rotations of a single shape forming a square.

FIGURE 15.7.3

Polyominoes of order 4 under 90° rotation.

Another way to combine four identical shapes to form a rectangle uses the fourfold symmetry of the rectangle itself: left-right, up-down, and 180-rotational symmetry. Some examples of this appear in Figure 15.7.4.

FIGURE 15.7.4

Polyominoes of order 4 under rectangular symmetry.

There are also more complicated order-4 patterns that were found by Klarner [Kla69], two of which are illustrated in Figure 15.7.5.

FIGURE 15.7.5

Another order-4 construction by Klarner.

Beyond order 4, there is a systematic construction [Gol89] that gives examples of order $4s$ for every positive integer s ; numerous isolated examples of small polyominoes with orders including 10, 18, 24, 28, 50, 76, 92, 96, 138, 192, and 312 are also known.

Figure 15.7.6 shows the isolated examples of order 10 [Gol66] and orders 18, 24, and 28 [Kla69].

FIGURE 15.7.6

Four “sporadic” polyominoes, of orders 10, 18, 24, and 28, respectively.

Figure 15.7.7 shows an example of order 50, found by William Rex Marshall of Dunedin, New Zealand, in 1990 [Mar90].

FIGURE 15.7.7

An 11-omino of order 50.

Figure 15.7.8 shows examples of orders 76 and 92, found by Karl A. Dahlke in 1987, but anticipated by T.W. Marlow in 1985.

The heptomino of order 76 in Figure 15.7.8 cannot tile its minimum rectangle with 180° rotational symmetry. This is also true of the dekomino in Figure 15.7.9 of order 96, whose minimum rectangle (the 30×32) was discovered by W.R. Marshall

FIGURE 15.7.8

A heptomino of order 76 and a hexomino of order 92.

in 1991; in 1995, Marshall also found the minimum rectangles for the order 192 octomino (32×48) and the order 138 (30×46) dekomino [Mar95], later published in [Mar97].

FIGURE 15.7.9

A dekomino of order 96.

No polyomino whose order is an odd number greater than 1 has ever been found, but the possibility that such polyominoes exist (with orders greater than 3) has not been ruled out.

The known *even* orders of polyominoes are all the multiples of 4, as well as the numbers 2, 10, 18, 50, and 138. The smallest even order for which no example is known is 6. Figure 15.7.10 shows one way in which six copies of a polyomino can be fitted together to form a rectangle, but the polyomino in question (as shown) actually has order 2. Michael Reid found a *heptabolo* (a figure made of seven congruent isosceles right triangles) of order 6, also shown in Figure 15.7.10. (See also [Rei97].)

FIGURE 15.7.10

A 12-omino of order 2 that suggests an order-6 tiling, and Michael Reid's order-6 "heptabolo." (Is there any polyomino of order 6?)

The Golomb construction for polyominoes of order $4s$ gives its first new example, order 8, when $s = 2$. The underlying tiling concept of how to fit 8 congruent shapes together to form a rectangle is shown in Figure 15.7.11.

FIGURE 15.7.11

A rectangle formed from eight congruent pieces.

Although the shape used in Figure 15.7.11 is not a polyomino, the same concept can be realized using the 12-omino shown in Figure 15.7.12.

FIGURE 15.7.12

A polyomino of order 8.

PROBLEM 15.7.1

Given a polyomino, will it or won't it tile?

In recent years, whenever a specific polyomino whose ability to tile any rectangle had not yet been decided was publicized, someone with a good computer program has usually found a rectangle-tiling solution within a year. An infinite family of polyominoes, the first several of which are known to tile rectangles, as is every fourth one throughout the family, is illustrated in Figure 15.7.13. Two of the minimum rectangles, discovered in 1995 by Marshall (see [Mar97]) are shown in Figure 15.7.14. The general case is still open.

FIGURE 15.7.13

Infinite family of polyominoes. Does each one tile a rectangle? (The number below each figure is its order, if known.)

FIGURE 15.7.14

An octomino of order 192 and a dekomino of order 138.

15.8 SOURCES AND RELATED MATERIAL

FURTHER READING

A comprehensive recent survey of the subject, complete with an abundance of references, is [Gol94]. Another book on the subject is [Mar91]. Finally, there are a great many articles, puzzles, and problems concerning polyominoes to be found in the *Journal of Recreational Mathematics*.

POLYTOPES AND POLYHEDRA

16 BASIC PROPERTIES OF CONVEX POLYTOPES

Martin Henk, Jürgen Richter-Gebert, and Günter M. Ziegler

INTRODUCTION

Convex polytopes are fundamental geometric objects that have been investigated since antiquity. The beauty of their theory is nowadays complemented by their importance for many other mathematical subjects, ranging from integration theory, algebraic topology, and algebraic geometry (toric varieties) to linear and combinatorial optimization.

In this chapter we try to give a short introduction, provide a sketch of “what polytopes look like” and “how they behave,” with many explicit examples, and briefly state some main results (where further details are in the subsequent chapters of this Handbook). We concentrate on two main topics:

- Combinatorial properties: faces (vertices, edges, $\dots$, facets) of polytopes and their relations, with special treatments of the classes of low-dimensional polytopes and polytopes with few vertices;
- Geometric properties: volume and surface area, mixed volumes, and quermassintegrals, including explicit formulas for the cases of the regular simplices, cubes, and cross-polytopes.

We refer to Grünbaum [Grü03] for a comprehensive view of polytope theory, and to Ziegler [Zie95] and Schneider [Sch93] for thorough treatments of the combinatorial (resp. convex geometric) aspects of polytope theory.

16.1 COMBINATORIAL STRUCTURE

GLOSSARY

$\mathcal{V}$ -polytope: The convex hull of a finite set $X = \{x^1, \dots, x^n\}$ of points in $\mathbb{R}^d$:

$$P = \text{conv}(X) := \left\{ \sum_{i=1}^n \lambda_i x^i \mid \lambda_i \geq 0, \sum_{i=1}^n \lambda_i = 1 \right\}.$$

$\mathcal{H}$ -polytope: A bounded solution set of a finite system of linear inequalities:

$$P = P(A, b) := \{x \in \mathbb{R}^d \mid a_i^T x \leq b_i \text{ for } 1 \leq i \leq m\},$$

where $A \in \mathbb{R}^{m \times d}$ is a real matrix with rows a_i^T , and $b \in \mathbb{R}^m$ is a real vector with entries b_i . Here boundedness means that there is a constant N such that $\|x\| \leq N$ holds for all $x \in P$.

Polytope: A subset $P \subseteq \mathbb{R}^d$ that can be presented as a $\mathcal{V}$ -polytope or (equivalently, by the main theorem below!) as an $\mathcal{H}$ -polytope.

Dimension: The dimension of an arbitrary subset $S \subseteq \mathbb{R}^d$ is defined as the dimension of its affine hull: $\dim(S) := \dim(\text{aff}(S))$.

(Recall that $\text{aff}(S)$, the affine hull of a set S , is $\{ \sum_{j=1}^p \lambda_j x^j \mid x^1, \dots, x^p \in S, \sum_{j=1}^p \lambda_j = 1 \}$, the smallest affine subspace of $\mathbb{R}^d$ containing S .)

d -polytope: A d -dimensional polytope. In what follows, a subscript in the name of a polytope usually denotes its dimension.

Interior and relative interior: The interior $\text{int}(P)$ is the set of all points $x \in P$ such that for some $\epsilon > 0$, the ϵ -ball $B_\epsilon(x)$ around x is contained in P .

Similarly, the relative interior $\text{relint}(P)$ is the set of all points $x \in P$ such that for some $\epsilon > 0$, the intersection $B_\epsilon(x) \cap \text{aff}(P)$ is contained in P .

Affine equivalence: For polytopes $P \subseteq \mathbb{R}^d$ and $Q \subseteq \mathbb{R}^e$, an affine map $\pi: \mathbb{R}^d \rightarrow \mathbb{R}^e$, $x \mapsto Ax + b$ mapping P bijectively to Q . π need not be injective or surjective. However, it has to restrict to a bijective map $\text{aff}(P) \rightarrow \text{aff}(Q)$. In particular, if P and Q are affinely equivalent, then they have the same dimension.

THEOREM 16.1.1 *Main Theorem of Polytope Theory* (cf. [Zie95, pp. 27])

The definitions of $\mathcal{V}$ -polytopes and of $\mathcal{H}$ -polytopes are equivalent. That is, every $\mathcal{V}$ -polytope has a description by a finite system of inequalities, and every $\mathcal{H}$ -polytope can be obtained as the convex hull of a finite set of points (its vertices).

Geometrically, a $\mathcal{V}$ -polytope is the projection of an $(n-1)$ -dimensional simplex, while an $\mathcal{H}$ -polytope is the bounded intersection of m closed halfspaces [Zie95, Lecture 1]. To see the main theorem at work, consider the following two statements: the first one is easy to see for $\mathcal{V}$ -polytopes, but not for $\mathcal{H}$ -polytopes, and for the second statement we have the opposite effect.

1. **Projections:** Every image of a polytope P under an affine map $\pi: x \mapsto Ax + b$ is a polytope.
2. **Intersections:** Any intersection of a polytope with an affine subspace is a polytope.

However, the computational step from one of the main theorem's descriptions of polytopes to the other—a “convex hull computation”—is far from trivial. Essentially, there are three types of algorithms available: inductive algorithms (inserting vertices, using a so-called beneath-beyond technique), projection resp. intersection algorithms (known as Fourier-Motzkin elimination resp. double description algorithms), and reverse search methods (as introduced by Avis and Fukuda). For explicit computations one can use public domain codes as integrated in the software package `polymake` [GJ00] that we use here; see also [Chapters 22](#) and [64](#).

In the following definitions of d -simplices, d -cubes, and d -cross-polytopes we give both a $\mathcal{V}$ - and an $\mathcal{H}$ -presentation in each case. From this one can see that the $\mathcal{H}$ -presentation can have exponential “size” in terms of the size of the $\mathcal{V}$ -presentation (e.g., for the d -cross-polytopes), and vice versa (for the d -cubes).

Definition: A (regular) d -dimensional **simplex** in $\mathbb{R}^d$ is given by

$$T_d := \text{conv}\{e^1, e^2, \dots, e^d, \frac{1 - \sqrt{d+1}}{d}(e^1 + \dots + e^d)\}$$

$$= \left\{ x \in \mathbb{R}^d \mid \sum_{i=1}^d x_i \leq 1, \quad -(1 + \sqrt{d+1} + d)x_k + \sum_{i=1}^d x_i \leq 1 \text{ for } 1 \leq k \leq d \right\},$$

where $e^1, \dots, e^d$ denotes the coordinate unit vectors in $\mathbb{R}^d$.

The simplices T_d are **regular polytopes** (with a symmetry group that is flag-transitive—see [Chapter 19](#)): the parameters have been chosen so that all edges of T_d have length $\sqrt{2}$. Furthermore, the origin $0 \in \mathbb{R}^d$ is in the interior of T_d : this is clear from the $\mathcal{H}$ -presentation.

However, for the combinatorial theory one considers polytopes that differ only by a change of coordinates (an affine transformation) to be equivalent. Thus, we would refer to any d -polytope that can be presented as the convex hull of $d+1$ points as a d -*simplex*, since any two such polytopes are equivalent with respect to an affine map. Other standard choices include

$$\begin{aligned} \Delta_d &:= \text{conv}\{0, e^1, e^2, \dots, e^d\} \\ &= \left\{ x \in \mathbb{R}^d \mid \sum_{i=1}^d x_i \leq 1, \quad x_k \geq 0 \text{ for } 1 \leq k \leq d \right\} \end{aligned}$$

and the $(d-1)$ -dimensional simplex in $\mathbb{R}^d$ given by

$$\begin{aligned} \Delta'_{d-1} &:= \text{conv}\{e^1, e^2, \dots, e^d\} \\ &= \left\{ x \in \mathbb{R}^d \mid \sum_{i=1}^d x_i = 1, \quad x_k \geq 0 \text{ for } 1 \leq k \leq d \right\}. \end{aligned}$$

FIGURE 16.1.1

A 3-simplex, a 3-cube, and a 3-dimensional cross-polytope (octahedron).

Definition: A **d-cube** (a.k.a. the d -dimensional **hypercube**) is

$$\begin{aligned} C_d &:= \text{conv}\{\alpha_1 e^1 + \alpha_2 e^2 + \dots + \alpha_d e^d \mid \alpha_1, \dots, \alpha_d \in \{+1, -1\}\} \\ &= \left\{ x \in \mathbb{R}^d \mid -1 \leq x_k \leq 1 \text{ for } 1 \leq k \leq d \right\}, \end{aligned}$$

and a d -dimensional **cross-polytope** in $\mathbb{R}^d$ (known as the **octahedron** for $d = 3$) is given by

$$C_d^\Delta := \text{conv}\{\pm e^1, \pm e^2, \dots, \pm e^d\} = \left\{ x \in \mathbb{R}^d \mid \sum_{i=1}^d |x_i| \leq 1 \right\}.$$

Again, there are other natural choices, among them

$$\begin{aligned} [0, 1]^d &= \text{conv}\left\{ \sum_{i \in S} e^i \mid S \subseteq \{1, 2, \dots, d\} \right\} \\ &= \left\{ x \in \mathbb{R}^d \mid 0 \leq x_k \leq 1 \text{ for } 1 \leq k \leq d \right\}, \end{aligned}$$

the d -dimensional *unit cube*.

As another example to illustrate concepts and results we will occasionally use the unnamed polytope with six vertices shown in Figure 16.1.2.

FIGURE 16.1.2
Our unnamed “typical” 3-polytope. It has 6 vertices, 11 edges, and 7 facets.

This polytope without a name can be presented as a $\mathcal{V}$ -polytope by listing its six vertices. The following coordinates make it into a subpolytope of the 3-cube C_3 : the vertex set consists of all but two vertices of C_3 . Our list below (on the left) shows the vertices of our unnamed polytope in a format used as input for the `polymake` program, i.e., the vertices are given in homogeneous coordinates with an additional 1 as first entry. From these data the `polymake` program produces a description (on the right) of the polytope as an $\mathcal{H}$ -polytope, i.e., it computes facets defining hyperplanes with respect to the homogeneous coordinates. For instance, the entries in the last row of the section FACETS describe the halfspace $1x_0 - 1x_1 + 1x_2 - 1x_3 \geq 0$ which corresponds to the facet-defining inequality $x_1 - x_2 + x_3 \leq 1$ of our 3-dimensional unnamed polytope.

POINTS	FACETS
1 1 1 1	1 0 -1 0
1 -1 -1 1	1 -1 0 0
1 1 1 -1	1 1 0 0
1 1 -1 -1	1 0 1 0
1 -1 1 -1	1 0 0 1
1 -1 -1 -1	1 1 -1 -1
	1 -1 1 -1

Unbounded polyhedra can, via projective transformations, be treated as polytopes with a distinguished facet (see [Zie95, p. 75]). In this respect, we do not lose anything on the combinatorial level if we restrict the following discussion to the setting of full-dimensional convex polytopes: d -polytopes embedded in $\mathbb{R}^d$.

16.1.1 FACES

GLOSSARY

Support function: Given a polytope $P \subseteq \mathbb{R}^d$, the function

$$h(P, \cdot) : \mathbb{R}^d \rightarrow \mathbb{R}, \quad h(P, x) := \sup\{\langle x, y \rangle \mid y \in P\},$$

where $\langle x, y \rangle$ denotes the inner product on $\mathbb{R}^d$. (Since P is compact one may replace sup by max.)

For $v \in \mathbb{R}^d \setminus \{0\}$ the hyperplane

$$H(P, v) := \{x \in \mathbb{R}^d \mid \langle x, v \rangle = h(P, v)\}$$

is the **supporting hyperplane** of P with **outer normal vector** v . Note that $H(P, \mu v) = H(P, v)$ for $\mu \in \mathbb{R}$, $\mu > 0$. For a vector u of the $(d-1)$ -dimensional **unit sphere** S^{d-1} , $h(P, u)$ is the signed distance of the supporting plane $H(P, u)$ from the origin. (For $v = 0$ we set $H(P, 0) := \mathbb{R}^d$, which is not a hyperplane.)

The intersection of P with a supporting hyperplane $H(P, v)$ is called a (nontrivial) **face**, or more precisely a **k -face** if the dimension of $\text{aff}(P \cap H(P, v))$ is k . Each face is itself a polytope.

The set of all k -faces is denoted by $\mathcal{F}_k(P)$ and its cardinality by $f_k(P)$.

f -vector: The vector of face numbers $\mathbf{f}(P) = (f_0(P), f_1(P), \dots, f_{d-1}(P))$ associated with a d -polytope.

The empty set $\emptyset$ and the polytope P itself are considered **trivial faces** of P , of dimensions -1 and $\dim(P)$, respectively. All faces other than P are **proper faces**.

The faces of dimension 0 and 1 are called **vertices** and **edges**, respectively. The $(\dim(P)-1)$ -faces of P are called **facets**.

Facet-vertex incidence matrix: The matrix $M \in \{0, 1\}^{f_{d-1}(P) \times f_0(P)}$ that has an entry $M(F, v) = 1$ if the facet F contains the vertex v , and $M(F, v) = 0$ otherwise.

Graded poset: A partially ordered set $(P, \leq)$ with a unique minimal element $\hat{0}$, a unique maximal element $\hat{1}$, and a **rank function** $r: P \rightarrow \mathbb{N}_0$ that satisfies

- (1) $r(\hat{0}) = 0$, and $p < p'$ implies $r(p) < r(p')$, and
- (2) $p < p'$ and $r(p') - r(p) > 1$ implies that there is a $p'' \in P$ with $p < p'' < p'$.

Lattice L : A partially ordered set $(P, \leq)$ in which every pair of elements $p, p' \in P$ has a unique maximal lower bound, called the **meet** $p \wedge p'$, and a unique minimal upper bound, called the **join** $p \vee p'$.

Atom, coatom: If L is a graded lattice, the minimal elements of $L \setminus \{\hat{0}\}$ (i.e., the elements of rank 1) are the atoms of L . Similarly, the maximal elements of $L \setminus \{\hat{1}\}$ (i.e., the elements of rank $r(\hat{1})-1$) are the coatoms of L . A graded lattice is **atomic** if every element is a join of a set of atoms, and it is **coatomic** if every element is a meet of a set of coatoms.

Face lattice $L(P)$: The set of all faces of P , partially ordered by inclusion.

Combinatorially isomorphic: Polytopes whose face lattices are isomorphic as abstract (unlabeled) partially ordered sets/lattices.

Equivalently, P and P' are combinatorially equivalent if their facet-vertex incidence matrices differ only by column and row permutations.

Combinatorial type: An equivalence class of polytopes under combinatorial equivalence.

THEOREM 16.1.2 Face Lattices of Polytopes (cf. [Zie95, pp. 51])

The face lattices of convex polytopes are finite, graded, atomic, and coatomic lattices. The meet operation $G \wedge H$ is given by intersection, while the join $G \vee H$ is the intersection of all facets that contain both G and H . The rank function on $L(P)$ is given by $r(G) = \dim(G) + 1$.

The minimal nonempty faces of a polytope are its vertices: they correspond to atoms of the lattice $L(P)$. Every face is the join of its vertices, hence $L(P)$ is atomic. Similarly, the maximal proper faces of a polytope are its facets: they correspond to the coatoms of $L(P)$. Every face is the intersection of the facets it is contained in, hence face lattices of polytopes are coatomic.

FIGURE 16.1.3

The face lattice of our unnamed 3-polytope. The 7 coatoms (facets) and the 6 atoms (vertices) have been labeled in the order of their appearance in the lists on page 358. Thus, the downwards-path from the coatom “4” to the atom “2” represents the fact that the fourth facet contains the second vertex.

The face lattice is a complete encoding of the combinatorial structure of a polytope. However, in general the encoding by a facet-vertex incidence matrix is more efficient. The following matrix—also provided by `polymake`—represents our unnamed 3-polytope:

$$M = \begin{array}{c} \begin{array}{cccccc} & 1 & 2 & 3 & 4 & 5 & 6 \\ \begin{array}{l} 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array} & \begin{pmatrix} 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 \end{pmatrix} \end{array} \end{array}$$

How do we decide whether a set of vertices $\{v^1, \dots, v^k\}$ is (the vertex set of) a face of P ? This is the case if and only if no other vertex v^0 is contained in all the facets that contain $\{v^1, \dots, v^k\}$. This criterion makes it possible, for example, to derive the edges of a polytope P from a facet-vertex matrix.

For low-dimensional polytopes, the criterion can be simplified: if $d \leq 4$, then two vertices are connected by an edge if and only if there are at least $d - 1$ different facets that contain them both. However, the same is not true any longer for 5-dimensional polytopes, where vertices may be nonadjacent despite being contained in many common facets. (The best way to see this is by using polarity; see below.)

16.1.2 POLARITY

GLOSSARY

Polarity: If $P \subseteq \mathbb{R}^d$ is a d -polytope with the origin in its interior, then the **polar** of P is the d -polytope

$$P^\Delta := \{y \in \mathbb{R}^d \mid \langle y, x \rangle \leq 1 \text{ for all } x \in P\}.$$

Stellar subdivision: The stellar subdivision of a polytope P in a face F is the polytope $\text{conv}(P \cup x^F)$, where x^F is a point of the form $y^F - \epsilon(y^P - y^F)$, where y^P is in the interior of P , y^F is in the relative interior of F , and ϵ is small enough.

Vertex figure P/v : If v is a vertex of P , then $P/v := P \cap H$ is the polytope obtained by intersecting P with a hyperplane H that has v on one side and all the other vertices of P on the other side.

Cutting off a vertex: The polytope $P \cap H^-$ obtained by intersecting P with a closed halfspace H^- that does not contain the vertex v , but contains all other vertices of P in its interior. (In this situation, $P \cap H^+$ is a pyramid over the vertex figure P/v .)

Quotient of P : A polytope obtained from P by taking vertex figures (possibly) several times.

Simplicial polytope: A polytope all of whose facets (equivalently, proper faces) are simplices.

Simple polytope: A polytope all of whose vertex figures (equivalently, proper quotients) are simplices.

Polarity is a fundamental construction in the theory of polytopes. One always has $P^{\Delta\Delta} = P$, under the assumption that P has the origin in its interior. This condition can always be obtained after a change of coordinates. In particular, we speak of (combinatorial) polarity between d -polytopes Q and R that are combinatorially isomorphic to P and P^Δ , respectively.

Any $\mathcal{V}$ -presentation of P yields an $\mathcal{H}$ -presentation of P^Δ , and conversely, via

$$P = \text{conv}\{v^1, \dots, v^n\} \iff P^\Delta = \{x \in \mathbb{R}^d \mid \langle v^i, x \rangle \leq 1 \text{ for } 1 \leq i \leq n\}.$$

There are basic relations between polytopes and polytopal constructions under polarity. For example, the fact that the d -cross-polytopes C_d^Δ are the polars of the d -cubes C_d is built into our notation. More generally, the polars of simple polytopes are simplicial, and conversely. This can be deduced from the fact that the facets F of a polytope P correspond to the vertex figures P^Δ/v of its polar P^Δ . In fact, F and P^Δ/v are combinatorially polar in this situation. More generally, one has a correspondence between faces and quotients under polarity.

At a combinatorial level, all this can be derived from the fact that the face lattices $L(P)$ and $L(P^\Delta)$ are anti-isomorphic: $L(P^\Delta)$ may be obtained from $L(P)$ by reversing the order relations. Thus, lower intervals in $L(P)$, corresponding to faces of P , translate under polarity into upper intervals of $L(P^\Delta)$, corresponding to quotients of P^Δ .

16.1.3 BASIC CONSTRUCTIONS

GLOSSARY

For the following constructions, let

$P \subseteq \mathbb{R}^d$ be a d -dimensional polytope with n vertices and m facets, and

$P' \subseteq \mathbb{R}^{d'}$ a d' -dimensional polytope with n' vertices and m' facets.

Scalar multiple: For $\lambda \in \mathbb{R}$, the scalar multiple λP is defined by $\lambda P := \{\lambda x \mid x \in P\}$. P and λP are combinatorially (in fact, affinely) isomorphic for all $\lambda \neq 0$. In particular, $(-1)P = -P = \{-p \mid p \in P\}$, and $(+1)P = P$.

Minkowski sum: $P + P' := \{p + p' \mid p \in P, p' \in P'\}$.

It is also useful to define the difference as $P - P' = P + (-P')$. The polytopes $P + \lambda P'$ are combinatorially isomorphic for all $\lambda > 0$, and similarly for $\lambda < 0$.

If $P' = \{p'\}$ is one single point, then $P - \{p'\}$ is the image of P under the translation that takes p' to the origin.

Product: The $(d+d')$ -dimensional polytope $P \times P' := \{(p, p') \in \mathbb{R}^{d+d'} \mid p \in P, p' \in P'\}$. $P \times P'$ has $n \cdot n'$ vertices and $m + m'$ facets.

Join: The convex hull $P * P'$ of $P \cup P'$, after embedding P and P' in a space where their affine hulls are skew. For example,

$$P * P' := \text{conv}(\{(p, 0, 0) \in \mathbb{R}^{d+d'+1} \mid p \in P\} \cup \{(0, p', 1) \in \mathbb{R}^{d+d'+1} \mid p' \in P'\}).$$

$P * P'$ has dimension $d+d'+1$ and $n+n'$ vertices. Its k -faces are the joins of i -faces of P and $(k-i-1)$ -faces of P' , hence $f_k(P * P') = \sum_{i=-1}^k f_i(P)f_{k-i-1}(P')$.

Free sum: The free sum is the $(d+d')$ -dimensional polytope

$$P \oplus P' := \text{conv}(\{(p, 0) \in \mathbb{R}^{d+d'} \mid p \in P\} \cup \{(0, p') \in \mathbb{R}^{d+d'} \mid p' \in P'\}).$$

Thus the free sum $P \oplus P'$ is a projection of the join $P * P'$. If both P and P' have the origin in their interiors—this is the “usual” situation for creating free sums, then $P \oplus P'$ has $n + n'$ vertices and $m \cdot m'$ facets.

Pyramid: The join $\text{pyr}(P) := P * \{0\}$ of P with a point (a 0-dimensional polytope $P' = \{0\} \subseteq \mathbb{R}^0$). The pyramid $\text{pyr}(P)$ has $n + 1$ vertices and $m + 1$ facets.

Prism: The product $\text{prism}(P) := P \times I$, where I denotes the real interval $I = [-1, +1] \subseteq \mathbb{R}$.

Bipyramid: If P has the origin in its interior, then the bipyramid over P is the $(d+1)$ -dimensional polytope constructed as the free sum $\text{bipyr}(P) := P \oplus I$.

Lawrence extension: If $p \in \mathbb{R}^d$ is a point outside the polytope P , then the free sum $(P - \{p\}) \oplus [1, 2]$ is a *Lawrence extension of P at p* . (For $p \in P$ this is just a pyramid.)

Of course, the many constructions listed in the glossary above are not independent of each other. For instance, some of these constructions are related by polarity: for polytopes P and P' with the origin in their interiors, the product and the free sum constructions are related by polarity,

$$P \times P' = (P^\Delta \oplus P'^\Delta)^\Delta,$$

and this specializes to polarity relations among the pyramid, bipyramid, and prism constructions,

$$\text{pyr}(P) = (\text{pyr}(P^\Delta))^\Delta \quad \text{and} \quad \text{prism}(P) = (\text{bipyr}(P^\Delta))^\Delta.$$

Similarly, “cutting off a vertex” is polar to “stellar subdivision in a facet.”

It is interesting to study—and this has not been done systematically—how the basic polytope operations generate complicated convex polytopes from simpler ones. For example, starting from a one-dimensional polytope $I = C_1 = [-1, +1] \subset \mathbb{R}$, the

direct product construction generates the cubes C_d , while free sums generate the cross-polytopes C_d^Δ .

Even more complicated centrally symmetric polytopes, the *Hanner polytopes*, are obtained from copies of the interval I by using products and free sums. They are interesting since they achieve with equality the conjectured bound that all centrally symmetric d -polytopes have at least 3^d nonempty faces (Kalai [Kal89]).

Every polytope can be viewed as a region of a hyperplane arrangement: for this, take as $\mathcal{A}_P$ the set of all hyperplanes of the form $\text{aff}(F)$, where F is a facet of P . For additional points, such as the points outside the polytope used for Lawrence extensions, or those used for stellar subdivisions, it is often important only in which region, or in which lower-dimensional region, of the arrangement $\mathcal{A}_P$ they lie.

The Lawrence extension, by the way, may seem like quite a harmless little construction. However, it has the amazing property that it can encode the structure of a point *outside* a d -polytope into the boundary structure of a $(d+1)$ -polytope. This accounts for a large part of the “special” 4- and 5-polytopes in the literature, such as the 4-polytopes for which a facet, or even a 2-face, cannot be prescribed in shape [Ric96].

16.1.4 MORE EXAMPLES

There are many interesting classes of polytopes arising from diverse areas of mathematics (as well as physics, optimization, crystallography, etc.). Some of these are discussed below. You will find many more classes of examples discussed in other chapters of this Handbook. For example, regular and semiregular polytopes are discussed in [Chapter 19](#), while polytopes that arise as Voronoi cells of lattices appear in [Chapters 3](#), [7](#), and [62](#).

GLOSSARY

Graph of a polytope: The graph $G(P) = (V(P), E(P))$ with vertex set $V(P) = \mathcal{F}_0(P)$ and edge set $E(P) = \{\{v^1, v^2\} \subseteq \binom{V}{2} \mid \text{conv}\{v^1, v^2\} \in \mathcal{F}_1(P)\}$.

Zonotope: Any polytope Z that can be represented as the image of an n -dimensional cube C_n under an affine map; equivalently, any polytope that can be written as a Minkowski sum of n line segments (1-dimensional polytopes). The smallest n such that Z is an image of C_n is the **number of zones** of Z .

Moment curve: The curve γ in $\mathbb{R}^d$ defined by $\gamma: \mathbb{R} \rightarrow \mathbb{R}^d, t \mapsto (t, t^2, \dots, t^d)^T$.

Cyclic polytope: The convex hull of a finite set of points on a moment curve, or any polytope combinatorially equivalent to it.

k -neighborly polytope: A polytope such that each subset of at most k vertices forms the vertex set of a face. Thus every polytope is 1-neighborly, and a polytope is 2-neighborly if and only if its graph is complete.

Neighborly polytope: A d -dimensional polytope that is $\lfloor d/2 \rfloor$ -neighborly.

(0,1)-polytope: A polytope all of whose vertex coordinates are 0 or 1, that is, whose vertex set is a subset of the vertex set $\{0, 1\}^d$ of the unit cube.

ZONOTOPES

Zonotopes appear in quite different guises. They can equivalently be defined as the Minkowski sums of finite sets of line segments (1-dimensional polytopes), as the affine projections of d -cubes, or as polytopes all of whose faces (equivalently, all 2-faces) exhibit central symmetry. Thus a 2-dimensional polytope is a zonotope if and only if it is centrally symmetric.

FIGURE 16.1.4

A 2-dimensional and a 3-dimensional zonotope, each with 5 zones. (The 2-dimensional one is a projection of the 3-dimensional one; note that every projection of a zonotope is a zonotope.)

Among the most prominent zonotopes are the permutohedra: The **permutohedron** Π_{d-1} is constructed by taking the convex hull of all d -vectors whose coordinates are $\{1, 2, \dots, d\}$, in any order. The permutohedron Π_{d-1} is a $(d-1)$ -dimensional polytope (contained in the hyperplane $\{x \in \mathbb{R}^d \mid \sum_{i=1}^d x_i = d(d+1)/2\}$) with $d!$ vertices and $2^d - 2$ facets.

FIGURE 16.1.5

The 3-dimensional permutohedron Π_3 . The vertices are labeled by the permutations that, when applied to the coordinate vector in $\mathbb{R}^4$, yield $(1, 2, 3, 4)^T$.

One unusual feature of permutohedra is that they are simple zonotopes: these are rare in general, and the (unsolved) problem of classifying them is equivalent to the problem of classifying all simplicial arrangements of hyperplanes (see [Section 6.3.3](#)).

Zonotopes are important because their theory is equivalent to the theories of vector configurations (realizable oriented matroids) and of hyperplane arrange-

ments. In fact, the system of line segments that generates a zonotope can be considered as a vector configuration, and the hyperplanes that are orthogonal to the line segments provide the associated hyperplane arrangement. We refer to [BLS⁺99, Section 2.2] and [Zie95, Lecture 7].

Finally, we mention in passing a surprising bijective correspondence between the tilings of a zonotope with smaller zonotopes and oriented matroid liftings (realizable or not) of the oriented matroid of a zonotope. This correspondence is known as the *Bohne-Dress theorem*; we refer to Richter-Gebert and Ziegler [RZ94].

CYCLIC POLYTOPES

Cyclic polytopes can be constructed by taking the convex hull of $n > d$ points on the moment curve in $\mathbb{R}^d$. The “standard construction” is to define a cyclic polytope $C_d(n)$ as the convex hull of n integer points on this curve, such as

$$C_d(n) := \text{conv}\{\gamma(1), \gamma(2), \dots, \gamma(n)\}.$$

However, the combinatorial type of $C_d(n)$ is given by the—entirely combinatorial—**Gale evenness criterion**: If $C_d(n) = \text{conv}\{\gamma(t_1), \dots, \gamma(t_n)\}$, with $t_1 < \dots < t_n$, then $\gamma(t_{i_1}), \dots, \gamma(t_{i_d})$ determine a facet if and only if the number of indices in $\{i_1, \dots, i_d\}$ lying between any two indices *not* in that set is even. Thus, the combinatorial type does not depend on the specific choice of points on the moment curve [Zie95, Example 0.6; Theorem 0.7].

FIGURE 16.1.6

A 3-dimensional cyclic polytope $C_3(6)$ with 6 vertices. (In a projection of γ to the x_1x_2 -plane, the curve γ and hence the vertices of $C_3(6)$ lie on the parabola $x_2 = x_1^2$.)

The first property of cyclic polytopes to notice is that they are simplicial. The second, more surprising, property is that they are neighborly. This implies that among all d -polytopes P with n vertices, the cyclic polytopes maximize the number $f_i(P)$ of i -dimensional faces for $i < \lfloor d/2 \rfloor$. The same fact holds for all i : this is part of McMullen’s upper bound theorem (see below). In particular, cyclic polytopes have a very large number of facets,

$$f_{d-1}(C_d(n)) = \binom{n - \lceil \frac{d}{2} \rceil}{\lfloor \frac{d}{2} \rfloor} + \binom{n - 1 - \lceil \frac{d-1}{2} \rceil}{\lfloor \frac{d-1}{2} \rfloor}.$$

For example, we get that a cyclic 4-polytope $C_4(n)$ has $n(n-3)/2$ facets. Thus $C_4(8)$ has 8 vertices, any two of them adjacent, and 20 facets. This is more than the 16 facets of the 4-dimensional cross-polytope, which also has 8 vertices!

NEIGHBORLY POLYTOPES

Here are a few observations about neighborly polytopes. For more information, see [BLS⁺99, Section 9.4] and the references quoted there.

The first observation is that if a polytope is k -neighborly for some $k > \lfloor d/2 \rfloor$, then it is a simplex. Thus, if one ignores the simplices, then $\lfloor d/2 \rfloor$ -neighborly polytopes form the extreme case, which motivates calling them simply “neighborly.” However, only in even dimensions $d = 2m$ do the neighborly polytopes have very special structure. For example, one can show that even-dimensional neighborly polytopes are necessarily simplicial, but this is not true in general. For the latter, note that, for example, all 3-dimensional polytopes are neighborly by definition, and that if P is a neighborly polytope of dimension $d = 2m$, then $\text{pyr}(P)$ is neighborly of dimension $2m+1$.

All simplicial neighborly d -polytopes with n vertices have the same number of facets (in fact, the same f -vector $(f_0, f_1, \dots, f_{d-1})$) as $C_d(n)$. They constitute the class of polytopes with the maximal number of i -faces for all i : this is the statement of McMullen’s upper bound theorem. We refer to [Chapter 18](#) for a thorough discussion of f -vector theory.

For $n \leq d+3$, every neighborly polytope is combinatorially isomorphic to a cyclic polytope. This covers, for instance, the polar of the product of two triangles, $(\Delta_2 \times \Delta_2)^\Delta$, which is easily seen to be a 4-dimensional neighborly polytope with 6 vertices; see [Figure 16.1.9](#). The first example of an even-dimensional neighborly polytope that is not cyclic appears for $d = 4$ and $n = 8$. It can easily be described in terms of its affine Gale diagram; see below.

Neighborly polytopes may at first glance seem to be very peculiar and rare objects, but there are several indications that they are not quite as unusual as they seem. In fact, the class of neighborly polytopes is believed to be very rich. Thus, Shemer [She82] has shown that for fixed even d the number of nonisomorphic neighborly d -polytopes with n vertices grows superexponentially with n . Also, many of the $(0,1)$ -polytopes studied in combinatorial optimization turn out to be at least 2-neighborly. Both these effects illustrate that “neighborliness” is not an isolated phenomenon.

OPEN PROBLEMS

1. Can every neighborly d -polytope $P \subseteq \mathbb{R}^d$ with n vertices be extended by a new vertex $v \in \mathbb{R}^d$ to a neighborly polytope $P' := \text{conv}(P \cup \{v\})$ with $n+1$ vertices? [She82, p. 314]
2. It is a classic problem of Perles whether every simplicial polytope is a quotient of a neighborly polytope. (For polytopes with at most $d+4$ vertices this was confirmed by Kortenkamp [Kor97].)
3. In some models of random polytopes it seems that
 - one obtains a neighborly polytope with high probability (which increases rapidly with the dimension of the space),
 - the most probable combinatorial type is a cyclic polytope,
 - but still this probability of a cyclic polytope tends to zero.

However, none of this has been proved. (See Bokowski and Sturmfels [BS89, p. 101], Bokowski, Richter-Gebert, and Schindler [BRS92], and Vershik and Sporychev [VS92].)

(0,1)-POLYTOPES

There is a $(0,1)$ -polytope (given in terms of a $\mathcal{V}$ -presentation) associated with every finite set system $\mathcal{S} \subseteq 2^E$ (where E is a finite set, and 2^E denotes the collection of all of its subsets), via

$$P[\mathcal{S}] := \text{conv} \left\{ \sum_{i \in F} e^i \mid F \in \mathcal{S} \right\} \subseteq \mathbb{R}^E.$$

In combinatorial optimization, there is an extensive literature available on $\mathcal{H}$ -presentations of special $(0,1)$ -polytopes, such as

- the **traveling salesman polytopes** T^n , where E is the edge set of a complete graph K_n , and $\mathcal{F}$ is the set of all $(n-1)!$ Hamilton cycles (simple circuits through all the vertices) in E (see Grötschel and Padberg [GP85]);
- the **cut** and **equicut polytopes**, where E is again the edge set of a complete graph, and $\mathcal{S}$ represents, for example, the family of all cuts, or all equicuts, of the graph (see Deza and Laurent [DL97]).

Besides their importance for combinatorial optimization, there is a great deal of interesting polytope theory associated with such polytopes. For a striking example, see the equicut polytopes used by Kahn and Kalai [KK93] in their disproof of Borsuk's conjecture (see also [AZ01]).

Despite the detailed structure theory for the “special” $(0,1)$ -polytopes of combinatorial optimization, there is very little known about “general” $(0,1)$ -polytopes. For example, what is the “typical”, or the maximal, number of facets of a $(0,1)$ -polytope? Based on a random construction Bárány and Pór [BP01] proved the existence of d -dimensional $(0,1)$ -polytopes with $(cd/\log d)^{d/4}$ facets, where c is a universal constant. The best known upper bounds are of order $(d-2)!$. Another question, which is not only intrinsically interesting but might also provide new clues for basic questions of linear and combinatorial optimization, is: What is the maximal number of faces in a 2-dimensional projection of a $(0,1)$ -polytope? For a survey on $(0,1)$ -polytopes see [Zie00].

16.1.5 THREE-DIMENSIONAL POLYTOPES AND PLANAR GRAPHS

GLOSSARY

***d*-connected graph:** A connected graph that remains connected if any $d-1$ vertices are deleted.

Drawing of a graph: A representation in the plane where the vertices are represented by distinct points, and simple Jordan arcs are drawn between the pairs of adjacent vertices.

Planar graph: A graph that can be drawn in the plane with Jordan arcs that are disjoint except for their endpoints.

Realization space: The set of all coordinatizations of a combinatorial structure, modulo affine coordinate transformations. (See [Section 6.3.2.](#))

Isotopy property: A combinatorial structure (such as a combinatorial type of polytope) has the isotopy property if any two realizations can be deformed into each other continuously, while maintaining the combinatorial type. Equivalently, the isotopy property holds for a combinatorial structure if and only if its realization space is connected.

THEOREM 16.1.3 *Steinitz's Theorem* [SR34]

For every 3-dimensional polytope P , the graph $G(P)$ is a planar, 3-connected graph. Conversely, for every planar 3-connected graph, there is a unique combinatorial type of 3-polytope P with $G(P) \cong G$.

Furthermore, the realization space $\mathcal{R}(P)$ of a combinatorial type of 3-polytope is homeomorphic to $\mathbb{R}^{f_1(P)-6}$, and contains rational points. In particular, 3-dimensional polytopes have the isotopy property, and they can be realized with integer vertex coordinates.

FIGURE 16.1.7

A (planar drawing of a) 3-connected, planar, unnamed graph. The formidable task of any proof of Steinitz's theorem is to construct a 3-polytope with this graph.

There are two essentially different ways known to prove Steinitz's theorem. The first one [SR34] provides a construction sequence for any type of 3-polytope, starting from a tetrahedron, and using only local operations such as cutting off vertices and polarity. The second type of proof realizes any combinatorial type by a global minimization argument, which as an intermediate step provides a special planar representation of the graph by a framework with a positive self-stress [McM94, OS94].

OPEN PROBLEMS

Because of Steinitz's theorem and its extensions and corollaries, the theory of 3-dimensional polytopes is quite complete and satisfactory. Nevertheless, some basic open problems remain.

1. It can be shown that every combinatorial type of 3-polytope with n vertices and a triangular facet can be realized with integer coordinates belonging to $\{1, 2, \dots, 37^n\}^3$ (J. Richter-Gebert and G. Stein, improving on Onn and Sturmfels [OS94]), but it is not clear whether the bound of 37^n can be replaced by a polynomial bound.
2. If P has a group G of symmetries, then it also has a symmetric realization.

However, it is not clear whether the space of all G -symmetric realizations $\mathcal{R}^G(P)$ is still homeomorphic to some $\mathbb{R}^k$. (It does not contain rational points in general, e.g., for the icosahedron!)

16.1.6 FOUR-DIMENSIONAL POLYTOPES AND SCHLEGEL DIAGRAMS

GLOSSARY

Schlegel diagram: A $(d-1)$ -dimensional representation $\mathcal{D}(P, F)$ of a d -dimensional polytope P , obtained as follows. Take a point of view very close to (an interior point of) the facet F , and let $\mathcal{D}(P, F)$ be the decomposition of F given by all the other facets of P , as seen from this point of view.

$(d-1)$ -diagram: A polytopal decomposition $\mathcal{D}$ of a $(d-1)$ -polytope F such that
 (1) $\mathcal{D}$ is a polytopal complex (i.e., a finite collection of polytopes closed under taking faces, such that any intersection of two polytopes in the complex is a face of each), and
 (2) the intersection of any polytope in $\mathcal{D}$ with the boundary of F is a face of F (which may be empty).

Basic primary semialgebraic set defined over $\mathbb{Z}$: The solution set $S \subseteq \mathbb{R}^k$ of a finite set of equations and strict inequalities of the form $f_i(x) = 0$ resp. $g_j(x) > 0$, where the f_i and g_j are polynomials in k variables with integer coefficients.

Stable equivalence: Equivalence relation between semialgebraic sets generated by rational changes of coordinates and certain types of “stable” projections with contractible fibers. (See Richter-Gebert [Ric96, Section 2.5].)

In particular, if two sets are stably equivalent, then they have the same homotopy type, and they have the same arithmetic properties with respect to subfields of $\mathbb{R}$; e.g., either both or neither of them contain a rational point.

The situation for 4-polytopes is fundamentally different from that for 3-dimensional polytopes. One reason is that there is no similar reduction of 4-polytope theory to a combinatorial (graph) problem.

The main results about graphs of d -polytopes are that they are d -connected (Balinski [Ba61]), and that each contains a subdivision of the complete graph on $d+1$ vertices, $K_{d+1} = G(T_d)$ (Grünbaum, [Grü03, pp. 200]). In particular, all graphs of 4-polytopes are 4-connected, and none of them is planar. (See also [Chapter 20](#).)

Schlegel diagrams provide a reasonably efficient tool for visualization of 4-polytopes: we have a fighting chance to understand some of their theory in terms of the 3-dimensional (!) geometry of Schlegel diagrams.

A $(d-1)$ -diagram is a polytopal complex that “looks like” a Schlegel diagram, although there are diagrams (even 2-diagrams) that are not Schlegel diagrams. The situation is somewhat nicer for *simple* 4-polytopes. These are determined by their graphs (Blind and Mani-Levitska [BM87], and for a wonderful proof see Kalai [Kal88]), and they can be understood in terms of 3-diagrams: all simple 3-diagrams are projections of genuine 4-dimensional polytopes (Whiteley, see Rybnikov [Ryb99]).

FIGURE 16.1.8

Two Schlegel diagrams of our unnamed 3-polytope, the first based on a triangle facet, the second on the “bottom square.”

FIGURE 16.1.9

A Schlegel diagram of the product of two triangles. (This is a 4-dimensional polytope with 6 triangular prisms as facets, any two of them adjacent!)

The fundamental difference between the theories for polytopes in dimensions 3 and 4 is most apparent in the contrast between Steinitz’s theorem and the following result, which states simply that all the “nice” properties of 3-polytopes established in Steinitz’s theorem fail dramatically for 4-dimensional polytopes.

THEOREM 16.1.4 *Richter-Gebert’s Universality Theorem for 4-Polytopes* [Ric96]

The realization space of a 4-dimensional polytope can be “arbitrarily wild”: for every basic primary semialgebraic set S defined over $\mathbb{Z}$ there is a 4-dimensional polytope $P[S]$ whose realization space $\mathcal{R}(P[S])$ is stably equivalent to S .

In particular, this implies the following.

- *The isotopy property fails for 4-dimensional polytopes.*
- *There are nonrational 4-polytopes: combinatorial types that cannot be realized with rational vertex coordinates.*
- *The coordinates needed to represent all combinatorial types of rational 4-polytopes with integer vertices grow doubly exponentially with $f_0(P)$.*

The complete proof of this universality theorem is given in [Ric96]. One key component of the proof corresponds to another failure of a 3-dimensional phenomenon in dimension 4: for any facet (2-face) F of a 3-dimensional polytope P , the shape of F can be arbitrarily prescribed; in other words, the canonical map of realization spaces $\mathcal{R}(P) \rightarrow \mathcal{R}(F)$ is always surjective. Richter-Gebert shows that a similar statement fails in dimension 4, even if F is a 2-dimensional pentagonal face: see Figure 16.1.10 for the case of a hexagon.

A problem that is left open is the structure of the realization spaces of simplicial 4-polytopes. All that is available now is a universality theorem for simplicial polytopes without a dimension bound (see Section 6.3.4), and a single example of a simplicial 4-polytope that violates the isotopy property, by Bokowski, Ewald, and Kleinschmidt [BEK84].

FIGURE 16.1.10

Schlegel diagram of a 4-dimensional polytope with 8 facets and 12 vertices, for which the shape of the base hexagon cannot be prescribed arbitrarily.

16.1.7 POLYTOPES WITH FEW VERTICES—GALE DIAGRAMS

GLOSSARY

Polytope with few vertices: A polytope that has only a few more vertices than its dimension; usually a d -polytope with at most $d+4$ vertices.

(Affine) Gale diagram: A configuration of n (positive and negative) points in affine space $\mathbb{R}^{n-d-2}$ that encodes a d -polytope with n vertices uniquely up to projective transformations.

The computation of a Gale diagram involves only simple linear algebra. For this, let $V \in \mathbb{R}^{d \times n}$ be a matrix whose columns consist of coordinates for the vertices of a d -polytope. For simplicity, we assume that P is not a pyramid, and that the vertices $\{v^1, \dots, v^{d+1}\}$ affinely span $\mathbb{R}^d$. Let $\tilde{V} \in \mathbb{R}^{(d+1) \times n}$ be obtained from V by adding an extra (terminal) row of ones. The vector configuration given by the columns of $\tilde{V}$ represents the *oriented matroid* of P ; see Chapter 6.

Now perform row operations on the matrix $\tilde{V}$ to get it into the form $\tilde{V} \sim (I_{d+1} | A)$, where I_{d+1} denotes a unit matrix, and $A \in \mathbb{R}^{(d+1) \times (n-d-1)}$ is a real matrix. (The row operations do not change the oriented matroid.) The columns of the matrix $\tilde{V}^* := (-A^T | I_{n-d-1}) \in \mathbb{R}^{(n-d-1) \times n}$ then represent the dual oriented matroid. We find a vector $a \in \mathbb{R}^{n-d-1}$ that has nonzero scalar product with all the columns of $\tilde{V}^*$, divide each column w^* of $\tilde{V}^*$ by the value $\langle a, w^* \rangle$, and delete from the resulting matrix any row that affinely depends on the others, thus obtaining a matrix $W \in \mathbb{R}^{(n-d-2) \times n}$. The columns of W give a colored point configuration in $\mathbb{R}^{n-d-2}$, where *black* points are used for the columns where $\langle a, w^* \rangle > 0$, and *white* points for the others. This colored point configuration represents an affine Gale diagram of P .

FIGURE 16.1.11

Two affine Gale diagrams of 4-dimensional polytopes: for a noncyclic neighborly polytope with 8 vertices, and for the polar (with 8 vertices) of the polytope with 8 facets from Figure 16.1.10, for which the shape of a hexagonal face cannot be prescribed arbitrarily.

It turns out that an affine configuration of colored points (consisting of n points that affinely span $\mathbb{R}^e$) represents a polytope (with n vertices, of dimension $n - e - 2$) if and only if the following criterion is met: For any hyperplane spanned by some of the points, and for each side of it, the number of black points on this side, plus the number of white points on the other side, is at least 2.

The final information one needs is how to read off properties of a polytope from its affine Gale diagram. Here the criterion is that a set of points represents a face if and only if the following condition is satisfied: the colored points *not* in the set support an affine dependency, with positive coefficients on the black points, and with negative coefficients on the white points. Equivalently, the convex hull of all the black points not in our set, and the convex hull of all the white points not in the set, intersect in their relative interiors.

Affine Gale diagrams have been *very* successfully used to study and classify polytopes with few vertices.

$d+1$ vertices: The only d -polytopes with $d+1$ vertices are the d -simplices.

$d+2$ vertices: There are exactly $\lfloor d^2/4 \rfloor$ combinatorial types of d -polytopes with $d+2$ vertices; among these, $\lfloor d/2 \rfloor$ types are simplicial. This corresponds to the situation of 0-dimensional affine Gale diagrams.

$d+3$ vertices: All d -polytopes with $d+3$ vertices are realizable with (small) integral coordinates and satisfy the isotopy property: all this can be easily analyzed in terms of 1-dimensional affine Gale diagrams.

$d+4$ vertices: Here anything can go wrong: the universality theorem for oriented matroids of rank 3 yields a universality theorem for simplicial d -polytopes with $d+4$ vertices. (See [Section 6.3.4](#).)

We refer to [Zie95, Lecture 6] for a detailed introduction to affine Gale diagrams.

16.2 METRIC PROPERTIES

The combinatorial data of a polytope—vertices, edges, $\dots$, facets—have their counterparts in genuine geometric data, such as face volumes, surface areas, quermass-integrals, and the like. In this second half of the chapter, we give a brief sketch of some key geometric concepts related to polytopes.

However, the topics of combinatorial and of geometric invariants are not disjoint at all: much of the beauty of the theory stems from the subtle interplay between the two sides. Thus, the computation of volumes inevitably leads to the construction of triangulations (explicitly or implicitly), mixed volumes lead to mixed subdivisions of Minkowski sums (one “hot topic” for current research in the area), quermass-integrals relate to face enumeration, and so on.

Furthermore, the study of polytopes yields a powerful approach to the theory of convex bodies: sometimes one can extend properties of polytopes to arbitrary convex bodies by approximation [Sch93]. However, there are also properties valid for polytopes that fail for convex bodies in general. This bug/feature is designed to keep the game interesting.

16.2.1 VOLUME AND SURFACE AREA

GLOSSARY

Volume of a d -simplex T : $V(T) = \left| \det \begin{pmatrix} v^0 & \cdots & v^d \\ 1 & \cdots & 1 \end{pmatrix} \right| / d!$, where $T = \text{conv}\{v^0, \dots, v^d\}$ with $v^0, \dots, v^d \in \mathbb{R}^d$.

Subdivision of a polytope P : A collection of polytopes $P_1, \dots, P_l \subseteq \mathbb{R}^d$ such that $P = \bigcup P_i$, and for $i \neq j$ we have that $P_i \cap P_j$ is a proper face of P_i and P_j (possibly empty). In this case we write $P = \uplus P_i$.

Triangulation of a polytope: A subdivision into simplices. (See [Chapter 17](#).)

Volume of a d -polytope: $\sum_{T \in \Delta(P)} V(T)$, where $\Delta(P)$ is a triangulation of P .

k -volume $V^k(P)$ of a k -polytope $P \subseteq \mathbb{R}^d$: The volume of P , computed with respect to the k -dimensional Euclidean measure induced on $\text{aff}(P)$.

Surface area of a d -polytope P : $\sum_{T \in \Delta(P), F \in \mathcal{F}_{d-1}(P)} V^{d-1}(T \cap F)$, where $\Delta(P)$ is a triangulation of P .

The volume $V(P)$ (i.e., the d -dimensional Lebesgue measure) and the surface area $F(P)$ of a d -polytope $P \subseteq \mathbb{R}^d$ can be derived from any triangulation of P , since volumes of simplices are easy to compute. The crux for this is in the (efficient?) generation of a triangulation, a topic on which Chapters 17 and 25 of this Handbook have more to say.

The following recursive approach only implicitly generates a triangulation, but derives explicit volume formulas. Let $P \subseteq \mathbb{R}^d$ ($P \neq \emptyset$) be a polytope. If $d = 0$ then we set $V(P) = 1$. Otherwise we set $\mathcal{S}_{d-1}(P) := \{u \in S^{d-1} \mid \dim(H(P, u) \cap P) = d - 1\}$, and use this to define the volume of P as

$$V(P) := \frac{1}{d} \sum_{u \in \mathcal{S}_{d-1}(P)} h(P, u) \cdot V^{d-1}(H(P, u) \cap P).$$

Thus, for any d -polytope the volume is a sum of its facet volumes, each weighted by $1/d$ times its signed distance from the origin. Geometrically, this can be interpreted as follows. Assume for simplicity that the origin is in the interior of P . Then the collection $\{\text{conv}(F \cup \{0\}) \mid F \in \mathcal{F}_{d-1}(P)\}$ is a subdivision of P into d -dimensional pyramids, where the base of $\text{conv}(F \cup \{0\})$ has $(d-1)$ -dimensional volume $V^{d-1}(F)$ —to be computed recursively, the height of the pyramid is $h(P, u^F)$, and thus its volume is $\frac{1}{d} h(P, u^F) \cdot V^{d-1}(F)$; compare to Figure 16.2.1. The formula remains valid even if the origin is outside P or on its boundary.

FIGURE 16.2.1

This pentagon, with the origin in its interior, is decomposed into five pyramids (triangles), each with one of the pentagon facets (edges) F_i as its base. For each pyramid, the height, of length $h(P, u^{F_i})$, is drawn as a dotted line.

Note that $V(P) \geq 0$. This holds with strict inequality if and only if the polytope P has full dimension d . The surface area $F(P)$ can also be expressed as

$$F(P) = \sum_{u \in \mathcal{S}_{d-1}(P)} V^{d-1}(H(P, u) \cap P).$$

Thus for a d -polytope the surface area is the sum of the $(d-1)$ -volumes of its facets. If $\dim(P) = d-1$, then $F(P)$ is twice the $(d-1)$ -volume of P . One has $F(P) = 0$ if and only if $\dim(P) < d-1$.

Both the volume and the surface area are continuous, monotone, and invariant with respect to rigid motions. $V(\cdot)$ is homogeneous of degree d , i.e., $V(\mu P) = \mu^d V(P)$ for $\mu \geq 0$, and $F(\cdot)$ is homogeneous of degree $d-1$. For further properties of the functionals $V(\cdot)$ and $F(\cdot)$ see [Had57] and [Sch93].

Table 16.2.1 gives the numbers of k -faces, the volume, and the surface area of the d -cube C_d (with edge length 2), of the cross-polytope C_d^Δ with edge length $\sqrt{2}$, and of the regular simplex T_d with edge length $\sqrt{2}$.

TABLE 16.2.1

POLYTOPE	$f_k(\cdot)$	VOLUME	SURFACE AREA
C_d	$2^{d-k} \binom{d}{k}$	2^d	$2d \cdot 2^{d-1}$
C_d^Δ	$2^{k+1} \binom{d}{k+1}$	$\frac{2^d}{d!}$	$2^d \frac{\sqrt{d}}{(d-1)!}$
T_d	$\binom{d+1}{k+1}$	$\frac{\sqrt{d+1}}{d!}$	$(d+1) \cdot \frac{\sqrt{d}}{(d-1)!}$

16.2.2 MIXED VOLUMES

GLOSSARY

Volume polynomial: The volume of the Minkowski sum $\lambda_1 P_1 + \lambda_2 P_2 + \dots + \lambda_r P_r$, which is a homogeneous polynomial in $\lambda_1, \dots, \lambda_r$. (Here the P_i may be convex polytopes of any dimension, or more general (closed, bounded) convex sets.)

Mixed volumes: The coefficients of the volume polynomial of $P_1, \dots, P_r$.

Normal cone: The normal cone $N(F, P)$ of a face is the set of all vectors $v \in \mathbb{R}^d$ such that the supporting hyperplane $H(P, v)$ contains F , i.e.,

$$N(F, P) = \left\{ v \in \mathbb{R}^d \mid F \subseteq H(P, v) \cap P \right\}.$$

THEOREM 16.2.1 *Mixed Volumes* (cf. [Sch93, p. 270])

Let $P_1, \dots, P_r \subseteq \mathbb{R}^d$ be polytopes, $r \geq 1$, and $\lambda_1, \dots, \lambda_r \geq 0$. The volume of $\lambda_1 P_1 + \dots + \lambda_r P_r$ is a homogeneous polynomial in $\lambda_1, \dots, \lambda_r$ of degree d . Thus it can be written in the form

$$V(\lambda_1 P_1 + \dots + \lambda_r P_r) = \sum_{(i(1), \dots, i(d)) \in \{1, 2, \dots, r\}^d} \lambda_{i(1)} \cdots \lambda_{i(d)} \cdot V(P_{i(1)}, \dots, P_{i(d)}).$$

The coefficients in this expansion are symmetric in their indices. Furthermore, the coefficient $V(P_{i(1)}, \dots, P_{i(d)})$ depends only on $P_{i(1)}, \dots, P_{i(d)}$. It is called the **mixed volume** of the polytopes $P_{i(1)}, \dots, P_{i(d)}$.

With the abbreviation

$$V(P_1, k_1; \dots; P_r, k_r) := V(\underbrace{P_1, \dots, P_1}_{k_1 \text{ times}}, \dots, \underbrace{P_r, \dots, P_r}_{k_r \text{ times}}),$$

the polynomial becomes

$$V(\lambda_1 P_1 + \dots + \lambda_r P_r) = \sum_{\substack{k_1, \dots, k_r \geq 0 \\ k_1 + \dots + k_r = d}} \binom{d}{k_1, \dots, k_r} \lambda_1^{k_1} \cdots \lambda_r^{k_r} V(P_1, k_1; \dots; P_r, k_r).$$

In particular, the volume of the polytope P_i is given by the mixed volume $V(P_1, 0; \dots; P_i, d; \dots; P_r, 0)$. The theorem is also valid for arbitrary convex bodies: a good example where the general case can be derived from the polytope case by approximation. For more about the properties of mixed volumes from different points of view see Schneider [Sch93], Sangwine-Yager [San93], and McMullen [McM93].

The definition of the mixed volumes as coefficients of a polynomial is somewhat unsatisfactory. Schneider gave the following explicit rule, which generalizes an earlier result of Betke [Bet92] for the case $r = 2$. It uses information about the normal cones at certain faces. For this, note that $N(F, P)$ is a finitely generated cone, which can be written explicitly as the sum of the orthogonal complement of $\text{aff}(P)$ and the positive hull of those unit vectors u that are both parallel to $\text{aff}(P)$ and induce supporting hyperplanes $H(P, u)$ that contain a facet of P including F . Thus, for $P \subseteq \mathbb{R}^d$ the dimension of $N(F, P)$ is $d - \dim(F)$.

THEOREM 16.2.2 *Schneider's Summation Formula* [Sch94]

Let $P_1, \dots, P_r \subseteq \mathbb{R}^d$ be polytopes, $r \geq 2$. Let $x^1, \dots, x^r \in \mathbb{R}^d$ with $x^1 + \dots + x^r = 0$, $(x^1, \dots, x^r) \neq (0, \dots, 0)$, and

$$\bigcap_{i=1}^r (\text{relint} N(F_i, P_i) - x^i) = \emptyset$$

whenever F_i is a face of P_i and $\dim(F_1) + \dots + \dim(F_r) > d$. Then

$$\binom{d}{k_1, \dots, k_r} V(P_1, k_1; \dots; P_r, k_r) = \sum_{(F_1, \dots, F_r)} V(F_1 + \dots + F_r),$$

where the summation extends over the r -tuples $(F_1, \dots, F_r)$ of k_i -faces F_i of P_i with $\dim(F_1 + \dots + F_r) = d$ and $\bigcap_{i=1}^r (N(F_i, P_i) - x^i) \neq \emptyset$.

The choice of the vectors $x^1, \dots, x^r$ implies that the selected k_i -faces $F_i \subseteq P_i$ of a summand $F_1 + \dots + F_r$ are contained in complementary subspaces. Hence one may also write

$$\binom{d}{k_1, \dots, k_r} V(P_1, k_1; \dots; P_r, k_r) = \sum_{(F_1, \dots, F_r)} [F_1, \dots, F_r] \cdot V^{k_1}(F_1) \cdots V^{k_r}(F_r),$$

where $[F_1, \dots, F_r]$ denotes the volume of the parallelepiped that is the sum of unit cubes in the affine hulls of $F_1, \dots, F_r$.

Finally, we remark that the selected sums of faces in the formula of the theorem form a subdivision of the polytope $P_1 + \dots + P_r$, i.e.,

$$P_1 + \dots + P_r = \bigsqcup_{(F_1, \dots, F_r)} (F_1 + \dots + F_r).$$

See Figure 16.2.2 for an example.

FIGURE 16.2.2

Here the Minkowski sum of a square P_1 and a triangle P_2 is decomposed into translates of P_1 and of P_2 (this corresponds to two summands with $F_1 = P_1$ resp. $F_2 = P_2$), together with three “mixed” faces that arise as sums $F_1 + F_2$, where F_1 and F_2 are faces of P_1 and P_2 (corresponding to summands with $\dim(F_1) = \dim(F_2) = 1$).

VOLUMES OF ZONOTOPES

If all summands in a Minkowski sum $Z = P_1 + \dots + P_r$ are line segments, say $P_i = p^i + [0, 1]z^i = \text{conv}\{p^i, p^i + z^i\}$ with $p^i, z^i \in \mathbb{R}^d$ for $1 \leq i \leq r$, then the resulting polytope Z is a zonotope. In this case the summation rule immediately gives $V(P_1, k_1; \dots; P_r, k_r) = 0$ if the vectors

$$\underbrace{z^1, \dots, z^1}_{k_1 \text{ times}}, \dots, \underbrace{z^r, \dots, z^r}_{k_r \text{ times}}$$

are linearly dependent. (This can also be seen directly from dimension considerations.) Otherwise, for $k_{i(1)} = k_{i(2)} = \dots = k_{i(d)} = 1$, say,

$$V(P_1, k_1; \dots; P_r, k_r) = \frac{1}{d!} \left| \det \left(z^{i(1)}, z^{i(2)}, \dots, z^{i(d)} \right) \right|.$$

Therefore, one obtains McMullen's formula for the volume of the zonotope Z (cf. Shephard [Sh74]) :

$$V(Z) = \sum_{1 \leq i(1) < i(2) < \dots < i(d) \leq r} \left| \det(z^{i(1)}, \dots, z^{i(d)}) \right|.$$

16.2.3 QUERMASSEINTEGRALS AND INTRINSIC VOLUMES

GLOSSARY

*i*th quermassintegral $W_i(P)$: The mixed volume $V(P, d-i; B_d, i)$ of a polytope P and the d -dimensional unit ball B_d .

κ_d : The volume (Lebesgue measure) of B_d . (Hence $\kappa_0 = 1$, $\kappa_1 = 2$, $\kappa_2 = \pi$, etc.)

i th intrinsic volume $V_i(P)$: The $(d-i)$ th quermassintegral, scaled by the constant $\binom{d}{i}/\kappa_{d-i}$.

Outer parallel body of P at distance λ : The convex body $P + \lambda B_d$ for some $\lambda > 0$.

External angle $\gamma(F, P)$: The volume of $(\text{lin}(F - x^F) + N(F, P)) \cap B_d$ divided by κ_d , for $x^F \in \text{relint}(F)$. Thus $\gamma(F, P)$ is the “fraction of $\mathbb{R}^d$ taken up by $\text{lin}(F - x^F) + N(F, P)$.” Equivalently, the external angle at a k -face F is the fraction of the spherical volume of S covered by $N(F, P) \cap S$, where S denotes the $(d-k-1)$ -dimensional unit sphere in $\text{lin}(N(F, P))$.

Internal angle $\beta(F, G)$ for faces $F \subseteq G$: The “fraction” of $\text{lin}\{G - x^F\}$ taken up by the cone $\text{pos}\{x - x^F \mid x \in G\}$, for $x^F \in \text{relint}(F)$. (A detailed discussion of relations between external and internal angles can be found in McMullen [McM75].)

The quermassintegrals are generalizations of both the volume and the surface area of P . In fact, they can also be seen as the continuous convex geometry analogs of face numbers.

For a polytope $P \subseteq \mathbb{R}^d$ and the d -dimensional unit ball B_d , the mixed volume formula, applied to the outer parallel body $P + \lambda B_d$, gives

$$V(P + \lambda B_d) = \sum_{i=0}^d \binom{d}{i} \lambda^i W_i(P),$$

with the convention $W_i(P) = V(P, d-i; B_d, i)$. This formula is known as the **Steiner polynomial**. The mixed volume $W_i(P)$, the i th quermassintegral of P , is an important quantity and of significant geometric interest [Had57, Sch93]. As special cases, $W_0(P) = V(P)$ is the volume, $dW_1(P) = F(P)$ is the surface area, and $W_d(P) = \kappa_d$.

For the geometric interpretation of $W_i(P)$ for polytopes, we use a normalization of the quermassintegrals due to McMullen [McM75]: For $0 \leq i \leq d$, the i th intrinsic volume of P is defined by

$$V_i(P) := \frac{\binom{d}{i}}{\kappa_{d-i}} W_{d-i}(P).$$

With this notation the Steiner polynomial can be written as

$$V(P + \lambda B_d) = \sum_{i=0}^d \lambda^{d-i} \kappa_{d-i} V_i(P).$$

(See Figure 16.2.3 for an example.) $V_d(P)$ is the volume of P , $V_{d-1}(P)$ is half the surface area, and $V_0(P) = 1$. One advantage of this normalization is that the intrinsic volumes are unchanged if P is embedded in some Euclidean space of different dimension. Thus, for $\dim(P) = k \leq d$, $V_k(P)$ is the ordinary k -volume of P with respect to the Euclidean structure induced in $\text{aff}(P)$.

For a $(\dim(P) - 2)$ -face F , the concept of external angle (see the glossary) reduces to the “usual” concept: then the external angle is given by $\frac{1}{2\pi} \arccos \langle u^{F_1}, u^{F_2} \rangle$ for unit normal vectors $u^{F_1}, u^{F_2} \in S^{d-1}$ to the facets F_1, F_2 with $F_1 \cap F_2 = F$. One

FIGURE 16.2.3

The Minkowski sum of a square P with a ball λB^2 yields the outer parallel body. This outer parallel body can be decomposed into pieces, whose volumes, $V(P)$, $\lambda V_1(P)\kappa_1$, and $\lambda^2\kappa_2$, correspond to the three terms in the Steiner polynomial.

has $\gamma(P, P) = 1$ for the polytope itself and $\gamma(F, P) = 1/2$ for each facet F . Using this concept, we get

$$V_k(P) = \sum_{F \in \mathcal{F}_k(P)} \gamma(F, P) \cdot V^k(F).$$

Internal and external angles are also useful tools in order to express combinatorial properties of polytopes (see the application below). One classical example is **Gram's equation** [Gra74]

$$\sum_{k=0}^{d-1} (-1)^k \sum_{F \in \mathcal{F}_k(P)} \beta(F, P) = (-1)^{d-1}.$$

This formula is quite similar to the Euler relation for the face numbers of a polytope (see [Chapter 18](#)). For a short and elegant probabilistic proof of Gram's equation, reducing it to Euler's relation, see [Wel94].

SOME COMPUTATIONS

In principle, one can use the external angle formula to determine the intrinsic volumes of a given polytope, but in general it is hard to calculate external angles. Indeed, for the computation of spherical volumes there are explicit formulas only in small dimensions.

In what follows, we give formulas for the intrinsic volumes of the polytopes C_d , C_d^Δ , and T_d . For this, we identify the k -faces of C_d with the k -cube C_k and the k -faces of C_d^Δ and of T_d with T_k , for $0 \leq k < d$.

The case of the cube C_d is rather trivial. Since $\gamma(C_k, C_d) = 2^{-(d-k)}$ one gets (see [Table 16.2.1](#))

$$V_k(C_d) = 2^k \binom{d}{k}.$$

For the regular simplex T_d we have

$$V_k(T_d) = \binom{d+1}{k+1} \cdot \frac{\sqrt{k+1}}{k!} \cdot \gamma(T_k, T_d).$$

An explicit formula for the external angles of a regular simplex by Ruben (see [Rub60] or [Had79]) is:

$$\gamma(T_k, T_d) = \sqrt{\frac{k+1}{\pi}} \int_{-\infty}^{\infty} e^{-(k+1)x^2} \left(\frac{1}{\sqrt{\pi}} \int_{-\infty}^x e^{-y^2} dy \right)^{d-k} dx.$$

For the regular cross-polytope we find for $k \leq d-1$ that

$$V_k(C_d^\Delta) = 2^{k+1} \binom{d}{k+1} \cdot \frac{\sqrt{k+1}}{k!} \cdot \gamma(T_k, C_d^\Delta).$$

For this, the external angles of C_d^Δ were determined by Betke and Henk [BH93]:

$$\gamma(T_k, C_d^\Delta) = \sqrt{\frac{k+1}{\pi}} \int_0^\infty e^{-(k+1)x^2} \left(\frac{2}{\sqrt{\pi}} \int_0^x e^{-y^2} dy \right)^{d-k-1} dx.$$

AN APPLICATION

External angles and internal angles play a crucial role in work by Affentranger and Schneider [AS92] (see also [BV94]), who computed the expected number of k -faces of the orthogonal projection of a polytope $P \subseteq \mathbb{R}^d$ onto a randomly chosen isotropic subspace of dimension n . Let $E[f_k(P; n)]$ be that number. Then for $0 \leq k < n \leq d-1$ it was shown that

$$E[f_k(P; n)] = 2 \sum_{m \geq 0} \sum_{F \in \mathcal{F}_k(P)} \sum_{\substack{G \in \mathcal{F}_{n-1-2m}(P) \\ F \subseteq G}} \beta(F, G) \gamma(G, P),$$

where $\beta(F, G)$ is the internal angle of the face F with respect to a face $G \supseteq F$.

In the sequel we apply the above formula to the polytopes C_d , C_d^Δ , and T_d . For the cubes one has $\beta(C_k, C_l) = (1/2)^{l-k}$, while the number of l -faces of C_d containing any given k -face is equal to $\binom{d-k}{l-k}$. Hence

$$E[f_k(C_d; n)] = 2 \binom{d}{k} \sum_{m \geq 0} \binom{d-k}{n-1-k-2m}.$$

In particular, $E[f_k(C_d; d-1)] = (2^{d-k} - 2) \binom{d}{k}$.

For the cross-polytope C_d^Δ the number of l -faces that contain a k -face is equal to $2^{l-k} \binom{d-k-1}{l-k}$. Thus

$$E[f_k(C_d^\Delta; n)] = 2 \binom{d}{k+1} \sum_{m \geq 0} 2^{n-2m} \binom{d-k-1}{n-1-k-2m} \beta(T_k, T_{n-1-2m}) \gamma(T_{n-1-2m}, C_d^\Delta).$$

In the same way one obtains for T_d

$$E[f_k(T_d; n)] = 2 \binom{d+1}{k+1} \sum_{m \geq 0} \binom{d-k}{n-1-k-2m} \beta(T_k, T_{n-1-2m}) \gamma(T_{n-1-2m}, T_d).$$

For the last two formulas one needs the internal angles $\beta(T_k, T_l)$ of the regular simplex T_d , for $0 \leq k \leq l \leq d$. For this, one has the following complex integral [BH99]:

$$\beta(T_k, T_l) = \frac{(k+1+l)^{1/2} (k+1)^{(l-1)/2}}{\pi^{(l+1)/2}} \int_{-\infty}^{\infty} e^{-w^2} \left(\int_0^\infty e^{-(k+1)y^2 + 2iwy} dy \right)^l dw.$$

Using this formula one can determine the asymptotic behavior of $E[f_k(C_d^\Delta; n)]$ and $E[f_k(T_d; n)]$ as n tends to infinity [BH99].

16.3 SOURCES AND RELATED MATERIAL

FURTHER READING

The classic account of the combinatorial theory of convex polytopes was given by Grünbaum in 1967 [Grü03]. It inspired and guided a great part of the subsequent research in the field. Besides the related chapters of this Handbook, we refer to [Zie95] and the handbook surveys by Klee and Kleinschmidt [KK95] and by Bayer and Lee [BL93] for further reading.

For the geometric theory of convex bodies we refer to the *Handbook of Convex Geometry* [GW93], to Schneider [Sch93] for an excellent monograph, and as an introduction to modern convex geometry we recommend [Bal97]. As for the algorithmic aspects of computing volumes, etc., we refer to Chapter 31 of this Handbook, on computational convexity, and to the additional references given there.

17 SUBDIVISIONS AND TRIANGULATIONS OF POLYTOPES

Carl W. Lee

INTRODUCTION

Starting from a given finite set of points V in $\mathbb{R}^d$, we consider subdivisions of the convex hull of V into polytopes $\{P_1, \dots, P_m\}$. A subdivision is a triangulation if each P_i is a simplex. We start with definitions and properties, then turn to methods of constructing subdivisions and triangulations, face-counting results, some particular triangulations, and secondary and fiber polytopes. We confine ourselves to triangulations of convex structures for the most part.

17.1 BASIC CONCEPTS

GLOSSARY

Affine span: The affine span of a set V is the smallest affine space, or flat, containing V . It is denoted by $\text{aff}(V)$.

Convex hull: The convex hull of a set V is the smallest convex set containing V . It is denoted by $\text{conv}(V)$.

Polytope: A polytope P is the convex hull of a finite set of points. If it is d -dimensional, its boundary consists of faces of dimension -1 (the empty set), 0 (vertices), 1 (edges), $2, \dots$, and $d-1$ (facets). Its set of vertices will be denoted by $\text{vert}(P)$.

Face of a set: Suppose S is a subset of a finite set T of points. We say S is a face of the set T if there is face F of the polytope $P = \text{conv}(T)$ for which $S = T \cap F$. Note that S may include points that are not vertices of F . If F is not P itself we say S is a face of the boundary of T . The dimension of S is taken to be the dimension of $\text{conv}(S)$, and faces of dimension $0, 1$, and $\dim(T) - 1$ are referred to as vertices, edges, and facets, respectively, of the set T .

Subdivision: Suppose V is a finite set of points such that $P = \text{conv}(V)$ is d -dimensional (a d -polytope). A subdivision of V is a finite collection $S = \{S_1, \dots, S_m\}$ of subsets of V such that:

- For each i , $1 \leq i \leq m$, $P_i = \text{conv}(S_i)$ is a d -polytope;
- P is the union of $P_1, \dots, P_m$; and
- If $i \neq j$ then there is a common (possibly empty) face F of the boundaries of S_i and S_j such that $P_i \cap P_j = \text{conv}(F)$.

In this case we will also say that S is a subdivision of the polytope P . It is also usual to refer to the collection of polytopes $\{P_1, \dots, P_m\}$ rather than the subsets

$\{S_1, \dots, S_m\}$ as the subdivision, keeping in mind, though, that it may not be the case that $S_i = \text{vert}(P_i)$.

Trivial subdivision: The trivial subdivision of V is the subdivision $\{V\}$.

Simplex: A d -dimensional simplex is a d -polytope with exactly $d + 1$ vertices.

We will also refer to the set of vertices of a d -simplex as a d -simplex.

Triangulation: Suppose $\text{conv}(V)$ has dimension d . A subdivision $\{S_1, \dots, S_m\}$ of V is a triangulation if each S_i has cardinality $d + 1$, so that each P_i is a simplex.

Faces: The faces of a subdivision $\{S_1, \dots, S_m\}$ consist of $S_1, \dots, S_m$ together with their faces. It is also usual to say that the faces of the subdivision are the polytopes $P_1, \dots, P_m$ and their faces.

EXAMPLES

In Figure 17.1.1, (a) shows a set of points. The collection of three polygons in (b) is not a subdivision of that set since not every pair of polygons meets along a common edge or vertex; (c) shows a subdivision that is not a triangulation; and (d) gives a triangulation.

FIGURE 17.1.1

- (a) A set of points.
- (b) A nonsubdivision.
- (c) A subdivision.
- (d) A triangulation.

17.2 SEQUENTIAL CONSTRUCTION PROCEDURES

The convex hull of a finite set of points $V = \{v_1, \dots, v_n\}$ can be constructed sequentially by successively constructing $R_1 = \text{conv}(\{v_1\})$, $R_2 = \text{conv}(R_1 \cup \{v_2\})$, $R_3 = \text{conv}(R_2 \cup \{v_3\})$, $\dots$, $R_n = \text{conv}(R_{n-1} \cup \{v_n\})$. This inductive method for constructing the convex hull of V appears, for example, in [Grü67, Section 5.2]. See [Chapter 22](#) of this Handbook for a discussion of its implementation. With little additional effort, a triangulation of each R_i can also be constructed, resulting finally in a triangulation of V . Another method of constructing a triangulation of V is to begin with the trivial subdivision of V , and then obtain a sequence of refinements. See [Lee91a].

GLOSSARY

Refinement of a subdivision: Suppose $S = \{S_1, \dots, S_l\}$ and $T = \{T_1, \dots, T_m\}$ are two subdivisions of V . Then T is a refinement of S if for each j , $1 \leq j \leq m$, there exists i , $1 \leq i \leq l$, such that $T_j \subseteq S_i$. In this case we will write $T \leq S$.

Visible facet: Suppose $P = \text{conv}(V)$ is a d -polytope in $\mathbb{R}^d$, F is a facet of P , and v is a point in $\mathbb{R}^d$. There is a unique hyperplane H (affine set of dimension

$d-1$) containing F . The polytope P is contained in exactly one of the two closed halfspaces determined by H . If v is contained in the opposite open halfspace, then F is said to be visible from v . We also say that the facet $V \cap F$ of the set V is visible from v . If P is a k -polytope in $\mathbb{R}^d$ with $k < d$ and $v \in \text{aff}(P)$, then the above definition is modified in the obvious way so that everything is considered relative to the ambient space $\text{aff}(P)$.

Placing a vertex: Suppose $S = \{S_1, \dots, S_m\}$ is a subdivision of V and $v \notin V$. The subdivision T of $V \cup \{v\}$ that results from placing v is obtained as follows:

- If $v \notin \text{aff}(V)$, then for each $S_i \in S$, include $S_i \cup \{v\}$ in T .
- If $v \in \text{aff}(V)$, then for each $S_i \in S$, include S_i in T ; and if F is a facet of S_i that is contained in a facet of $\text{conv}(V)$ visible from v , then $F \cup \{v\} \in T$.
- Note: if $v \in \text{conv}(V)$, then $S = T$.

Pulling a vertex: Suppose $S = \{S_1, \dots, S_m\}$ is a subdivision of V and $v \in S_1 \cup \dots \cup S_m$. The result of pulling v is the subdivision T of V obtained by modifying each $S_i \in S$ as follows:

- If $v \notin S_i$, then $S_i \in T$.
- If $v \in S_i$, then +for every facet F of S_i not containing v , $F \cup \{v\} \in T$.

Note that T is a refinement of S . Pulling is described in Hudson [Hud69, Lemma 1.4].

Pushing a vertex: Suppose $S = \{S_1, \dots, S_m\}$ is a subdivision of V (where $\dim(\text{conv}(V)) = d$) and $v \in S_1 \cup \dots \cup S_m$. The result of pushing v is the subdivision T of V obtained by modifying each $S_i \in S$ as follows:

- If $v \notin S_i$, then $S_i \in T$.
- If $v \in S_i$ and $S_i \setminus \{v\}$ is $(d-1)$ -dimensional (i.e., $\text{conv}(S_i)$ is a pyramid with apex v), then $S_i \in T$.
- If $v \in S_i$ and $S_i \setminus \{v\}$ is d -dimensional, then $S_i \setminus \{v\} \in T$. Also, if F is any facet of $S_i \setminus \{v\}$ that is visible from v , then $F \cup \{v\} \in T$.

Note that T is a refinement of S .

Lexicographic subdivisions: If T is any subdivision of V constructed by starting with the trivial subdivision of V and then pushing and/or pulling some/all of the points in V in some order, then T is a lexicographic subdivision. Such triangulations were introduced by Sturmfels [Stu91]; see also [Stu96].

Diameter of a subdivision: Suppose $\{S_1, \dots, S_m\}$ is a subdivision, and $P_i = \text{conv}(S_i)$, $1 \leq i \leq m$. Polytopes $P_i \neq P_j$ are **adjacent** if they share a common facet. A sequence $P_{i_0}, \dots, P_{i_k}$ is a **path** if P_{i_j} and $P_{i_{j-1}}$ are adjacent for each j , $1 \leq j \leq k$. The **length** of such a path is k . The **distance** between polytopes P_i and P_j is the length of the shortest path connecting them. The diameter of the subdivision is the maximum distance occurring between pairs of polytopes P_i, P_j .

MAIN RESULTS

Results (1) through (6) below are all discussed in [Lee91a].

1. If the points of V are ordered $\{v_1, \dots, v_n\}$ and T is the subdivision obtained by placing the points of V in that order, then
 - (a) T is a triangulation of V .
 - (b) The same triangulation is obtained by starting with the trivial subdivision of V and pushing the points of V in the opposite order $v_n, \dots, v_1$.
 - (c) The diameter of T does not exceed $2(n-d-1)$, where $d = \dim(\text{conv}(V))$ [Lee91a].

Billera and Munson [BM84] defined triangulations by placing in the more general context of oriented matroids.

2. If S is any subdivision of $V = \{v_1, \dots, v_n\}$, then S can be refined to a triangulation by sequentially pushing and/or pulling all the points in some order.
3. For any specified point $v_k \in V = \{v_1, \dots, v_n\}$, there is a triangulation of V in which every simplex of maximum dimension contains v_k as a vertex—begin with the trivial subdivision $S = \{V\}$, pull v_k first, then pull the remaining points in any order.
4. For any specified simplex F with vertices in $V = \{v_1, \dots, v_n\}$, there is a triangulation of V in which F is a face—first place the vertices of F , then place the remaining vertices in any order.
5. If $\dim(\text{conv}(V)) = d$ and $\text{card}(V) \leq d+3$, then every triangulation of V can be obtained by placing the points of V in some order (equivalently, pushing the points of V in the opposite order) [Lee91a].
6. If V is the set of vertices of a convex n -gon in $\mathbb{R}^2$, then every triangulation of V can be obtained by placing the points of V in some order (equivalently, pushing the points of V in the opposite order).
7. Suppose $V = \{v_1, \dots, v_n\}$ is the set of vertices of some d -polytope P . For a face F of P , define $v(F) = v_k$, where $k = \min\{i \mid v_i \in F\}$. A **full flag** of P is a chain C of faces $F_0 \subset F_1 \subset F_2 \subset \dots \subset F_{d-1} \subset F_d = P$ such that $\dim(F_i) = i$, $0 \leq i \leq d$, and $v(F_i) \neq v(F_{i-1})$, $1 \leq i \leq d$. For a full flag C , write $v(C) = \{v(F_0), \dots, v(F_d)\}$. Then the simplices of the triangulation of P determined by pulling the vertices of P in the order $v_1, \dots, v_n$ are $\{v(C) \mid C \text{ is a full flag of } P\}$ [Sta80, Lee85].

EXAMPLES

Figure 17.2.1 gives three triangulations of a set of seven points that can be obtained from the trivial subdivision by pulling and pushing [Lee91a]. The triangulation in (a) is obtained by pulling point 1, but cannot be obtained by pushing alone. The triangulation in (b) is obtained by pushing the points in the indicated order, or placing them in the opposite order, but cannot be obtained by pulling points alone. The lexicographic triangulation in (c) is obtained by pushing point 1 and then pulling point 2, but cannot be obtained by pulling points alone or by pushing points alone.

 (c) A *lexicographic triangulation*.

17.3 REGULAR TRIANGULATIONS AND SUBDIVISIONS

GLOSSARY

Regular subdivision: Any convex hull algorithm for points in $\mathbb{R}^{d+1}$ (see [Chapter 22](#) of this Handbook) can be used to compute subdivisions of sets of points $V = \{v_1, \dots, v_n\}$ in $\mathbb{R}^d$.

Such subdivisions are called regular and are obtained in the following way:

- (i) Regard V as sitting naturally in $(\mathbb{R}^d, 0)$.
- (ii) Choose arbitrary real numbers $\alpha_1, \dots, \alpha_n$.
- (iii) Determine $Q = \text{conv}(\{(v_1, \alpha_1), \dots, (v_n, \alpha_n)\})$.
- (iv) Project the lower facets of Q onto $(\mathbb{R}^d, 0)$.

Here, a lower facet is a facet of Q that is visible from the point $(0, -\alpha)$ for α sufficiently large. See [GKZ94, Lee91a, Zie95]. Some algorithmic aspects of computing regular triangulations can be found in [ES96].

Weakly regular subdivision: A subdivision S of a set V is weakly regular if there exists a set V' of the same dimension having a regular subdivision S' such that (V', S') is combinatorially isomorphic to (V, S) . That is, there is a one-to-one correspondence between the points of V and the points of V' such that for every subset $F \subseteq V$ and corresponding subset $F' \subseteq V'$, F is a face of S if and only if F' is a face of S' of the same dimension.

Polytopal complex: A polytopal complex is a finite, nonempty collection S of polytopes in $\mathbb{R}^d$ that contains all the faces of its polytopes, and such that the intersection of any two of its polytopes is a common face of each of them (possibly empty). The dimension of S , $\dim(S)$, is the largest dimension of a polytope in S , and S is **pure** if every polytope in S is contained in one of dimension $\dim(S)$ [Zie95]. (Thus every subdivision $\{S_1, \dots, S_m\}$ has an associated pure polytopal complex consisting of the polytopes $\text{conv}(S_1), \dots, \text{conv}(S_m)$ and their faces.)

Shellable: A pure polytopal complex S is shellable if it is 0-dimensional (i.e., a nonempty finite set of points) or else $\dim(S) = k > 0$ and S has a **shelling**, i.e., an ordering of its maximal faces $P_1, \dots, P_m$ such that for $2 \leq j \leq m$ the intersection of P_j with $P_1 \cup \dots \cup P_{j-1}$ is nonempty and is the beginning segment of a shelling of the $(k-1)$ -dimensional boundary complex of P_j [Zie95].

MAIN RESULTS

1. All regular subdivisions are shellable. This is a consequence of the fact that every polytope admits a line shelling [BM71, Zie95], and so in particular one

can begin shelling the polytope Q above by choosing a point in the interior of Q in sufficiently general position, moving in the direction $(O, -1)$, and listing the lower facets of Q in the order in which their supporting hyperplanes are crossed. On the other hand, there exist nonshellable subdivisions, starting in dimension 3. The first example was Rudin's nonshellable triangulation of a tetrahedron [Rud58]. For some additional discussion, including a nonshellable triangulation of the 3-cube, see Ziegler [Zie95].

2. All lexicographic triangulations are regular. In particular, if $v_1, \dots, v_n$ are pushed/pulled in that order, then the corresponding triangulation is obtained by choosing $|\alpha_1| \gg |\alpha_2| \gg \dots \gg |\alpha_n| \gg 0$, where $\alpha_i > 0$ if v_i is pushed and $\alpha_i < 0$ if v_i is pulled [Lee91a].
3. If $\text{card}(V) = \dim(\text{conv}(V)) + 2$, then there are exactly two triangulations of V , and both are regular [Lee91a].
4. If $\text{card}(V) = \dim(\text{conv}(V)) + 3$, then all subdivisions of V are regular [Lee91a].
5. If V is the set of vertices of a convex n -gon in $\mathbb{R}^2$, then all subdivisions of V are regular.
6. If $V \subset \mathbb{R}^2$, then all subdivisions of V are weakly regular as a consequence of Steinitz's Theorem (see [Grü67, Zie95] and [Chapter 16](#) of this Handbook). However, there exists a set V of 6 points in $\mathbb{R}^2$ having a nonregular triangulation [Lee91a] (see [Figure 17.3.2\(b\)](#)).
7. There exists a set V of 7 points that are the vertices of a 3-polytope having a nonregular triangulation that is not even weakly regular [Lee91a] (see [Figure 17.3.3\(b\)](#)).
8. If V is the vertex set of $C_{4n-4}(4n)$, the cyclic polytope of dimension $4n - 4$ with $4n$ vertices, then V has at least 2^n triangulations, of which only $O(n^4)$ are regular [dHSS96]. (See [Chapter 16](#) of this Handbook for the definition of the cyclic polytope.) If V is the vertex set of $C_{n-4}(n)$, then V has exactly $(n+4)2^{(n-4)/2} - n$ triangulations if n is even and $((3n+11)/2)2^{(n-5)/2} - n$ triangulations if n is odd. Of these, at most $6\binom{m}{4} + 3\binom{m}{3} + 4\binom{m}{2} - m + 2$ are regular if $n = 2m$ is even, and $6\binom{m}{4} + 5\binom{m}{2} - 4m + 5$ are regular if $n = 2m - 1$ is odd, and this number is tight for sufficiently generic coordinatizations of the polytope [AS02].
9. If $\alpha_i = \|v_i\|^2$, then the resulting subdivision is the Delaunay subdivision. If $\alpha_i = -\|v_i\|^2$, then the resulting subdivision is the "farthest site" Delaunay subdivision. (See [Chapters 23](#) and [25](#) of this Handbook.)
10. Given a subdivision of V , one can test its regularity by using linear programming to check the existence of appropriate α_i , $1 \leq i \leq n$. On the other hand, checking weak regularity is quite hard, as difficult as determining solutions to systems of real polynomial inequalities (see comments on the Universality Theorem in [Chapters 6](#) and [16](#) of this Handbook, and in [Zie95]).

EXAMPLES

Figure 17.3.1 shows the two triangulations (both regular) of the vertices of a 3-dimensional bipyramid over a triangle. In (a) there are two tetrahedra in the triangulation, sharing a common internal triangle; in (b) there are three, sharing a common internal edge.

FIGURE 17.3.1

The two triangulations of a set of 5 points in $\mathbb{R}^3$.

Figure 17.3.2 shows triangulations of two different sets of 6 points in $\mathbb{R}^2$. The first triangulation is regular, the second is not. But by virtue of the first triangulation, the second is weakly regular.

FIGURE 17.3.2

A regular and a nonregular (but weakly regular) triangulation.

Figure 17.3.3 shows two 3-polytopes, each with 7 vertices. The polytope in (a) is a “capped triangular prism” and its vertex set admits two nonregular triangulations. Denoting the simplices by their vertex sets, these are: $\{1257, 1457, 1236, 1267, 1345, 1346, 1467\}$ and $\{1245, 1247, 1237, 1367, 1356, 1456, 1467\}$. Both triangulations are, however, weakly regular. The polytope in (b) is obtained from the capped triangular prism by rotating the top triangle by a small amount. Its vertex set has one nonregular triangulation, which is not even weakly regular: $\{1245, 1247, 1237, 1367, 1356, 1456, 1467, 2457, 2367, 2345\}$. See [Lee91a].

17.3.1 TRIANGULATING REGIONS BETWEEN POLYTOPES

Suppose P and Q are two d -polytopes in $\mathbb{R}^d$ with disjoint vertex sets V and W , respectively, and Q is contained in P . One can triangulate the region inside of P and outside of Q by the following procedure [GP88]:

FIGURE 17.3.3

Two polytopes with nonregular triangulations.

1. Construct the regular subdivision of $V \cup W$ by setting $\alpha_i = 1$ for $v_i \in V$ and $\alpha_i = 0$ for $v_i \in W$.
2. Refine this subdivision to a triangulation by pushing and/or pulling each point in $V \cup W$.
3. Ignore the portion of the triangulation within Q .

Now suppose P and Q are two d -polytopes in $\mathbb{R}^d$ with disjoint vertex sets V and W , respectively, and that there is a hyperplane H for which P and Q are contained in opposite open halfspaces. One can triangulate the region in $\text{conv}(P \cup Q)$ that is exterior to P and Q by the following procedure [GP88]:

1. Construct the regular subdivision of $V \cup W$ by setting α equal to the distance of v_i to H for each $v_i \in V \cup W$. For example, if $H = \{x \mid a \cdot x = \beta\}$, then α_i can be taken to equal $|a \cdot v_i - \beta|$. (It would also suffice to use these values of α_i for $v_i \in V$ and to set $\alpha_i = 0$ for $v_i \in W$.)
2. Refine this subdivision to a triangulation by pushing and/or pulling each point in $V \cup W$.
3. Ignore the portion of the triangulation within P or Q .

17.4 SUBDIVISIONS, TRIANGULATIONS, AND FACE VECTORS

Suppose $S = \{S_1, \dots, S_m\}$ is a subdivision of V such that $\dim(\text{conv}(V)) = d$. In this section we examine some of the properties of its face numbers. See [Bay93].

GLOSSARY

Boundary: Suppose S is as above. The boundary complex ∂S of S is the set of those faces of S given by $\{F \mid F \text{ is a face of } S, \text{ and } F \subseteq G \text{ for some face } G \text{ of dimension } d-1 \text{ contained in exactly one } S_i\}$. In particular, the empty set is a member of ∂S .

Interior: Suppose S is as above. The interior $\text{int } S$ is the set of those faces of S that are not in the boundary.

***f*-vector:** Suppose S is as above. Let $f_j(S)$ denote the number of j -dimensional faces of S , $-1 \leq j \leq d$. Note that $f_{-1}(S) = 1$ since the empty set is the unique face of S of dimension -1 . The *f*-vector of S is $f(S) = (f_0(S), \dots, f_d(S))$. In an analogous way we define $f(\partial S)$ and $f(\text{int } S)$. Note that $f_{-1}(\partial S) = 1$ and $f_{-1}(\text{int } S) = 0$.

Simplicial polytope: A simplicial polytope is one for which every facet (and hence every face) is a simplex.

17.4.1 *h*-VECTORS and *g*-VECTORS

Suppose S is any polytopal complex of dimension d . For example, S might be the boundary complex of a polytope of dimension $d+1$ or the polytopes corresponding to a subdivision of a finite set V such that $\text{conv}(V)$ has dimension d .

We define the *h*-vector $h(S) = (h_0(S), \dots, h_{d+1}(S))$ with generating function $h(S, x) = \sum_{i=0}^{d+1} h_i x^{d+1-i}$, and the *g*-vector $g(S) = (g_0(S), \dots, g_{\lfloor (d+1)/2 \rfloor}(S))$ with generating function $g(S, x) = \sum_{i=0}^{\lfloor (d+1)/2 \rfloor} g_i x^i$ in the following recursive way:

1. $g_0(S) = h_0(S)$.
2. $g_i(S) = h_i(S) - h_{i-1}(S)$, $1 \leq i \leq \lfloor (d+1)/2 \rfloor$.
3. $g(\emptyset, x) = h(\emptyset, x) = 1$. (Here $\emptyset$ denotes the empty polytopal complex, as distinguished from $\{\emptyset\}$, the polytopal complex consisting of a single set.)
4. $h(S, x) = \sum_{G \text{ face of } S} g(\partial G, x)(x-1)^{d-\dim(G)}$.

Take $h_i(S) = 0$ if $i < 0$ or $i > d+1$, and $g_i(S) = 0$ if $i < 0$ or $i > \lfloor (d+1)/2 \rfloor$. For more information on *f*-vectors, *g*-vectors, and *h*-vectors, refer to [Chapter 18](#) of this Handbook. The formulas are simpler when all of the faces of S are simplices.

MAIN RESULTS

1. Assume that T is a triangulation of a d -polytope.
 - (a) The number of d -simplices in T equals the sum of the components of the *h*-vector of T .
 - (b) The *h*-vector of T is nonnegative [Sta96].
 - (c) The *h*-vector of ∂T is symmetric; i.e., $h_i(\partial T) = h_{d-i}(\partial T)$, $0 \leq i \leq d$. These are the Dehn-Sommerville equations; see [MS71, Sta96, Zie95] and Chapter 18 of this Handbook.
 - (d) The *h*-vectors of T , ∂T , and $\text{int } T$ are related in the following ways [MW71]:

$$h_i(T) - h_{d+1-i}(T) = h_i(\partial T) - h_{i-1}(\partial T), \quad 0 \leq i \leq d+1.$$

$$h_i(T) = h_{d+1-i}(\text{int } T), \quad 0 \leq i \leq d+1.$$

In particular, the *h*-vectors and the *f*-vectors of ∂T and $\text{int } T$ are completely determined by the *h*-vector (and hence the *f*-vector) of T .

- (e) Assume further that T is shellable and that $P_1, \dots, P_m$ is a shelling order of the d -dimensional simplices in T . In particular, each P_j meets $\bigcup_{i=1}^{j-1} P_i$ in some positive number s_j of facets of P_j , $2 \leq j \leq m$. Define also $s_1 = 0$. Then $h_i(T)$ equals $\text{card} \{j \mid s_j = i\}$, $0 \leq i \leq d+1$ [McM70, MS71, Sta96].
- (f) Assume further that T is regular. Then for every integer k , $0 \leq k \leq d+2$, $(h_0(T) - h_{d+k+1}(T), h_1(T) - h_{d+k}(T), h_2(T) - h_{d+k-1}(T), \dots, h_{\lfloor (d+k+1)/2 \rfloor}(T) - h_{\lfloor (d+k+2)/2 \rfloor}(T))$ is an M -sequence [BL81]. (See Chapter 18 of this Handbook for the definition of M -sequence.)

2. If S is the trivial subdivision of a convex d -polytope P consisting of P itself, then

$$h_i(S) = \begin{cases} h_i(\partial P) - h_{i-1}(\partial P), & 1 \leq i \leq \lfloor d/2 \rfloor, \\ 0, & \lfloor d/2 \rfloor < i \leq d. \end{cases}$$

See [Bay93].

3. Suppose V is a finite set of points with rational coordinates, S is a subdivision of V , and $P = \text{conv}(V)$. Then for all i , $h_i(S) \geq h_i(P)$ and $h_i(\partial S) \geq h_i(\partial P)$. Further, if P is simplicial and S is a triangulation, the result holds even without the rationality assumption. In either case, $f_d(S) \geq h_{\lfloor d/2 \rfloor}(\partial S) \geq h_{\lfloor d/2 \rfloor}(\partial P)$ [Bay93, Sta92].

EXAMPLES

In Table 17.4.1, we give the h -vectors and g -vectors of some polytopal complexes.

TABLE 17.4.1 h - and g -vectors of polytopal complexes.

S	h -vector	g -vector
$\{\emptyset\}$	(1)	(1)
Set of n points	$(1, n-1)$	(1)
Line segment	$(1, 0, 0)$	$(1, -1)$
Boundary of convex n -gon	$(1, n-2, 1)$	$(1, n-3)$
Trivial subdivision of convex n -gon	$(1, n-3, 0, 0)$	$(1, n-4)$
Boundary of tetrahedron	$(1, 1, 1, 1)$	(1, 0)
Trivial subdivision of tetrahedron	$(1, 0, 0, 0, 0)$	$(1, -1, 0)$
Boundary of cube	$(1, 5, 5, 1)$	(1, 4)
Trivial subdivision of cube	$(1, 4, 0, 0, 0)$	$(1, 3, -4)$
Triangulation of cube into 6 tetrahedra (See Figure 17.5.3(a))	$(1, 4, 1, 0, 0)$	$(1, 3, -3)$
Boundary of triangular prism	$(1, 3, 3, 1)$	(1, 2)
Trivial subdivision of triangular prism	$(1, 2, 0, 0, 0)$	$(1, 1, -2)$
Triangulation of triangular prism into 3 tetrahedra (See Figure 17.5.1)	$(1, 2, 0, 0, 0)$	$(1, 1, -2)$

17.4.2 SHALLOW TRIANGULATIONS

The concept of shallow triangulation is motivated by an attempt to understand the case of equality in the last main result mentioned above. See [Bay93, BL93].

GLOSSARY

The following definitions concern triangulations T of a finite set V of vertices of a convex d -polytope P .

Carrier: If F is a face of T , the carrier $C(F)$ of F is the smallest face of P containing F .

Shallow: If $\dim(C(F)) \leq 2 \dim(F)$ for every face F of T , then T is a shallow triangulation.

Weakly neighborly: If all triangulations of V are shallow, then P is weakly neighborly.

Equidecomposable: If all triangulations of V have the same f -vector, then P is equidecomposable.

Stacked: If P has a triangulation in which there are no interior faces of dimension less than $d - 1$, then P is stacked.

k -stacked: If P is a simplicial d -polytope that has a triangulation in which there are no interior faces of dimension less than $d - k$, then P is k -stacked. In particular, a simplicial polytope is stacked if and only if it is 1-stacked.

MAIN RESULTS

1. A polytope P is weakly neighborly if and only if every set of $k + 1$ vertices is contained in a face of dimension at most $2k$ for all k [Bay93].
2. If P is weakly neighborly, then P is equidecomposable.
3. If T is a shallow triangulation of a polytope P , then $h(T) = h(P)$ and $h(\partial T) = h(\partial P)$ [Bay93].
4. If T is a triangulation of a polytope P with rational vertices and $h(T) = h(P)$, then T is shallow. Hence, if P is a rational polytope and $h(T) = h(P)$ for all triangulations T of P , then P is weakly neighborly [Bay93].
5. If P is a simplicial d -polytope, then it has a shallow triangulation if and only if it is k -stacked for some $1 \leq k \leq d/2$. In this case there is exactly one triangulation T of P having no interior faces of dimension less than $d - k$ (and this triangulation is the unique shallow one) [Bay93].
6. Suppose P is a d -polytope where $d > 3$. Then P is 1-stacked if and only if $g_2(\partial P) = 0$ [Bar71, Bar73].
7. Suppose P is a simplicial d -polytope such that $g_k(\partial P) = 0$ for some k with $3 \leq k \leq \lfloor d/2 \rfloor$. Then there is another simplicial d -polytope that has the same f -vector and is $(k-1)$ -stacked [KL84]. It is an open problem whether P itself

is always $(k-1)$ -stacked under this hypothesis [MW71]; this is known to be true if $f_0(P) \leq d+3$ or $k < f_0(P)/(f_0(P)-d)$ [Lee91b].

Some classes of weakly neighborly polytopes are given below [Bay93]:

- In dimension less than 3, all polytopes are weakly neighborly.
- In dimension 3, the only weakly neighborly polytopes are pyramids (over polygons) and the triangular prism.
- The product of two simplices of any dimensions is weakly neighborly. (See [Section 17.5.1](#) for the definition of product.)
- The only simplicial weakly neighborly polytopes are simplices and even-dimensional neighborly polytopes (those for which every subset of $d/2$ vertices determines a face of the polytope).
- Lawrence polytopes are weakly neighborly. (**Lawrence polytopes** are polytopes with centrally symmetric Gale diagrams; see [Chapters 6](#) and [16](#) of this Handbook for the definition of a Gale diagram. Equivalently, a Lawrence polytope is the result of executing a Lawrence extension on each vertex of a given arbitrary polytope; refer to Chapter 16 of this Handbook for the definition of a Lawrence extension. See also [Bay93, Zie95].)
- Pyramids over weakly neighborly polytopes are weakly neighborly.
- Subpolytopes of weakly neighborly polytopes are weakly neighborly.

17.4.3 RELATIONSHIPS TO COUNTING LATTICE POINTS

Triangulations of polytopes can be used to enumerate lattice points in polytopes [Sta96].

GLOSSARY

Integral: A polytope is integral if every vertex has integer coordinates.

$i(P, n)$: For an integral polytope P and a nonnegative integer n , $i(P, n)$ is the number of points $x \in P$ for which nx has integer coordinates. Equivalently, it is the number of integer points in nP .

Compressed ordering: An ordering of the vertices of an integral polytope P is compressed if every d -dimensional simplex of the triangulation obtained by pulling the vertices of P in that order has volume $1/d!$. P itself is **compressed** if every ordering of its vertices is compressed. (For example, the standard d -dimensional unit cube is compressed.)

MAIN RESULTS

Results (1) through (4) below are discussed in [Sta96].

1. $i(P, n)$ is a polynomial in n of degree d , called the Ehrhart polynomial of P (see [Chapter 7](#) of this Handbook).
2. For integral d -polytope P write $J(P, t) = 1 + \sum_{n=1}^{\infty} i(P, n)t^n$. Then $J(P, t) = W(P, t)/(1 - t)^{d+1}$, where $W(P, t)$ is a polynomial of degree at most d with nonnegative integer coefficients.
3. If P is an integral d -polytope with compressed order σ , then

$$i(P, n) = \sum_{i=0}^d \binom{n-1}{i} f_i(T),$$

and $W(P, t) = h_0(T) + h_1(T)t + \cdots + h_d(T)t^d$, where T is the pulling triangulation induced by σ .

4. If P is a compressed integral d -polytope and σ is an ordering of its vertices, then the f -vector of the triangulation induced by σ depends only on P , not on σ .

For example, if P is the standard unit 3-cube, then any ordering σ produces a compressed triangulation T with h -vector $h(T) = (1, 4, 1, 0, 0)$. Thus $J(P, t) = (1 + 4t + t^2)/(1 - t)^4 = (1 + 4t + t^2)(1 + 4t + 10t^2 + 20t^3 + 35t^4 + \cdots) = 1 + 8t + 27t^2 + 64t^3 + 125t^4 + \cdots$.

17.5 SOME PARTICULAR TRIANGULATIONS

We gather together some information on some particular triangulations, including triangulations of the product of two simplices, the d -dimensional cube, the convex n -gon, and complete barycentric subdivisions.

17.5.1 PRODUCT OF TWO SIMPLICES

Consider the $(k+l)$ -polytope $P = \Delta_k \times \Delta_l$, the product of a k -dimensional simplex Δ_k and an l -dimensional simplex Δ_l . We consider triangulations of P using the points in its vertex set V . See [BCS88, deL96, GKZ94, Hai91].

GLOSSARY

Product: If P is a subset of $\mathbb{R}^k$ and Q is a subset of $\mathbb{R}^l$, then the product of P and Q is the subset of $\mathbb{R}^{k+l}$ given by $\{(v, w) \mid v \in P, w \in Q\}$.

MAIN RESULTS

1. As mentioned before, $P = \Delta_k \times \Delta_l$ is weakly neighborly, and so every triangulation has the same f -vector and h -vector. In particular, if T is a triangulation of P , then $f_{k+l}(T) = (k+l)!/(k!l!)$, and $h_i(T) = \binom{k}{i} \binom{l}{i}$ for $0 \leq i \leq k+l$ (with $h_i(T)$ taken to be zero if $i > \min\{k, l\}$) [BCS88].

2. Given a triangulation $\{P_1, \dots, P_s\}$ of a k -polytope P and a triangulation $\{Q_1, \dots, Q_t\}$ of an l -polytope Q , then there is a triangulation of $P \times Q$ using $s \cdot t \cdot (k+l)!/(k!l!)$ simplices of dimension $k+l$. To see this, observe that $\{P_i \times Q_j \mid 1 \leq i \leq s, 1 \leq j \leq t\}$ is a subdivision of $P \times Q$. Now refine this subdivision to a triangulation by, for example, pulling the vertices of $P \times Q$. Each $P_i \times Q_j$ will thereby be refined into $(k+l)!/(k!l!)$ simplices [Hai91].
3. All triangulations of $\Delta_2 \times \Delta_3$ and $\Delta_2 \times \Delta_4$ are regular. On the other hand, if $k, l \geq 3$, then there exist nonregular triangulations of $\Delta_k \times \Delta_l$ [deL96].

To describe one triangulation of $\Delta_k \times \Delta_l$ explicitly [BCS88, GKZ94], assume that Δ_k has vertex set $\{v_0, \dots, v_k\}$ and that Δ_l has vertex set $\{w_0, \dots, w_l\}$. Then $P = \Delta_k \times \Delta_l$ has vertex set $\{(v_i, w_j) \mid 0 \leq i \leq k, 0 \leq j \leq l\}$.

Consider paths from the vertex (v_0, w_0) to the vertex (v_k, w_l) in which each step involves increasing either the index of v or the index of w by one. Each such path selects a subset of $k+l+1$ vertices of P , which determines a $(k+l)$ -dimensional simplex. The collection of simplices associated with all such paths constitutes a triangulation of P . This is the same triangulation of P as the one obtained by starting with the trivial subdivision of P and pulling the vertices in the order

$$\begin{aligned} &(v_0, w_0), (v_0, w_1), \dots, (v_0, w_l), \\ &(v_1, w_0), (v_1, w_1), \dots, (v_1, w_l), \\ &\quad \vdots \\ &(v_k, w_0), (v_k, w_1), \dots, (v_k, w_l). \end{aligned}$$

Figure 17.5.1 shows this triangulation for $\Delta_2 \times \Delta_1$, a prism. The label ij on a vertex is an abbreviation for (v_i, w_j) .

FIGURE 17.5.1
A triangulation of $\Delta_2 \times \Delta_1$.

17.5.2 d -CUBES

Here we consider triangulations of a d -dimensional cube using only the set V of its vertices. See [Hai91, OS03].

GLOSSARY

d -cube: The unit d -dimensional cube I^d is the d -fold product of the unit interval $I = [0, 1]$ with itself.

Index: A vertex of the d -dimensional cube is a point of the form $(a_1, \dots, a_d) \in \{0, 1\}^d$. Define the index of the vertex to be $\sum_{i=0}^{d-1} a_{i+1} 2^i$.

Size: The size of a triangulation T is the number $f_d(T)$ of d -simplices in T .

$\varphi(d)$: The size of the smallest triangulation of I^d . That is, $\varphi(d) = \min\{f_d(T) \mid T \text{ is a triangulation of } I^d\}$.

MAIN RESULTS

1. The maximum size of a triangulation of I^d is $d!$ (since the minimum volume of a d -simplex using the vertices of I^d is $1/d!$), and this is achievable for every d by pulling the vertices in any order.
2. $\varphi(d) \geq 2^d(d+1)^{-(d+1)/2}d!$. This bound is derived by observing that I^d can be inscribed in a sphere of diameter $\sqrt{d}$, and that the maximum volume of a simplex contained in this sphere is $(d+1)^{(d+1)/2}/(2^d d!)$ (the volume of a regular simplex) [Hai91].
3. There are precisely 74 triangulations of the 3-cube, and these fall into 6 classes of combinatorially different types [Big91, deL95]. All are regular. On the other hand, if $d \geq 4$, then not all triangulations of the d -cube are regular [deL96].
4. If I^d can be triangulated into $T(d)$ simplices, then I^{kd} can be triangulated into $[(kd)!/(d!)^k]T(d)^k = \rho^{kd}(kd)!$ simplices, where $\rho = (T(d)/d!)^{1/d}$. One measure of the efficiency of a triangulation is the number ρ . This result shows that any value of ρ achievable for one triangulation is achievable asymptotically. The smallest value of ρ obtainable from triangulations to date is $\rho \approx 0.816$ [OS03].
5. It is not known whether smaller size triangulations of I^d can be constructed if additional points other than vert (I^d) are allowed, but there are examples of other polytopes for which this happens [BBdR00].

Table 17.5.1 lists the known values of $\varphi(d)$ [Hug93, HA96].

TABLE 17.5.1 Minimal triangulations of d -cubes.

d	1	2	3	4	5	6	7
$\varphi(d)$	1	2	5	16	67	308	1493

It is also known that the smallest size of a triangulation of I^6 that slices off alternate vertices of I^6 is 324 [Hug93], and the smallest size of a triangulation of I^7 that slices off alternate vertices of I^7 is 1820 [HA96].

Figure 17.5.2 shows a triangulation of the 3-cube of size 5.

FIGURE 17.5.2

A minimum size triangulation of the 3-cube.

SOME SPECIFIC TRIANGULATIONS OF I^d

Pushing vertices: Start from the trivial subdivision of I^d and push the vertices in order of decreasing index (or place them in order of increasing index). The resulting triangulation will have $d!$ simplices [Big91].

Pulling vertices: Start from the trivial subdivision of I^d and pull the vertices in order of increasing index to obtain the triangulation T . Pulling the vertices in any order yields a triangulation with $d!$ simplices, so $f_d(T) = d!$. $h_d(T) = h_{d+1}(T) = 0$ and $h_i(T) = A(d, i)$, $0 \leq i \leq d-1$, where $A(d, i)$ is the Eulerian number (it equals the number of permutations of $\{1, \dots, d\}$ having exactly i descents). There is a one-to-one correspondence between the simplices in T and the permutations of $\{1, \dots, d\}$, given in the following way: For a given permutation σ , the corresponding simplex has vertices $(0, \dots, 0) + e_{\sigma(1)} + e_{\sigma(2)} + \dots + e_{\sigma(k)}$, $0 \leq k \leq d$, where e_i denotes the standard i th unit vector. This is also known as Kuhn's triangulation [Big91, Tod76].

Sallee's corner slicing triangulation: Assume $d \geq 3$. For each vertex with an odd number of coordinates equaling 1, construct the simplex consisting of this vertex and its d neighbors (those joined to this vertex by an edge). These simplices, together with the central polytope remaining when these simplices are removed, constitute a subdivision of I^d . Refine this subdivision to a triangulation by pulling the vertices in order of increasing index. This triangulation has size $O(d!)$ [Hai91, Sal82].

Sallee's middle cut triangulation: Assume $d \geq 2$. Slice the cube into two polytopes by the hyperplane $x_1 + \dots + x_d = \lfloor d/2 \rfloor$. Refine this subdivision to a triangulation by pulling the vertices in order of increasing index. This triangulation has size $O(d!/d^2)$ [Sal84].

Haiman's triangulation: This triangulation method, which bootstraps a triangulation of I^d to a triangulation of I^{kd} as described in Section 17.5.1, Main Result 2, has size $O(\rho^d d!)$, where $\rho < 1$ [Hai91].

EXAMPLES

Figure 17.5.3 shows two triangulations of the 3-cube: (a) the one resulting from pulling the vertices in order of increasing index, and (b) the one resulting from pushing the vertices in order of decreasing index (equivalently, placing the vertices in order of increasing index).

FIGURE 17.5.3

- (a) *The pulling triangulation of the 3-cube.*
 (b) *The pushing triangulation of the 3-cube.*

17.5.3 CONVEX n -GONS

There is no difficulty in finding subdivisions and triangulations of a convex n -gon using its set V of vertices. All subdivisions are regular, and all triangulations are constructible by pushing (or placing). Any subdivision is determined by a collection of mutually noncrossing internal diagonals. The set of all triangulations of the n -gon is isomorphic to many other combinatorial structures, including the set of all ways to parenthesize a string of $n - 1$ symbols and the set of all rooted binary trees with $n - 2$ nodes. See [Lee89, Zie95].

MAIN RESULTS

1. There are $\frac{1}{n-1} \binom{n-3}{j} \binom{n+j-1}{j+1}$ subdivisions of a convex n -gon having exactly j diagonals, $0 \leq j \leq n - 3$. In particular, the number of triangulations is the **Catalan number** $\frac{1}{n-1} \binom{2n-4}{n-2}$.
2. Two triangulations are **adjacent** if they share all but one diagonal. The **distance** between two triangulations T and T' is the length k of the shortest path $T = T_0, T_1, T_2, \dots, T_k = T'$ of triangulations in which T_i and T_{i-1} are adjacent for all $1 \leq i \leq k$. The distance between two triangulations of a convex n -gon does not exceed $2n - 6$ [Luc89]. This bound is achievable for infinitely many values of n [STT88].
3. The set of all triangulations of a convex n -gon is connected by a Hamiltonian cycle—a closed path $T_0, T_1, T_2, \dots, T_m = T_0$ containing each triangulation exactly once (except for T_0 , which starts and ends the path), in which T_i and T_{i-1} are adjacent for all i , $1 \leq i \leq m$ [Luc87].

17.5.4 COMPLETE BARYCENTRIC SUBDIVISIONS

For a given d -polytope P , let V be the collection of the centroids of the nonempty faces. Give the centroid of each k -dimensional face the label k , $0 \leq k \leq d$. Note that points labeled 0 are the vertices of P . Triangulate P by pulling the points of V in order of nonincreasing label. The resulting triangulation is the **complete barycentric subdivision** of P . The procedure can be extended in the obvious way to be applied to any polytopal complex. See [Bay88].

Figure 17.5.4 shows the complete barycentric subdivision of a 3-cube, a triangulation of size 48—there are eight pyramids into the center of the cube from each of the six original facets.

FIGURE 17.5.4

The complete barycentric subdivision of a 3-cube.

MAIN RESULTS

1. For every polytope P , there is a **dual polytope** (or polar polytope: see [Chapter 16](#) of this Handbook) P^* of the same dimension, whose face lattice is anti-isomorphic to that of P . The complete barycentric subdivisions T and T^* of P and P^* , respectively, are combinatorially isomorphic. That is to say, there is a bijection between the vertices of T and of T^* such that a subset of vertices of T determines a simplex in T precisely when the corresponding subset of vertices of T^* determines a simplex in T^* .
2. If T is the complete barycentric subdivision of a polytope P , then the combinatorial structure of the face lattice of P (up to lattice reversal by the previous result) can be recovered from the combinatorial structure of T , even if one is not given the specific geometric realization or the labels of the points [Bay88].
3. Suppose T is the complete barycentric subdivision of a d -dimensional simplex. Then $f_d(T) = d!$, $h_{d+1}(T) = 0$, and $h_i(T) = A(d+1, i)$, $0 \leq i \leq d$. These are the Eulerian numbers encountered in Kuhn's triangulation of I^{d+1} . In fact, Kuhn's triangulation is combinatorially isomorphic to the join of T to a new point (make a pyramid with this new point over every d -simplex in T) [Big91].
4. If T is the complete barycentric subdivision of I^d , then $f_d(T) = d!2^d$. Also, $h_{d+1}(T) = 0$, and $h_i(T)$ equals the number of signed permutations of $\{1, \dots, d\}$ with exactly i descents [Bre94].

17.6 SECONDARY AND FIBER POLYTOPES

This section concerns itself with the structure of the collection of all regular subdivisions of a given finite set of points $V = \{v_1, \dots, v_n\} \subset \mathbb{R}^d$. See [GKZ94, Lee91a, Zie95]. Assume that $\dim(\text{conv}(V)) = d$.

GLOSSARY

z -vector: Suppose T is a triangulation of V . Define the z -vector $z(T) = (z_1, \dots, z_n) \in \mathbb{R}^n$ by $z_i = \sum \text{vol}(F)$, where the sum is taken over all d -simplices F in T having v_i as a vertex.

Secondary polytope: The secondary polytope $\Sigma(V)$ is the convex hull of the z -vectors of all triangulations of V .

Link: If F is a face of a triangulation T , then the link of F is the set $\{G \mid G \text{ is a face of } T, F \cup G \text{ is a face of } T \text{ of dimension } \dim F + \dim G + 1, \text{ and } F \cap G = \emptyset\}$.

Adjacent triangulations: Suppose T is a triangulation of V . Suppose there is a subset W of $k + 2$ points in V such that $\dim(\text{aff}(W)) = k$, T contains one of the (only) two triangulations of W , and the links with respect to T of all the k -dimensional faces F in the triangulation of W are identical. Then it is possible to interchange the triangulations of W , giving the new k -simplices the same links with respect to T , and thereby obtain a new triangulation of V . This operation is called a **flip**, and the resulting triangulation is said to be adjacent to T .

Connected: Two triangulations are said to be connected if one can be obtained from the other by a sequence of flips. The set of triangulations, under adjacency by flips, forms a graph.

The secondary polytope plays an important role in the study of Gröbner bases [Stu96] and generalized discriminants and determinants [GKZ94].

MAIN RESULTS

1. The collection of all regular subdivisions of the set V , partially ordered by refinement, is combinatorially equivalent to the boundary complex of the secondary polytope $\Sigma(V)$, which has dimension $n - d - 1$ [GKZ94].
2. The vertices of $\Sigma(V)$ are precisely the z -vectors of the regular triangulations. In particular, no two regular triangulations have the same z -vector. The edges of $\Sigma(V)$ correspond to adjacent regular triangulations [GKZ94].
3. $\Sigma(V)$ can also be expressed as a discrete or continuous Minkowski sum of polytopes coming from a representation of V as a projection of the vertices of an $(n-1)$ -dimensional simplex. See [BFS90, BS92, Zie95].
4. Suppose $S = \{S_1, \dots, S_m\}$ is a regular triangulation of $V = \{v_1, \dots, v_n\} \subset \mathbb{R}^d$ determined by lifting numbers $\alpha_1, \dots, \alpha_n$. Let $f : \text{conv}(V) \rightarrow \mathbb{R}$ be the piecewise-linear convex function whose graph is given by the lower facets of $Q = \text{conv}(\{(v_1, \alpha_1), \dots, (v_n, \alpha_n)\})$. Define c_j to be the centroid of the polytope $P_j = \text{conv}(S_j)$, $1 \leq j \leq m$. Then the inequality

$$\sum_{i=1}^n \alpha_i z_i \geq (d+1) \sum_{j=1}^m \text{vol}(P_j) f(c_j)$$

is valid for the secondary polytope and holds with equality precisely for those subdivisions refining S . In particular, it describes a facet of $\Sigma(V)$ if S is a minimal nontrivial regular subdivision. These facet-defining inequalities, together with the set of $d + 1$ equations

$$\sum_{i=1}^n z_i = (d+1) \text{vol}(P),$$

$$\sum_{i=1}^n z_i v_i = (d+1) \operatorname{vol}(P) c,$$

where c is the centroid of $P = \operatorname{conv}(V)$, fully describe $\Sigma(V)$ [C.W. Lee, unpublished].

5. As an immediate consequence of the existence of $\Sigma(V)$, every regular triangulation has at least $n - d - 1$ adjacent triangulations, and every pair of regular triangulations is connected.
6. In the special case that $n = d + 2$, there are precisely two nontrivial subdivisions of V (both regular), so $\Sigma(V)$ is a line segment.
7. In the special case that $n = d + 3$, all subdivisions are regular, and $\Sigma(V)$ is a convex polygon [Lee91a].
8. In the special case that V is the set of vertices of a convex n -gon, $\Sigma(V)$ is called the **associahedron** [Lee89]. Its dual is a simplicial polytope Q of dimension $n - 3$ having the following f -vector and h -vector:

$$f_{j-1}(Q) = \frac{1}{n-1} \binom{n-3}{j} \binom{n+j-1}{j+1}, \quad 0 \leq j \leq n-3,$$

$$h_i(Q) = \frac{1}{n-1} \binom{n-3}{i} \binom{n-1}{i+1}, \quad 0 \leq i \leq n-3.$$

From the discussion in Section 17.5.3, $f_{j-1}(Q)$ is the number of subdivisions of the n -gon having exactly j diagonals. There are various combinatorial interpretations of the h -vector. Explicit coordinates and inequalities for $\Sigma(V)$ can be found in [Zie95].

9. It is not necessarily the case that the collection of all triangulations, whether regular or not, is connected, though this is the case for triangulations of point sets in $\mathbb{R}^2$, for triangulations of vertex sets of cyclic polytopes [Ram96], and for the special case that $n = d + 4$ (for which the graph of triangulations is 3-connected, and in particular every triangulation has at least 3 neighbors) [AS00]. The first example found of a triangulation of a point set with no adjacent triangulations is of a certain set of 324 points in $\mathbb{R}^6$ [San00]. There are now examples of point sets of size 50 and 26 that are vertex sets of 5-polytopes whose triangulation graphs are disconnected [San02].

Figure 17.6.1 shows the five regular triangulations of a set of 5 points in $\mathbb{R}^2$, marking which pairs of triangulations are adjacent.

The secondary polytope of the product of two simplices is discussed, for example, in [deL96, GKZ94]. See [dHSS96] for properties of the polytope that is the convex hull of the $(0, 1)$ incidence vectors of all triangulations of V , and for the relationship of this polytope to $\Sigma(V)$. The special case when V is the set of vertices of a convex n -gon was first described in [DHH85].

17.6.1 FIBER POLYTOPES

A secondary polytope is a special case of a fiber polytope, which is associated with an affine map $\pi : P \rightarrow Q$ from a polytope P in $\mathbb{R}^p$ onto a polytope Q in $\mathbb{R}^q$. Such

FIGURE 17.6.1

A polygon of regular triangulations.

a map induces certain regular subdivisions of Q (called π -coherent subdivisions). The fiber polytope $\Sigma(P, Q)$ has dimension $\dim(P) - \dim(Q)$, and its nonempty faces correspond to these π -coherent subdivisions.

A **section** is a continuous map $\gamma : Q \rightarrow P$ with $\pi(\gamma(x)) = x$ for all $x \in Q$. The **fiber polytope** is defined to be the set of all average values of the sections of π :

$$\Sigma(P, Q) = \left\{ \frac{1}{\text{vol}(Q)} \int_Q \gamma(x) dx \mid \gamma \text{ is a section of } \pi \right\}.$$

The associahedron and the permutohedron (see [Chapter 16](#) of this Handbook) are examples of fiber polytopes, and there are applications to zonotopal subdivisions and oriented matroids. For more details, see [BS92, RZ94, Zie95]. A subdivision of Q is π -induced if it corresponds to some subcomplex of P that π maps bijectively onto Q . This subdivision is proper if it is not the trivial subdivision of Q , and such subdivisions form a poset under refinement, called the **Baues poset**. A natural extension of the connectivity questions on regular triangulations is the

PROBLEM 17.6.1 *Generalized Baues Problem* [BKS94]

When is the Baues poset homotopy equivalent to a sphere of dimension $\dim P - \dim Q - 1$?

See [Rei99] for a survey of this problem.

18 FACE NUMBERS OF POLYTOPES AND COMPLEXES

Louis J. Billera and Anders Björner

INTRODUCTION

Geometric objects are often put together from simple pieces according to certain combinatorial rules. As such, they can be described as *complexes* with their constituent *cells*, which are usually polytopes and often simplices. Many constraints of a combinatorial and topological nature govern the incidence structure of cell complexes and are therefore relevant in the analysis of geometric objects. Since these incidence structures are in most cases too complicated to be well understood, it is worthwhile to focus on simpler invariants that still say something nontrivial about their combinatorial structure. The invariants to be discussed in this chapter are the *f-vectors* $f = (f_0, f_1, \dots)$, where f_i is the number of i -dimensional cells in the complex.

The theory of *f-vectors* can be discussed at two levels: (1) the numerical relations satisfied by the f_i numbers, and (2) the algebraic, combinatorial, and topological facts and constructions that give rise to and explain these relations. This chapter will summarize the main facts in the numerology of *f-vectors* (i.e., at level 1), with emphasis on cases of geometric interest.

The chapter is organized as follows. To begin with, we treat simplicial complexes, first the general case (Section 18.1), then complexes with various Betti number constraints (Section 18.2), and finally triangulations of spheres, polytope boundaries, and manifolds (Section 18.3). Then we move on to nonsimplicial complexes, discussing first the general case (Section 18.4) and then polytopes and spheres (Section 18.5).

18.1 SIMPLICIAL COMPLEXES

GLOSSARY

The convex hull of any set of $j + 1$ affinely independent points in $\mathbb{R}^n$ is called a *j-simplex*. See [Chapter 16](#) for more about this definition, and for the notions of *faces* and *vertices* of a simplex.

A *geometric simplicial complex* Γ is a finite nonempty family of simplices in $\mathbb{R}^n$ such that (i) $\sigma \in \Gamma$ implies that $\tau \in \Gamma$ for every face τ of σ , and (ii) if $\sigma, \tau \in \Gamma$ and $\sigma \cap \tau \neq \emptyset$ then $\sigma \cap \tau$ is a face of both σ and τ .

An *abstract simplicial complex* Δ is a finite nonempty family of subsets of some ground set V (the *vertex set*) such that if $A \in \Delta$ and $B \subseteq A$ then $B \in \Delta$. (Note that always $\emptyset \in \Delta$.) The elements $A \in \Delta$ are called *faces*.

Define the **dimension** of a face A and of Δ itself by $\dim A = |A| - 1$; $\dim \Delta = \max_{A \in \Delta} \dim A$. By a **d -complex** we mean a d -dimensional complex.

With every geometric simplicial complex Γ we associate an abstract simplicial complex by taking the family of vertex sets of its simplices. Conversely, every d -dimensional abstract simplicial complex Δ can be realized in $\mathbb{R}^n$ for $n \geq 2d + 1$ (and sometimes less) by some geometric simplicial complex. The latter is unique up to homeomorphism, so it is correct to think of the realization map as a one-to-one correspondence between abstract and geometric simplicial complexes. We will therefore drop the adjectives “abstract” and “geometric” and speak only of a **simplicial complex**.

For a simplicial complex Δ , let $\Delta^i = \{i\text{-dimensional faces}\}$ and let $f_i = |\Delta^i|$. The integer sequence $f(\Delta) = (f_0, f_1, \dots)$ is called the **f -vector** of Δ . (The entry $f_{-1} = 1$ is usually suppressed.) The subcomplex $\Delta^{\leq i} = \bigcup_{j \leq i} \Delta^j$ is called the **i -skeleton** of Δ .

A simplicial complex Δ is called **pure** if all maximal faces are of equal dimension. It is called **r -colorable** if there exists a partition of the vertex set $V = V_1 \cup \dots \cup V_r$ such that $|A \cap V_i| \leq 1$ for all $A \in \Delta$ and $1 \leq i \leq r$. Equivalently, Δ is r -colorable if and only if its 1-skeleton $\Delta^{\leq 1}$ is r -colorable in the standard sense of graph theory. An $(r-1)$ -complex that is both pure and r -colorable is sometimes called **balanced**.

For integers $k, n \geq 1$ there is a unique way of writing

$$n = \binom{a_k}{k} + \binom{a_{k-1}}{k-1} + \dots + \binom{a_i}{i}$$

so that $a_k > a_{k-1} > \dots > a_i \geq i \geq 1$. Then define

$$\partial_k(n) = \binom{a_k}{k-1} + \binom{a_{k-1}}{k-2} + \dots + \binom{a_i}{i-1},$$

and

$$\partial^k(n) = \binom{a_k-1}{k-1} + \binom{a_{k-1}-1}{k-2} + \dots + \binom{a_i-1}{i-1}.$$

Also let $\partial_k(0) = \partial^k(0) = 0$.

Let $\mathbb{N}^\infty$ denote the set of sequences $(n_0, n_1, \dots)$ of nonnegative integers, and $\mathbb{N}^{(\infty)}$ the subset of sequences such that $n_k = 0$ for all sufficiently large k . We call $n \in \mathbb{N}^{(\infty)}$ a **K -sequence** if

$$\partial_{k+1}(n_k) \leq n_{k-1} \quad \text{for all } k \geq 1.$$

We call $n \in \mathbb{N}^\infty$ an **M -sequence** if

$$n_0 = 1 \text{ and } \partial^k(n_k) \leq n_{k-1} \quad \text{for all } k \geq 2.$$

THE KRUSKAL-KATONA THEOREM AND SOME RELATIVES

The following basic result characterizes the f -vectors of simplicial complexes.

THEOREM 18.1.1 *Kruskal-Katona Theorem*

For $f = (f_0, f_1, \dots) \in \mathbb{N}^{(\infty)}$ the following are equivalent:

- (i) f is the f -vector of a simplicial complex;
- (ii) f is a K -sequence.

A simplicial complex is **connected** if its 1-skeleton is connected in the sense of graph theory.

THEOREM 18.1.2

For $f \in \mathbb{N}^{(\infty)}$ the following are equivalent:

- (i) f is the f -vector of a connected simplicial complex;
- (ii) f is a K -sequence and $\partial^3(f_2) \leq f_1 - f_0 + 1$.

Theorem 18.1.1 has a generalization to colored complexes, whose statement will require some additional definitions. Fix an integer $r > 0$. Then define $\binom{n}{k}_r$ as follows: partition $\{1, \dots, n\}$ into r subsets $V_1, \dots, V_r$ as evenly as possible (so every subset V_i will have $\lfloor \frac{n}{r} \rfloor$ or $\lfloor \frac{n}{r} \rfloor + 1$ elements), and let $\binom{n}{k}_r$ be the number of k -subsets $F \subseteq \{1, \dots, n\}$ such that $|F \cap V_i| \leq 1$ for $1 \leq i \leq r$. For $k \leq r$ every positive integer n can be uniquely written

$$n = \binom{a_k}{k}_r + \binom{a_{k-1}}{k-1}_{r-1} + \dots + \binom{a_i}{i}_{r-k+i},$$

where $\frac{a_j}{a_{j-1}} > \frac{r-k+j}{r-k+j-1}$ for $j = k, k-1, \dots, i+1$, and $a_i \geq i \geq 1$. Then define

$$\partial_k^{(r)}(n) = \binom{a_k}{k-1}_r + \binom{a_{k-1}}{k-2}_{r-1} + \dots + \binom{a_i}{i-1}_{r-k+i},$$

and let $\partial_k^{(r)}(0) = 0$.

THEOREM 18.1.3

For $f = (f_0, \dots, f_{d-1})$, $d \leq r$, the following are equivalent:

- (i) f is the f -vector of an r -colorable simplicial complex;
- (ii) $\partial_{k+1}^{(r)}(f_k) \leq f_{k-1}$, for all $1 \leq k \leq d-1$.

Note that for r sufficiently large Theorem 18.1.3 specializes to Theorem 18.1.1.

MULTICOMPLEXES AND MACAULAY'S THEOREM

A **multicomplex** $\mathcal{M}$ is a nonempty collection of monomials in finitely many variables such that if m is in $\mathcal{M}$ then so is every divisor of m . Let $f_i(\mathcal{M})$ be the number of degree i monomials in $\mathcal{M}$; $f(\mathcal{M}) = (f_0, f_1, \dots)$ is called the **f -vector** of $\mathcal{M}$.

THEOREM 18.1.4 Macaulay's Theorem

For $f \in \mathbb{N}^\infty$ the following are equivalent:

- (i) f is the f -vector of a multicomplex;
- (ii) f is an M -sequence;
- (iii) $f_i = \dim_{\mathbf{k}} R_i$, $i \geq 0$, for some finitely generated commutative graded $\mathbf{k}$ -algebra $R = \bigoplus_{i \geq 0} R_i$ such that $R_0 \cong \mathbf{k}$ (a field) and R_1 generates R .

A simplicial complex can be viewed as a multicomplex of squarefree monomials. Hence, a K -sequence is (except for a shift in the indexing) an M -sequence: If $(f_0, \dots, f_{d-1})$ is a K -sequence then $(1, f_0, \dots, f_{d-1})$ is an M -sequence. For this reason (and others, see, e.g., Theorem 18.2.2), properties of M -sequences are of interest also if one cares mainly about the special case of simplicial complexes.

A multicomplex is **pure** if all its maximal (under divisibility) monomials have the same degree.

THEOREM 18.1.5

Let $(f_0, \dots, f_r)$ be the f -vector of a pure multicomplex, $f_r \neq 0$. Then $f_i \leq f_j$ for all $i < j \leq r - i$.

COMMENTS

Simplicial complexes (abstract and geometric) are treated in most books on algebraic topology; see, e.g., [Mun84, Spa66]. The Kruskal-Katona theorem (independently discovered by M.-P. Schützenberger, J.B. Kruskal, G.O.H. Katona, L.H. Harper, and B. Lindström during the years 1959-1966) is discussed in many places and several proofs have appeared; see, e.g., [And87, Zie95].

A Kruskal-Katona type theorem for simplicial complexes with vertex-transitive symmetry group appears in [FK96].

Theorems 18.1.2 and 18.1.3 are from [Bjö96] and [FFK88] respectively. (*Remark:* The definition of the $\partial_k^{(r)}(\cdot)$ operator is incorrectly stated in [FFK88], in particular the uniqueness claim in [FFK88, Lemma 1.1] is incorrect. The version stated here was suggested to us by J. Eckhoff.)

For Macaulay's theorem we refer to [And87, Sta96]. There is a common generalization of Macaulay's theorem and the Kruskal-Katona theorem due to Clements and Lindström; see [And87]. Theorem 18.1.5 is from [Hib89].

18.2 BETTI NUMBER CONSTRAINTS

GLOSSARY

The **Euler characteristic** $\chi(\Delta)$ of a simplicial complex Δ with f -vector $(f_0, \dots, f_{d-1})$ is $\chi(\Delta) = \sum_{i=0}^{d-1} (-1)^i f_i$.

The **h -vector** $(h_0, \dots, h_d)$ of a $(d-1)$ -dimensional simplicial complex is defined by

$$\sum_{i=0}^d h_i x^{d-i} = \sum_{i=0}^d f_{i-1} (x-1)^{d-i}.$$

The corresponding **g -vector** $(g_0, \dots, g_{\lfloor d/2 \rfloor})$ is defined by $g_0 = 1$ and $g_i = h_i - h_{i-1}$, for $i \geq 1$.

The **Betti number** $\beta_i(\Delta)$ is the dimension (as a $\mathbb{Q}$ -vector space) of the i th reduced simplicial homology group $\tilde{H}_i(\Delta, \mathbb{Q})$; see any textbook on algebraic topology (e.g., [Mun84]) for the definition. We call $(\beta_0, \dots, \beta_{\dim \Delta})$ the **Betti sequence** of Δ .

The **link** $\ell k_\Delta(F)$ of a face F is the subcomplex of Δ defined by $\ell k_\Delta(F) = \{A \in \Delta \mid A \cap F = \emptyset, A \cup F \in \Delta\}$. Note that $\ell k_\Delta(\emptyset) = \Delta$.

A simplicial complex Δ is **acyclic** if $\beta_i(\Delta) = 0$ for all i .

A simplicial complex Δ is **Cohen-Macaulay** if $\beta_i(\ell k_\Delta(F)) = 0$ for all $F \in \Delta$ and all $i < \dim \ell k_\Delta(F)$.

A simplicial complex Δ is **m -Leray** if $\beta_i(\ell k_\Delta(F)) = 0$ for all $F \in \Delta$ and all $i \geq m$.

FIXED BETTI NUMBERS

The most basic relationship between f -vectors and Betti numbers is the **Euler-Poincaré formula**:

$$\chi(\Delta) = f_0 - f_1 + f_2 - \dots = 1 + \beta_0 - \beta_1 + \beta_2 - \dots$$

This is in fact the only linear one in the following complete set of relations.

THEOREM 18.2.1

For $f = (f_0, f_1, \dots) \in \mathbb{N}^{(\infty)}$ and $\beta = (\beta_0, \beta_1, \dots) \in \mathbb{N}^{(\infty)}$ the following are equivalent:

- (i) f is the f -vector of some simplicial complex with Betti sequence β ;
- (ii) if $\chi_{k-1} = \sum_{j \geq k} (-1)^{j-k} (f_j - \beta_j)$, $k \geq 0$, then $\chi_{-1} = 1$ and $\partial_{k+1}(\chi_k + \beta_k) \leq \chi_{k-1}$ for all $k \geq 1$.

By putting $\beta_i = 0$ for all i one gets as a special case a characterization of the f -vectors of acyclic simplicial complexes, viz., $\sum_{i \geq 0} f_{i-1} x^i = (1+x) \sum_{i \geq 0} f'_i x^i$, where $(f'_0, f'_1, \dots)$ is a K -sequence.

COHEN-MACAULAY COMPLEXES

Examples of Cohen-Macaulay complexes are triangulations of manifolds whose Betti numbers vanish below the top dimension, in particular triangulations of spheres and balls. Other examples are matroid complexes (the independent sets of a matroid), Tits buildings, and the order complexes (simplicial complex of totally ordered subsets) of several classes of posets, e.g., semimodular lattices (including distributive and geometric lattices). Shellable complexes (see [Chapters 17](#) and [20](#)) are Cohen-Macaulay. Cohen-Macaulay complexes are always pure.

The definition of h -vector given in the glossary shows that the h -vector and the f -vector of a complex mutually determine each other via the formulas:

$$h_i = \sum_{j=0}^i (-1)^{i-j} \binom{d-j}{i-j} f_{j-1}, \quad f_{i-1} = \sum_{j=0}^i \binom{d-j}{i-j} h_j,$$

for $0 \leq i \leq d$. Hence, we may state f -vector results in terms of h -vectors whenever convenient.

THEOREM 18.2.2

For $h = (h_0, \dots, h_d) \in \mathbb{Z}^{d+1}$ the following are equivalent:

- (i) h is the h -vector of a $(d-1)$ -dimensional Cohen-Macaulay complex;
- (ii) h is the h -vector of a $(d-1)$ -dimensional shellable complex;
- (iii) h is an M -sequence.

Since there are a total of $\binom{n+k-1}{k}$ monomials of degree k in n variables, and by Theorems 18.1.4 and 18.2.2 the h -vector of a $(d-1)$ -dimensional Cohen-Macaulay complex counts certain monomials in $h_1 = f_0 - d$ variables, we derive the inequalities

$$0 \leq h_i \leq \binom{f_0 - d + i - 1}{i}$$

for the h -vectors of Cohen-Macaulay complexes. The lower bound can be improved for complexes with fixed-point-free involutive symmetry.

THEOREM 18.2.3

Let $h = (h_0, \dots, h_d)$ be the h -vector of a Cohen-Macaulay complex admitting an automorphism α of order 2, such that $\alpha(F) \neq F$ for all $F \in \Delta \setminus \{\emptyset\}$. Then

$$h_i \geq \binom{d}{i} \quad \text{for } 0 \leq i \leq d.$$

Consequently, $f_{d-1} = h_0 + \dots + h_d \geq 2^d$.

Another condition on a Cohen-Macaulay complex that forces stricter conditions on its h -vector is being r -colorable.

THEOREM 18.2.4

For $h = (h_0, \dots, h_d) \in \mathbb{Z}^{d+1}$ the following are equivalent:

- (i) h is the h -vector of a $(d-1)$ -dimensional and d -colorable Cohen-Macaulay complex;
- (ii) $(h_1, \dots, h_d)$ is the f -vector of a d -colorable simplicial complex.

Hence in this case the h -vector is not only an M -sequence, but the special kind of K -sequence characterized in Theorem 18.1.3.

LERAY COMPLEXES

Examples of Leray complexes arise as follows. Let $\mathcal{K} = \{K_1, \dots, K_t\}$ be a family of convex sets in $\mathbb{R}^m$, and let $\Delta(\mathcal{K}) = \{A \subseteq \{1, \dots, t\} \mid \bigcap_{i \in A} K_i \neq \emptyset\}$. Then the simplicial complex $\Delta(\mathcal{K})$ is m -Leray.

Fix $m \geq 0$, and let $f = (f_0, \dots, f_{d-1})$ be the f -vector of a simplicial complex Δ . Define

$$h_k^* = \begin{cases} f_k & \text{for } 0 \leq k \leq m-1 \\ \sum_{j \geq 0} (-1)^j \binom{k+j-m}{j} f_{k+j} & \text{for } k \geq m. \end{cases}$$

The sequence $h^* = (h_0^*, \dots, h_{d-1}^*)$ is the h^* -vector of Δ . The two vectors f and h^* mutually determine each other.

THEOREM 18.2.5

For $h^* = (h_0^*, h_1^*, \dots) \in \mathbb{Z}^{(\infty)}$ the following are equivalent:

- (i) h^* is the h^* -vector of an m -Leray complex;
- (ii) h^* is the h^* -vector of $\Delta(\mathcal{K})$ for some family $\mathcal{K}$ of convex sets in $\mathbb{R}^m$;
- (iii)

$$\begin{cases} h_k^* \geq 0 & \text{for } k \geq 0 \\ \partial_{k+1}(h_k^*) \leq h_{k-1}^* & \text{for } 1 \leq k \leq m-1 \\ \partial_m(h_k^*) \leq h_{k-1}^* - h_k^* & \text{for } k \geq m. \end{cases}$$

COMMENTS

The Euler-Poincaré formula (due to Poincaré 1899) is proved in most books on algebraic topology. Theorem 18.2.1 is from [BK88]. A good general source on Cohen-Macaulay complexes is [Sta96]; Theorems 18.2.2, 18.2.3, and 18.2.4, as well as references to the original sources, can be found there. A generalization of Theorem 18.2.2 to complexes whose k -skeleton is Cohen-Macaulay appears in [Bjö96]. There are several additional results about h -vectors of Cohen-Macaulay complexes. For instance, for complexes with nontrivial automorphism groups, see [Sta96, Section III.8]; for matroid complexes, see [Sta96, Section III.3]; and for Cohen-Macaulay complexes that are r -colorable for $r < d$, see the references mentioned in [Sta96, Section III.4].

Cohen-Macaulay complexes are closely related to certain commutative rings [Sta96], and via this connection such complexes have also been of use in the theory of splines; see [Sta96, Section III.5] and also [Chapter 53](#) of this Handbook.

Theorem 18.2.5 was conjectured by Eckhoff and proved by Kalai [Kal84, Kal86].

18.3 SIMPLICIAL POLYTOPES, SPHERES, AND MANIFOLDS**GLOSSARY**

A **triangulated d -ball** is a simplicial complex Δ whose realization $\|\Delta\|$ is homeomorphic to the ball $\{x \in \mathbb{R}^d \mid x_1^2 + \dots + x_d^2 \leq 1\}$. A **triangulated $(d-1)$ -sphere** is a simplicial complex whose realization is homeomorphic to the sphere $\{x \in \mathbb{R}^d \mid x_1^2 + \dots + x_d^2 = 1\}$. Equivalently, it is the boundary of a triangulated d -ball. Examples of triangulated $(d-1)$ -spheres are given by the boundary complexes of simplicial d -polytopes.

A **pseudomanifold** is a pure simplicial complex Δ such that

- (i) each face of codimension 1 is contained in precisely two maximal faces; and
- (ii) the dual graph (whose vertices are the maximal faces of Δ and whose edges are the faces of codimension 1) is connected.

An **Eulerian pseudomanifold** is a pseudomanifold Δ such that Δ and the link of each face have the Euler characteristic of a sphere of the corresponding dimension.

A pure $(d-1)$ -dimensional simplicial complex Δ is a **homology manifold** if it is connected and the link of each nonempty face has the Betti numbers of a sphere of the same dimension. It is a **homology sphere** if, in addition, Δ itself has the Betti numbers of a $(d-1)$ -sphere. Examples of homology manifolds are given by triangulations of compact connected topological manifolds, i.e., spaces that are locally Euclidean.

The **cyclic d -polytope with n vertices** $C_d(n)$ is the convex hull of any n points on the moment curve in $\mathbb{R}^d$. (See [Section 16.1.4](#).)

The following implications hold among these various classes, all of them strict:

$$\begin{aligned} \text{polytope boundary} &\Rightarrow \text{sphere} \Rightarrow \text{homology sphere} \Rightarrow \\ &\quad \text{Eulerian pseudomanifold} \Rightarrow \text{pseudomanifold} \\ \text{homology sphere} &\Rightarrow \text{homology manifold} \Rightarrow \text{pseudomanifold} \\ \text{homology sphere} &\Rightarrow \text{Cohen-Macaulay complex} \end{aligned}$$

PSEUDOMANIFOLDS

The following results give the basic lower and upper bounds on f -vectors of pseudomanifolds.

THEOREM 18.3.1 Lower Bound Theorem

For a $(d-1)$ -dimensional pseudomanifold Δ with n vertices,

$$f_k(\Delta) \geq \begin{cases} \binom{d}{k}n - \binom{d+1}{k+1}k & \text{for } 1 \leq k \leq d-2 \\ (d-1)n - (d-2)(d+1) & \text{for } k = d-1. \end{cases}$$

THEOREM 18.3.2 Upper Bound Theorem

Let Δ be a $(d-1)$ -dimensional homology manifold with n vertices, such that either

- (i) d is even, or
- (ii) $d = 2k + 1$ is odd, and either $\chi(\Delta) = 2$ or $\beta_k \leq 2\beta_{k-1} + 2\sum_{i=0}^{k-3} \beta_i$.

Then $f_k(\Delta) \leq f_k(C_d(n))$ for $1 \leq k \leq d-1$.

This upper bound theorem applies when the homology manifold is Eulerian (irrespective of dimension); in particular, it applies to all simplicial polytopes and spheres. By the geometric operation of “pulling vertices” (Section 17.2), one can extend this to all convex polytopes.

THEOREM 18.3.3

If P is any convex d -polytope with n vertices, then $f(P) \leq f(C_d(n))$.

The given lower and upper bounds are best possible within the class of simplicial polytope boundaries. The lower bound is attained by the class of stacked polytopes

(Sections 17.4.2 and 20.2). To make the upper bound numerically explicit, we give the formula for the f -vector of a cyclic polytope.

THEOREM 18.3.4

For $d \geq 2$ and $0 \leq k \leq d-1$, the number of k -faces of the cyclic polytope $C_d(n)$ with n vertices is

$$f_k(C_d(n)) = \frac{n - \delta(n - k - 2)}{n - k - 1} \sum_{j=0}^{\lfloor d/2 \rfloor} \binom{n-1-j}{k+1-j} \binom{n-k-1}{2j-k-1+\delta},$$

where $\delta = d - 2\lfloor d/2 \rfloor$.

In particular,

$$f_{d-1}(C_d(n)) = \binom{n - \lceil \frac{d}{2} \rceil}{\lfloor \frac{d}{2} \rfloor} + \binom{n - \lceil \frac{d+1}{2} \rceil}{\lfloor \frac{d-1}{2} \rfloor},$$

which shows that for fixed d the number of facets is $O(n^{\lfloor d/2 \rfloor})$.

POLYTOPES AND SPHERES

For boundaries of simplicial d -polytopes and, more generally, for Eulerian pseudomanifolds, we have the following basic relations.

THEOREM 18.3.5 Dehn-Sommerville Equations

For d -dimensional Eulerian pseudomanifolds,

$$h_i = h_{d-i} \quad \text{for all } 0 \leq i \leq d.$$

These equations give a complete description of the linear span of all f -vectors of d -polytopes (equivalently, $(d-1)$ -spheres). (The affine span is defined by including the relation $h_0 = 1$.)

One consequence of the Dehn-Sommerville equations is the following relation between the h -vector of a triangulated ball K and the g -vector of its boundary ∂K .

THEOREM 18.3.6

For a triangulated d -ball K and its boundary $(d-1)$ -sphere ∂K ,

$$g_i(\partial K) = h_i(K) - h_{d+1-i}(K) \quad \text{for } i \geq 1.$$

A complete characterization of the f -vectors of simplicial (and, by duality, simple) convex polytopes is given in terms of the h -vector and g -vector.

THEOREM 18.3.7 g -Theorem

A nonnegative integer vector $h = (h_0, \dots, h_d)$ is the h -vector of a simplicial convex d -polytope if and only if

- (i) $h_i = h_{d-i}$, and
- (ii) $(g_0, \dots, g_{\lfloor d/2 \rfloor})$ is an M -sequence.

One consequence of (ii) is that $g_i \geq 0$. For centrally symmetric polytopes, we get a better lower bound.

THEOREM 18.3.8

For centrally symmetric simplicial d -polytopes,

$$g_i = h_i - h_{i-1} \geq \binom{d}{i} - \binom{d}{i-1} \quad \text{for } i \leq \lfloor d/2 \rfloor.$$

The following arithmetic property of the numbers of k -faces of all simplicial d -polytopes is a consequence of the g -theorem.

THEOREM 18.3.9

Given $0 \leq k < d$ there exist positive integers $G(k, d)$ and $N(k, d)$ such that

- (i) $G(k, d)$ divides $f_k(P)$ for every simplicial d -polytope P , and*
- (ii) if $G(k, d)$ divides n and $n > N(k, d)$, then $n = f_k(P)$ for some simplicial d -polytope P .*

COMMENTS

The Lower Bound Theorem 18.3.1 is due to Kalai and Gromov in the generality given here; see [Kal87] including the note added in proof. The $k = d - 1$ case had earlier been done by Klee and the case of polytope boundaries by Barnette. See [Kal87] for a discussion of the history of this result.

The Upper Bound Theorem 18.3.2 is due to Novik [Nov98]. The case of polytopes (Theorem 18.3.3) was first proved by McMullen (see [MS71]), and extended to spheres by Stanley (see [Sta96]). The computation of the f -vector of the cyclic polytope can be found in [Grü67, Sections 4.7.3 and 9.6.1] or [MS71].

The Dehn-Sommerville equations for polytopes are classical; proofs can be found in [Grü67, Sta86, Zie95]. The extension to Eulerian pseudomanifolds is due to Klee [Kle64]; an equivariant version appears in [Bar92]. The D-S equations imply an upper bound on the average number of j -faces contained in a k -face of a simple polytope (roughly, the number of j -faces of a k -dimensional cube) due to Nikulin. This has been useful in the theory of hyperbolic reflection groups. See [Nik87, Theorem C] for references and ramifications; see also Theorem 18.5.16, which is a similar result for arrangements and zonotopes.

The g -theorem was conjectured by McMullen and proved by Billera, Lee, and Stanley [BL81, Sta80]. More recently, another proof of the necessity of these conditions was given by McMullen [McM93]. It is not known whether the second condition of Theorem 18.3.7 holds for general triangulated spheres. The g -theorem has a convenient reformulation as a one-to-one correspondence (via matrix multiplication) between f -vectors of simplicial polytopes and M -sequences, see [Bjö87, Zie95]. Theorem 18.3.8 was proved by Stanley [Sta87a], for another proof see [Nov99]. Theorem 18.3.9 is from Björner and Linusson [BL99], where also an explicit expression for the modulus $G(k, d)$ is given.

The question of characterizing f -vectors for compact manifolds more general than spheres is at the present far beyond our reach. However, much interesting

work has been done on the more restrictive question of minimizing the number of vertices of triangulations for given manifolds, see e.g. [Küh90, Küh95, BL00, Lu02]. This is of interest for efficient presentations of manifolds to computers.

The study of f -vectors of unbounded polyhedra can be approached by studying the f -vectors of **polytope pairs** (P, F) , where P is a polytope and F is a maximal face of P . See [BL93] for a summary of such results.

18.4 CELL COMPLEXES

GLOSSARY

Convex polytopes and *faces* of such are defined in [Chapter 16](#).

A **polyhedral complex** Γ is a finite collection of convex polytopes in $\mathbb{R}^n$ such that (i) if $\pi \in \Gamma$ and σ is a face of π , then $\sigma \in \Gamma$; and (ii) if $\pi, \sigma \in \Gamma$ and $\pi \cap \sigma \neq \emptyset$, then $\pi \cap \sigma$ is a face of both. The **space** of Γ is $\|\Gamma\| = \bigcup_{\pi \in \Gamma} \pi$, a subspace of $\mathbb{R}^n$. Examples of polyhedral complexes are given by **boundary complexes** ∂P of convex polytopes P (i.e., the collection of all proper faces). A geometric simplicial complex (defined in Section 18.1) is a polyhedral complex all of whose cells are simplices. A **cubical complex** is a polyhedral complex all of whose cells are (combinatorially isomorphic to) cubes.

A **regular cell complex** Γ is a family of closed balls (homeomorphs of $\{x \in \mathbb{R}^j \mid |x| \leq 1\}$) in a Hausdorff space $\|\Gamma\|$ such that (i) the interiors of the balls partition $\|\Gamma\|$ and (ii) the boundary of each ball in Γ is a union of other balls in Γ . The members of Γ are called (closed) **cells** or **faces**. The **dimension** of a cell is its topological dimension and $\dim \Gamma = \max_{\sigma \in \Gamma} \dim \sigma$.

A regular cell complex has the **intersection property** if, whenever the intersection of two cells is nonempty, then this intersection is also a cell in the complex. Polyhedral complexes are examples of regular cell complexes with the intersection property. Regular cell complexes with the intersection property can be reconstructed up to homeomorphism from the corresponding “abstract” complex consisting of the family of vertex sets of its cells.

For a regular cell complex Γ , let f_i be the number of i -dimensional cells, and let $\beta_i = \dim_{\mathbb{Q}} \tilde{H}_i(\|\Gamma\|, \mathbb{Q})$. The latter denotes i -dimensional reduced singular homology with rational coefficients of the space $\|\Gamma\|$; see [Mun84, Spa66] for explanations of this concept. Then we have the **f -vector** $f = (f_0, f_1, \dots)$ and the **Betti sequence** $\beta = (\beta_0, \beta_1, \dots)$ of Γ . These definitions generalize those previously given in the simplicial case.

BASIC f -VECTOR RELATIONS

Among the classes of complexes

- simplicial complexes
- polyhedral complexes

- regular cell complexes with the intersection property
- regular cell complexes

each is a proper subclass of its successor. Thus one may wonder how many of the relations for f -vectors of simplicial complexes given in Sections 18.1–18.3 can be extended to these broader classes of complexes. Also, what new phenomena (not visible in the simplicial case) arise? Some answers are given in this section and the following one, but current knowledge is quite fragmentary. We begin here with the most general relations.

THEOREM 18.4.1

$(f_0, \dots, f_d)$ is the f -vector of a d -dimensional regular cell complex if and only if $f_d \geq 1$ and $f_i \geq 2$ for all $0 \leq i < d$.

THEOREM 18.4.2

f is the f -vector of a regular cell complex with the intersection property if and only if f is a K -sequence.

Let $\beta = (\beta_0, \beta_1, \dots) \in \mathbb{N}^{(\infty)}$ be fixed, and for every sequence $f = (f_0, f_1, \dots)$ let

$$\chi_{k-1} = \sum_{j \geq k} (-1)^{j-k} (f_j - \beta_j) \quad \text{for } k \geq 0.$$

THEOREM 18.4.3

$(f_0, \dots, f_d)$ is the f -vector of a d -dimensional regular cell complex with Betti sequence β if and only if $\chi_{-1} = 1$ and $\chi_k \geq 1$ for $0 \leq k < d$.

THEOREM 18.4.4

For $f \in \mathbb{N}^{(\infty)}$ the following are equivalent:

- f is the f -vector of a regular cell complex with the intersection property and with Betti sequence β ;
- $\chi_{-1} = 1$ and $\partial_{k+1}(\chi_k + \beta_k) \leq \chi_{k-1}$ for all $k \geq 1$.

These results show that the f -vectors of regular cell complexes (with or without Betti number constraints) are considerably more general than the f -vectors of simplicial complexes, but that the two classes of f -vectors agree in the presence of the intersection property.

COMMENTS

Regular cell complexes are known as **regular CW complexes** in the topological literature [LW69]. The nonregular CW complexes offer an even more general class of cell complexes [LW69, Mun84, Spa66], but there is very little one can say about f -vectors in that generality. See [BLS⁺93, Section 4.7] for a detailed discussion of regular cell complexes from a combinatorial point of view.

For the results of this section see [BK88, BK91, BK89]. A characterization of f -vectors of (cubical) subcomplexes of a cube can be found in [Lin71], and of regular cell decompositions of spheres in [Bay88].

18.5 GENERAL POLYTOPES AND SPHERES

GLOSSARY

A **flag** of faces in a (polyhedral) $(d-1)$ -complex Δ is a chain $F_1 \subsetneq F_2 \subsetneq \cdots \subsetneq F_k$ of faces F_i in Δ . It is an ***S*-flag** if

$$S = \{\dim F_1, \dots, \dim F_k\} \subseteq \{0, 1, \dots, d-1\}.$$

Let $f_S = f_S(\Delta)$ denote the number of S -flags in Δ . The function $S \mapsto f_S$, $S \subseteq \{0, 1, \dots, d-1\}$, is called the **flag *f*-vector** of Δ . If

$$h_S = \sum_{T \subseteq S} (-1)^{|S|-|T|} f_T,$$

then the function $S \mapsto h_S$, $S \subseteq \{0, 1, \dots, d-1\}$, is called the **flag *h*-vector**.

For $S \subseteq \{0, \dots, d-1\}$ and noncommuting symbols ***a*** and ***b***, let $u_S = u_0 u_1 \cdots u_{d-1}$ be the ***ab*-word** defined by $u_i = \mathbf{a}$ if $i \notin S$ and $u_i = \mathbf{b}$ otherwise. When Δ is spherical (or, more generally, Eulerian), then the ***ab*-polynomial** $\sum h_S u_S$ is also a polynomial in $\mathbf{c} = \mathbf{a} + \mathbf{b}$ and $\mathbf{d} = \mathbf{ab} + \mathbf{ba}$. (Note that the degree of $\mathbf{c}$ is 1 and the degree of $\mathbf{d}$ is 2.) The resulting ***cd*-polynomial**

$$\sum h_S u_S = \sum \phi_w w,$$

where the right-hand sum is over all ***cd*-words** w of degree d , is called the ***cd*-index** $\Phi(\Delta)$ of Δ . For 2-, 3-, and 4-polytopes, the ***cd*-index** is $\mathbf{c}^2 + (f_0 - 2)\mathbf{d}$, $\mathbf{c}^3 + (f_0 - 2)\mathbf{dc} + (f_2 - 2)\mathbf{cd}$, and $\mathbf{c}^4 + (f_0 - 2)\mathbf{dc}^2 + (f_1 - f_0)\mathbf{cdc} + (f_3 - 2)\mathbf{c}^2\mathbf{d} + (f_{02} - 2f_2 - 2f_0 + 4)\mathbf{d}^2$, respectively.

For *any* convex d -polytope P , we define the **toric *h*-vector** and **toric *g*-vector** recursively by $h(P, x) = \sum_{i=0}^d h_i x^{d-i}$ and $g(P, x) = \sum_{i=0}^{\lfloor d/2 \rfloor} g_i x^i$, where $g_i = h_i - h_{i-1}$ and the following relations hold:

- (i) $g(\emptyset, x) = h(\emptyset, x) = 1$; and
- (ii) $h(P, x) = \sum_{G \text{ face of } P, G \neq P} g(G, x)(x-1)^{d-1-\dim G}$.

(Compare to Section 17.4.1, where this toric h -vector is defined for any polyhedral complex. In the notation given there, we have defined h and g for the complex ∂P .) When P is simplicial, this definition coincides with that of the usual h -vector, as defined in Section 18.2. For 2-, 3-, and 4-polytopes, the g -polynomial is $1 + (f_0 - 3)x$, $1 + (f_0 - 4)x$, and $1 + (f_0 - 5)x + (10 - 3f_0 - 3f_3 + f_{03})x^2$, respectively.

A **rational polytope** is one whose vertices all have rational coordinates. Equivalently, all maximal faces are determined by linear forms with rational coefficients.

A **cubical polytope** is one that has a cubical boundary complex. For any cubical $(d-1)$ -complex with f -vector $(f_0, \dots, f_{d-1})$, define the **cubical *h*-vector** $h^c = (h_0^c, \dots, h_d^c)$ by

$$h_i^c = (-1)^i 2^{d-1} + \sum_{j=1}^i (-1)^{i-j} 2^{j-1} f_{j-1} \sum_{k=0}^{i-j} \binom{d-j}{k} \quad \text{for } i = 0, \dots, d.$$

The **cubical *g*-vector** $g^c = (g_0^c, \dots, g_{\lfloor d/2 \rfloor}^c)$ is defined by $g_0^c = h_0^c = 2^{d-1}$ and $g_i^c = h_i^c - h_{i-1}^c$ for $i \geq 1$.

An **Eulerian polyhedral complex** is one whose first barycentric subdivision is an Eulerian pseudomanifold. Examples are boundary complexes of polytopes and **spherical** polyhedral complexes, i.e., those whose underlying space is homeomorphic to a sphere.

A (central) **hyperplane arrangement** is a collection $\mathcal{H}$ of n linear hyperplanes in $\mathbb{R}^d$, given by normal vectors $x_1, \dots, x_n$ (see [Section 6.1.3](#)). The arrangement is **essential** if the normals x_i span $\mathbb{R}^d$. The associated **zonotope** is the Minkowski sum of the n line segments $[-x_i, x_i]$, i.e., $Z = \{\sum \lambda_i x_i \mid -1 \leq \lambda_i \leq 1\}$ (see [Section 16.1.4](#)).

LINEAR RELATIONS

We give the linear equalities on the invariants defined above that are known to hold for all boundary complexes of polytopes and, more generally, for all Eulerian polyhedral complexes.

THEOREM 18.5.1

For $(d-1)$ -dimensional Eulerian polyhedral complexes, the following relations always hold for the flag h , the toric h , and the flag f :

- (i) $h_S = h_{\{0, \dots, d-1\} \setminus S}$ for all $S \subseteq \{0, \dots, d-1\}$;
- (ii) $h_i = h_{d-i}$ for $0 \leq i \leq d$; and
- (iii) $\sum_{j=i+1}^{k-1} (-1)^{j-i-1} f_{S \cup \{j\}} = (1 - (-1)^{k-i-1}) f_S$ whenever $i, k \in S \cup \{-1, d\}$ with $i \leq k-2$ and $S \cap \{i+1, \dots, k-1\} = \emptyset$.

It is known that the relations in Theorem 18.5.1(iii), the **generalized Dehn-Sommerville equations**, completely describe the linear span of all flag f -vectors of Eulerian complexes, and so they imply those in (i). Since the toric h is known to be a linear function of the flag f , they imply those in (ii) as well. The linear span of flag f -vectors has dimension e_d , where e_d is the d th Fibonacci number (defined by the recurrence $e_d = e_{d-1} + e_{d-2}$, $e_0 = e_1 = 1$). There are e_d **cd**-words of degree d . Furthermore, the coefficients ϕ_w of the **cd**-index, considered as linear expressions in the f_S , form a linear basis for the span of flag f -vectors of d -polytopes. The affine span of all flag f -vectors is defined by including the relation $f_\emptyset = 1$.

For cubical polytopes and spheres, the cubical h -vector satisfies the analogue of the Dehn-Sommerville equations.

THEOREM 18.5.2

For cubical d -polytopes and cubical $(d-1)$ -spheres,

$$h_i^c = h_{d-i}^c \quad \text{for all } 0 \leq i \leq d.$$

These give all linear relations satisfied by f -vectors of cubical polytopes and spheres. The cubical h -vector satisfies, as well, the equations of Theorem 18.3.6, linking the h of a cubical ball to the g of its boundary sphere.

LINEAR INEQUALITIES

Some linear inequalities that hold for flag f -vectors of all polytope boundaries are given in this section. The list is not thought to be complete, although there are no conjectures for what the complete set might be.

For a Cohen-Macaulay polyhedral complex, i.e., one whose first barycentric subdivision is a Cohen-Macaulay simplicial complex, the flag h is always nonnegative.

THEOREM 18.5.3

For a Cohen-Macaulay polyhedral $(d-1)$ -complex Γ , we have $h_S(\Gamma) \geq 0$ for all $S \subseteq \{0, \dots, d-1\}$.

For general convex polytopes, we also have nonnegativity of the **cd**-index. In fact, the **cd**-index of any d -polytope is minimized termwise by the **cd**-index of the d -simplex $\Delta^{(d)}$.

THEOREM 18.5.4

For a convex d -polytope P ,

$$\phi_w(P) \geq \phi_w(\Delta^{(d)}) \geq 0$$

for all **cd**-words w of degree d .

There are also relations between the **cd**-coefficients ϕ_w for any polytope.

THEOREM 18.5.5

For any d -polytope P

$$\phi_{u\mathbf{d}v}(P) \geq \phi_{uc^2v}(P),$$

for any **cd**-words u and v with $\deg u + \deg v = d - 2$.

For *rational* convex polytopes, it is known, further, that the toric h is unimodal.

THEOREM 18.5.6

For a rational¹ convex d -polytope, $g_i \geq 0$ for $i \leq \lfloor d/2 \rfloor$.

Related to this is the following *nonlinear* inequality holding between the g -vectors of a polytope P and any of its faces F . We denote by P/F the **link** of F in P , i.e., the polytope whose lattice of faces is (isomorphic to) the interval $[F, P]$ in the face lattice of P .

THEOREM 18.5.7

For a rational¹ polytope P and any face F , we have the polynomial inequality

$$g(P, t) - g(F, t)g(P/F, t) \geq 0,$$

i.e., all coefficients of this polynomial are nonnegative.

We have a similar relation between the **cd**-index of a polytope and that of any face.

THEOREM 18.5.8

For any polytope P and any face F , we have the polynomial inequalities

$$\Phi(P) \geq \begin{cases} \mathbf{c} \cdot \Phi(F) \cdot \Phi(P/F) \\ \Phi(F) \cdot \mathbf{c} \cdot \Phi(P/F) \\ \Phi(F) \cdot \Phi(P/F) \cdot \mathbf{c} \end{cases}$$

¹Note (added in January 2003): As a consequence of recent work by K. Karu (Hard Lefschetz theorem for nonrational polytopes, preprint, December 2002, arXiv:math AG/0112087), it appears that the word “rational” can be removed in Theorems 18.5.6 and 18.5.7.

where $\Phi(P)$, $\Phi(F)$, and $\Phi(P/F)$ are the **cd**-indices of P , F , and P/F , respectively.

As with f -vectors of polytopes, their flag f -vectors, flag h -vectors and **cd**-indices satisfy the upper bound theorem.

THEOREM 18.5.9

If P is a d -dimensional polytope with n vertices, then for any S ,

$$\begin{aligned} f_S(P) &\leq f_S(C_d(n)) \\ h_S(P) &\leq h_S(C_d(n)) \end{aligned}$$

and termwise as polynomials

$$\Phi(P) \leq \Phi(C_d(n))$$

where $C_d(n)$ is the cyclic d -polytope with n vertices.

Finally, we have the following lower bounds for the number of vertices of polytopes with no triangular faces (this includes the class of cubical polytopes), and for the combined numbers of vertices and facets of centrally symmetric polytopes.

THEOREM 18.5.10

A d -polytope with no triangular 2-face has at least 2^d vertices.

THEOREM 18.5.11

There exists a constant $c > 0$ such that

$$\log f_0 \cdot \log f_{d-1} > cd,$$

for any centrally symmetric d -polytope.

HYPERPLANE ARRANGEMENTS AND ZONOTOPES

An essential hyperplane arrangement $\mathcal{H}$ defines a decomposition of $\mathbb{R}^d$ into polyhedral cones (as in Section 6.1.3). This decomposition $\Gamma_{\mathcal{H}}$, a regular cell complex if intersected with the unit sphere, has a flag f -vector dual to that of its associated zonotope Z , in the sense that $f_S(\Gamma_{\mathcal{H}}) = f_{d-S}(Z)$, where $S = \{i_1, \dots, i_k\} \subseteq \{1, \dots, d\}$ and $d - S = \{d - i_k, \dots, d - i_1\}$.

THEOREM 18.5.12

The flag f -vector of an arrangement (or zonotope) depends only on the matroid (linear dependency structure) of the underlying point configuration $\{x_1, \dots, x_n\}$.

Although a fairly special subclass of polytopes, the zonotopes nonetheless are varied enough to carry all the linear information carried by flag numbers of general polytopes.

THEOREM 18.5.13

The flag f -vectors of zonotopes (and thus of hyperplane arrangements) satisfy the generalized Dehn-Sommerville equations, and there are no other linear relations not implied by these.

When it comes to linear *inequalities*, however, a difference between zonotopes and general polytopes emerges. As with general convex polytopes, we have non-negativity of the **cd**-index for zonotopes. However, the **cd**-index of any d -zonotope is minimized termwise by the **cd**-index of the d -cube $C^{(d)}$.

THEOREM 18.5.14

For a convex d -zonotope Z , $\phi_w(Z) \geq \phi_w(C^{(d)}) \geq 0$ for all **cd**-words w of degree d . Further, if the word w has k **d**'s, then 2^k divides $\phi_w(Z)$.

There is also a strengthening of Theorem 18.5.5 for zonotopes.

THEOREM 18.5.15

For any d -zonotope Z

$$\phi_{udv}(Z) - \phi_{uc^2v}(Z) \geq \phi_{udv}(C^{(d)}) - \phi_{uc^2v}(C^{(d)})$$

for any **cd**-words u and v with $\deg u + \deg v = d - 2$.

The following result has the most direct interpretation when it is stated for arrangements, where it bounds the average number of $\{i_1, \dots, i_k\}$ -flags in an i_k -face by the number of $\{i_1 - 1, \dots, i_k - 1\}$ -flags in an $(i_k - 1)$ -cube.

THEOREM 18.5.16

For a hyperplane arrangement $\mathcal{H}$ in $\mathbb{R}^d$ and $S = \{i_1, \dots, i_k\} \subseteq \{1, \dots, d\}$ with $k \geq 2$,

$$\frac{f_S(\Gamma_{\mathcal{H}})}{f_{i_k}(\Gamma_{\mathcal{H}})} < \binom{i_k - 1}{i_1 - 1, i_2 - i_1, \dots, i_k - i_{k-1}} 2^{i_k - i_1}.$$

There is a straightforward reformulation of Theorem 18.5.16 for zonotopes that is easily seen not to be valid for all polytopes.

GENERAL 3- AND 4-POLYTOPES

We describe here the situation for flag f -vectors of 3- and 4-polytopes. The equations in Theorem 18.5.1(iii) reduce consideration to (f_0, f_2) when $d = 3$ and to (f_0, f_1, f_2, f_0_2) when $d = 4$.

THEOREM 18.5.17

For 3-polytopes, the following is known about the vector (f_0, f_2) .

- (i) An integer vector (f_0, f_2) is the f -vector of a 3-polytope if and only if $f_0 \leq 2f_2 - 4$ and $f_2 \leq 2f_0 - 4$.
- (ii) An integer vector (f_0, f_2) is the f -vector of a cubical 3-polytope if and only if $f_2 = f_0 - 2$, $f_0 \geq 8$, and $f_0 \neq 9$.
- (iii) If $(f_0, f_2) = (f_0(Z), f_2(Z))$ for a 3-zonotope Z , then f_0 and f_1 are both even integers, $f_0 \leq 2f_2 - 4$, and $f_2 \leq f_0 - 2$.

For 4-polytopes, much less is known.

THEOREM 18.5.18

Flag f -vectors (f_0, f_1, f_2, f_0_2) of 4-polytopes satisfy the following inequalities.

- (i) $f_{02} \geq 3f_2$
- (ii) $f_{02} \geq 3f_1$
- (iii) $f_{02} + f_1 + 10 \geq 3f_2 + 4f_0$
- (iv) $6f_1 \geq 6f_0 + f_{02}$
- (v) $f_0 \geq 5$
- (vi) $f_0 + f_2 \geq f_1 + 5$
- (vii) $2(f_{02} - 3f_2) \leq \binom{f_0}{2}$
- (viii) $2(f_{02} - 3f_1) \leq \binom{f_2 - f_1 + f_0}{2}$
- (ix) $f_{02} - 4f_2 + 3f_1 - 2f_0 \leq \binom{f_0}{2}$
- (x) $f_{02} + f_2 - 2f_1 - 2f_0 \leq \binom{f_2 - f_1 + f_0}{2}$.

It is not known, for example, whether (i)–(vi) give all linear inequalities holding for flag f -vectors of 4-polytopes.

COMMENTS

It is thought that the best route to an eventual characterization of f -vectors of general polytopes lies in an understanding of their flag f -vectors. The latter inherit many of the algebraic properties of f -vectors of simplicial polytopes that led to their characterization, while having a rich theory of their own.

The relations in Theorem 18.5.1 hold more generally for the case of enumeration of chains in Eulerian posets; see the article by Stanley in [BMSW94]. The relations in Theorem 18.5.1(iii) are proved in [BB85]. An expression for the toric h in terms of the flag f can be found in the article by Bayer in [BMSW94]. The article by Kalai in the same volume contains an extensive discussion of g -vectors for both simplicial and general polytopes. Expressions for the (toric) g and h -vectors in terms of the flag h -vector or the **cd**-index can be found in [BE00]. The form of the cubical Dehn-Sommerville equations given in Theorem 18.5.2 appeared in [Adi96].

Theorem 18.5.3 can be found in [Sta96, Theorem III.4.4] (where h_S is denoted $\beta(S)$). The nonnegativity of the **cd**-index for polytopes in Theorem 18.5.4 holds as well for certain shellable spheres and is due to Stanley (see [Sta96, Section III.4]). That the **cd**-index is minimized over polytopes by simplices is shown in [BE00], while Theorem 18.5.5 is proved in [Ehr01]. Theorem 18.5.6 appears in [Sta87b]. Relationships between these classes of inequalities and those that can be derived from them are discussed in [Ste01b]. Nonnegativity of *certain* **cd**-coefficients for all spheres is shown in [Bay01] and [Rea02], and for odd-dimensional simplicial manifolds in [Nov00].

The problem of determining all linear inequalities for flag f -vectors has been considered for classes of partially ordered sets more general than the face posets of polytopes and spheres. In [BH00a], the (Catalan many) extreme rays are determined for the closed convex cone determined by flag f -vectors of all graded posets (posets with a rank function and having minimum and maximum elements). A nice description of the finite minimum set of inequalities is lacking, however. In [BH01], a partial family of extreme rays is determined for the subcone determined by all Eulerian posets. See [BH00b] for more such results.

There is a notion of convolution product of flag f numbers, originally due to Kalai [Kal88], that can be used to produce new linear inequalities from given ones;

see, for example, [BL93, Section 3.10]. The algebraic properties of this product have been developed in [BL00]; this has led to a deeper understanding of the combinatorial and algebraic properties of the **cd**-index via duality of Hopf algebras (see [BHvW03]).

Theorem 18.5.7, due to Braden and MacPherson [BM99], gives a connection between the g -vector of a polytope P and that of one of its faces. The analogous Theorem 18.5.8 for **cd**-indices can be found in [BE00] (as can the upper bound theorem, 18.5.9). These are examples of “monotonicity theorems” related to face numbers. For similar theorems relating h -vectors of subcomplexes and subdivisions of a simplicial complex Δ , see Sections III.9–10 of [Sta96] and the references given there.

Theorems 18.5.10 and 18.5.11 are due to Blind and Blind [BB90] and Figiel, Lindenstrauss, and Milman [FLM77], respectively.

For the fact that the flag f -vector of a zonotope or arrangement (or, more generally, of an oriented matroid) depends only on the underlying matroid, see [BLS⁺93, Cor. 4.6.3]. For expressions giving the **cd**-index of a zonotope in terms of the flag h -vector of its underlying geometric lattice, see [BER97, Corollary 3.2] and [BHvW03, Proposition 3.5]. That the only linear relations satisfied by zonotopes are the generalized Dehn-Sommerville equations of Theorem 18.5.1(iii), as well as the divisibility property in Theorem 18.5.14, is proved in [BER98]. The bounds on the **cd**-indices of zonotopes in Theorem 18.5.14 are proved in [BER97]; the bounds in Theorem 18.5.15 can be found in [Ehr01]. Theorem 18.5.16 is due to Varchenko for the case $k = 2$ (see [BLS⁺93, Proposition 4.6.9]) and to Liu. The stronger version given here is due to Stenson; in fact, [Ste02, Theorem 9] gives a stronger inequality (see also [Ste01a]).

Theorem 18.5.17(i) can be found in [Grü67, Section 10.3]; 18.5.17(ii) appears in dual form (for 4-valent 3-polytopes) in [Bar83]; 18.5.17(iii) can be derived using the methods of [Grü67, Section 18.2] (see also [BER98]). Theorem 18.5.18 can be found in [Bay87]; see also [HZ00]. An interesting general discussion of f -vectors of 4-polytopes (ordinary and flag) and an up-to-date survey of this topic is given by Ziegler [Zie02]. In particular, a good case is made there that the situation for f -vectors of 4-polytopes is much more complicated than that for polytopes in dimension 3. One reason for this is that *neighborly cubical* d -polytopes begin to exist for $d = 4$: for any $n \geq d \geq 2r + 2$, there is a cubical convex d -polytope whose r -skeleton is combinatorially equivalent to that of the n -dimensional cube [JZ00] (see also [BBC97], where spheres having this property are constructed). In particular, for any $n \geq 4$, there is a cubical 4-polytope with the graph of the n -cube. These polytopes show that the ratio f_3/f_0 is not bounded over cubical 4-polytopes.

18.6 OPEN PROBLEMS

PROBLEM 18.6.1

Characterize the f -vectors of triangulations of the $(d-1)$ -sphere.

[It has been conjectured that the conditions of the g -theorem provide the answer.]

PROBLEM 18.6.2

Characterize the f -vectors of triangulations of the d -ball.

PROBLEM 18.6.3

Characterize the f -vectors of triangulations of the d -torus.

[It is known that $f(2\text{-torus}) = \{(n, 3n, 2n) \mid n \geq 7\}$, but the question is open for $d \geq 3$.]

PROBLEM 18.6.4

Characterize the f -vectors of d -polytopes.

[The answer is known for $d \leq 3$ (Theorem 18.5.17(i)), but for $d \geq 4$ there is not even a conjectured answer.]

PROBLEM 18.6.5 *I. Bárány*

Does there exist a constant $c_d > 0$ such that $f_i \geq c_d \cdot \min\{f_0, f_{d-1}\}$ for all d -polytopes and all i ? Will $c_d = 1$ do?

PROBLEM 18.6.6

Characterize the f -vectors of centrally symmetric d -polytopes.

[The question is open in the simplicial as well as in the general case. Even an upper bound conjecture in the simplicial and centrally symmetric case is missing.]

PROBLEM 18.6.7 *Conjecture of G. Kalai*

The total number of faces (counting P but not $\emptyset$) of a centrally symmetric convex d -polytope P is $\geq 3^d$.

[Verified in the simplicial case as a consequence of Theorem 18.3.8.]

PROBLEM 18.6.8

*The **clique complex** of a graph is the collection of vertex sets of all its cliques (complete induced subgraphs). Characterize the f -vectors of clique complexes.*

PROBLEM 18.6.9 *J. Eckhoff and G. Kalai*

Is the f -vector of any $(r-1)$ -dimensional clique complex the f -vector of some r -colorable complex?

PROBLEM 18.6.10 *Conjecture of Charney and Davis [Sta96, p. 100]*

Let $(g_0, \dots, g_k)$ be the g -vector of a clique complex homeomorphic to the sphere S^{2k-1} . Then $g_k - g_{k-1} + \dots + (-1)^k g_0 \geq 0$.

PROBLEM 18.6.11 *Conjecture of Stanley [Sta96, p. 102]*

*Every coefficient ϕ_w of the **cd-index** of a spherical regular cell complex is nonnegative.*

[This conjecture, if true, gives the most general possible linear inequalities for flag f -vectors of spherical regular cell complexes (i.e., regular cell complexes homeomorphic to the sphere).]

[For simplicial spheres, the **cd**-coefficients satisfy the conclusion of Theorem 18.5.4.]

PROBLEM 18.6.12 *Conjecture of Ehrenborg [Ehr01, Conj. 5.1]*

*For d -polytopes P (and more generally for simplicial $(d-1)$ -spheres) the **cd-index***

satisfies

$$\phi_{udv}(P) - \phi_{uc^2v}(P) \geq \phi_{udv}(\Delta^{(d)}) - \phi_{uc^2v}(\Delta^{(d)}),$$

where $\deg u + \deg v = d - 2$, and $\Delta^{(d)}$ is the d -simplex.

PROBLEM 18.6.13 Adin [Adi96]

The “generalized lower bound conjecture” for cubical d -polytopes and $(d-1)$ -spheres: $g_i^c \geq 0$ for $i \leq \lfloor d/2 \rfloor$.

[This has been shown to be the best possible set of linear inequalities for cubical $(d-1)$ -spheres [BBC97]. The case $i = 1$ is implied by Theorem 18.5.10.]

More generally, characterize the f -vectors of cubical polytopes.

PROBLEM 18.6.14

Characterize the flag f -vectors of polytopes and of zonotopes. In particular, determine a complete set of linear inequalities holding for flag f -vectors of polytopes and of zonotopes.

PROBLEM 18.6.15

Characterize (toric) h -vectors of general polytopes.

PROBLEM 18.6.16

Characterize flag f -vectors of colored complexes (here f_S is the number of simplices with color set S); of pure colored complexes; of graded posets [all linear inequalities are known here [BH00a]]; of Eulerian posets [see [BH01]]; of Eulerian lattices.

19 SYMMETRY OF POLYTOPES AND POLYHEDRA

Egon Schulte

INTRODUCTION

Symmetry of geometric figures is among the most frequently recurring themes in science. The present chapter discusses symmetry of discrete geometric structures, namely of polytopes, polyhedra, and related polytope-like figures. These structures have an outstanding history of study unmatched by almost any other geometric object. The most prominent symmetric figures, the regular solids, occur from very early times and are attributed to Plato (427–347 B.C.E.). Since then, many changes in point of view have occurred about these figures and their symmetry. With the arrival of group theory in the 19th century, many of the early approaches were consolidated and the foundations were laid for a more rigorous development of the theory. In this vein, Schläfli (1814–1895) extended the concept of regular polytopes and tessellations to higher dimensional spaces and explored their symmetry groups as reflection groups.

Today we owe much of our present understanding of symmetry in geometric figures (in a broad sense) to the influential work of Coxeter, which provided a unified approach to regularity of figures based on a powerful interplay of geometry and algebra [Cox73]. Coxeter's work also greatly influenced modern developments in this area, which received a further impetus from work by Grünbaum and Danzer [Grü77a, DS82]. In the past 25 years, the study of regular figures has been extended in several directions that are all centered around an abstract combinatorial polytope theory and a combinatorial notion of regularity [MS02].

History teaches us that the subject has shown an enormous potential for revival. One explanation for this is the appearance of polyhedral structures in many contexts that have little apparent relation to regularity, such as the occurrence of many of them in nature as crystals [Fej64, Sen95, Wel77].

19.1 REGULAR CONVEX POLYTOPES AND REGULAR TESSELLATIONS IN $\mathbb{E}^d$

Perhaps the most important (but certainly the most investigated) symmetric polytopes are the regular convex polytopes in Euclidean spaces. See [Grü67] and [Zie95] for general properties of convex polytopes, or [Chapter 16](#) in this Handbook. The most comprehensive text on regular convex polytopes and regular tessellations is [Cox73]; many combinatorial aspects are also discussed in [MS02].

GLOSSARY

Convex d -polytope: The intersection P of finitely many closed halfspaces in a

Euclidean space, which is bounded and d -dimensional.

Face: The empty set and P itself are *improper faces* of dimension -1 and d , respectively. A *proper face* F of P is the (nonempty) intersection of P with a supporting hyperplane of P . (Recall that a hyperplane H *supports* P at F if $P \cap H = F$ and P lies in one of the closed halfspaces bounded by H .)

Vertex, edge, i -face, facet: Face of P of dimension $0, 1, i$, or $d-1$, respectively.

Vertex figure: A vertex figure of P at a vertex x is the intersection of P with a hyperplane H that strictly separates x from the other vertices of P . (If P is regular, one can take H to be the hyperplane passing through the midpoints of the edges that contain x .)

Face lattice of a polytope: The set $\mathcal{F}(P)$ of all faces of P , ordered by inclusion. As a partially ordered set, this is a ranked lattice. Also, $\mathcal{F}(P) \setminus \{P\}$ is called the *boundary complex* of P .

Flag: A maximal totally ordered subset of $\mathcal{F}(P)$.

Isomorphism of polytopes: A bijection $\varphi : \mathcal{F}(P) \mapsto \mathcal{F}(Q)$ between the face lattices of two polytopes P and Q such that φ preserves incidence in both directions; that is, $F \subseteq G$ in $\mathcal{F}(P)$ if and only if $F\varphi \subseteq G\varphi$ in $\mathcal{F}(Q)$. If such an isomorphism exists, P and Q are *isomorphic*.

Dual of a polytope: A convex d -polytope Q is the dual of P if there is a *duality* $\varphi : \mathcal{F}(P) \mapsto \mathcal{F}(Q)$; that is, a bijection reversing incidences in both directions, meaning that $F \subseteq G$ in $\mathcal{F}(P)$ if and only if $F\varphi \supseteq G\varphi$ in $\mathcal{F}(Q)$. A polytope has many duals but any two are isomorphic, justifying speaking of “the dual.” (If P is regular, one can take Q to be the convex hull of the facet centers of P , or a rescaled copy of this.)

Self-dual polytope: A polytope that is isomorphic to its dual.

Symmetry: A Euclidean isometry of the ambient space (affine hull of P) that maps P to itself.

Symmetry group of a polytope: The group $G(P)$ of all symmetries of P .

Regular polytope: A polytope whose symmetry group $G(P)$ is transitive on the flags.

Schläfli symbol: A symbol $\{p_1, \dots, p_{d-1}\}$ that encodes the local structure of a regular polytope. For each $i = 1, \dots, d-1$, if F is any $(i+1)$ -face of P , then p_i is the number of i -faces of F that contain a given $(i-2)$ -face of F .

Tessellation: A family T of convex d -polytopes in Euclidean d -space $\mathbb{E}^d$, called the *tiles* of T , such that the union of all tiles of T is $\mathbb{E}^d$, and any two distinct tiles do not have interior points in common. All tessellations are assumed to be *locally finite*, meaning that each point of $\mathbb{E}^d$ has a neighborhood meeting only finitely many tiles, and *face-to-face*, meaning that the intersection of any two tiles is a face of each (possibly the empty face); see [Chapter 3](#). The concept of a tessellation extends to other spaces including spherical space (Euclidean unit sphere) and hyperbolic space.

Face lattice of a tessellation: A *proper face* of T is a nonempty face of a tile of T . *Improper faces* of T are the empty set and the whole space $\mathbb{E}^d$. The set $\mathcal{F}(T)$ of all (proper and improper) faces is a ranked lattice called the face lattice of T . Concepts such as isomorphism and duality carry over from polytopes.

Symmetry group of a tessellation: The group $G(T)$ of all symmetries of T ; that is, of all isometries of the ambient (spherical, Euclidean, or hyperbolic) space that preserve T . Concepts such as regularity and Schläfli symbol carry over from polytopes.

Apeirogon: A tessellation of the real line with closed intervals of the same length. This can also be regarded as an infinite polygon whose edges are given by the intervals.

ENUMERATION AND CONSTRUCTION

The convex regular polytopes P in $\mathbb{E}^d$ are known for each d . If $d = 1$, P is a line segment and $|G(P)| = 2$. In all other cases, up to similarity, P can be uniquely described by its Schläfli symbol $\{p_1, \dots, p_{d-1}\}$. For convenience one writes $P = \{p_1, \dots, p_{d-1}\}$. If $d = 2$, P is a convex regular p -gon for some $p \geq 3$, and $P = \{p\}$; also, $G(P) = D_p$, the dihedral group of order $2p$.

The regular polytopes P with $d \geq 3$ are summarized in Table 19.1.1, which also includes the numbers f_0 and f_{d-1} of vertices and facets, the order of $G(P)$, and the diagram notation (Section 19.6) for the group (following [Hum90]). Here and below, p^n will be used to denote a string of n consecutive p 's. For $d = 3$ the list consists of the five Platonic solids (Figure 19.1.1). The regular d -simplex, d -cube, and d -cross-polytope occur in each dimension d . (These are line segments if $d = 1$, and triangles or squares if $d = 2$.) The dimensions 3 and 4 are exceptional in that there are 2 (respectively 3) more regular polytopes. If $d \geq 3$, the facets and vertex figures of $\{p_1, \dots, p_{d-1}\}$ are the regular $(d-1)$ -polytopes $\{p_1, \dots, p_{d-2}\}$ and $\{p_2, \dots, p_{d-1}\}$, respectively, whose Schläfli symbols, when superposed, give the original. The dual of $\{p_1, \dots, p_{d-1}\}$ is $\{p_{d-1}, \dots, p_1\}$. Self-duality occurs only for $\{3^{d-1}\}$, $\{p\}$, and $\{3, 4, 3\}$. Except for $\{3^{d-1}\}$ and $\{p\}$ with p odd, all regular polytopes are centrally symmetric.

TABLE 19.1.1 The convex regular polytopes in $\mathbb{E}^d$ ($d \geq 3$).

DIMENSION	NAME	SCHLÄFLI SYMBOL	f_0	f_{d-1}	$ G(P) $	DIAGRAM
$d \geq 3$	d -simplex	$\{3^{d-1}\}$	$d+1$	$d+1$	$(d+1)!$	A_d
	d -cross-polytope	$\{3^{d-2}, 4\}$	$2d$	2^d	$2^d d!$	B_d (or C_d)
	d -cube	$\{4, 3^{d-2}\}$	2^d	$2d$	$2^d d!$	B_d (or C_d)
$d = 3$	icosahedron	$\{3, 5\}$	12	20	120	H_3
	dodecahedron	$\{5, 3\}$	20	12	120	H_3
$d = 4$	24-cell	$\{3, 4, 3\}$	24	24	1152	F_4
	600-cell	$\{3, 3, 5\}$	120	600	14400	H_4
	120-cell	$\{5, 3, 3\}$	600	120	14400	H_4

The regular tessellations T in $\mathbb{E}^d$ are also known. If $d = 1$, T is an apeirogon and $G(T)$ is the infinite dihedral group. For $d \geq 2$ see the list in Table 19.1.2. The first $d - 1$ entries in $\{p_1, \dots, p_d\}$ give the Schläfli symbol for the (regular) tiles of T , the last $d - 1$ that for the (regular) vertex figures. (A vertex figure at a vertex x is the convex hull of the midpoints of the edges emanating from x .) The cubical

FIGURE 19.1.1
The five Platonic solids.

Tetrahedron Cube Octahedron Dodecahedron Icosahedron

tessellation occurs for each d , while for $d = 2$ and $d = 4$ there is a dual pair of exceptional tessellations.

TABLE 19.1.2 The regular tessellations in $\mathbb{E}^d$ ($d \geq 2$).

DIMENSION	SCHLÄFLI SYMBOL	TILES	VERTEX-FIGURES
$d \geq 2$	$\{4, 3^{d-2}, 4\}$	d -cubes	d -cross-polytopes
$d = 2$	$\{3, 6\}$ $\{6, 3\}$	triangles hexagons	hexagons triangles
$d = 4$	$\{3, 3, 4, 3\}$ $\{3, 4, 3, 3\}$	4-cross-polytopes 24-cells	24-cells 4-cross-polytopes

As vertices of the plane polygon $\{p\}$ we can take the points corresponding to the p th roots of unity. The d -simplex can be defined as the convex hull of the $d + 1$ points in $\mathbb{E}^{d+1}$ corresponding to the permutations of $(1, 0, \dots, 0)$. As vertices of the d -cross-polytope in $\mathbb{E}^d$ choose the $2d$ permutations of $(\pm 1, 0, \dots, 0)$, and for the d -cube take the 2^d points $(\pm 1, \dots, \pm 1)$. The midpoints of the edges of a 4-cross-polytope are the 24 vertices of a regular 24-cell. The coordinates for the remaining regular polytopes are more complicated [Cox73, pp. 52,157].

For the cubical tessellation $\{4, 3^{d-2}, 4\}$ take the vertex set to be $\mathbb{Z}^d$ (giving the square tessellation if $d = 2$). For the triangle tessellation $\{3, 6\}$ choose as vertices the integral linear combinations of two unit vectors inclined at $\pi/3$. Locating the face centers gives the vertices of the hexagonal tessellation $\{6, 3\}$. For $\{3, 3, 4, 3\}$ in $\mathbb{E}^4$ take the alternating vertices of the cubical tessellation; that is, the integral points with an even coordinate sum. Its dual $\{3, 4, 3, 3\}$ (with 24-cells as tiles) has the vertices at the centers of the tiles of $\{3, 3, 4, 3\}$.

The regular polytopes and tessellations have been with us since before recorded history, and a strong strain of mathematics since classical times has centered on them. The classical theory intersects with diverse mathematical areas such as Lie algebras and Lie groups, Tits buildings [Tit74], finite and combinatorial group theory [Bue95, Mag74], geometric and algebraic combinatorics, graphs and combinatorial designs [BCN89], singularity theory, and Riemann surfaces.

SYMMETRY GROUPS

For a convex regular d -polytope P in $\mathbb{E}^d$, pick a fixed (*base*) flag Φ , and consider the maximal simplex C (*chamber*) in the barycentric subdivision (*chamber complex*) of P whose vertices are the centers of the nonempty faces in Φ . Then

C is a fundamental region for $G(P)$ in P and $G(P)$ is generated by the reflections $R_0, \dots, R_{d-1}$ in the walls of C that contain the center of P , where R_i is the reflection in the wall opposite to the vertex of C corresponding to the i -face in Φ . If $P = \{p_1, \dots, p_{d-1}\}$, then

$$\begin{cases} R_i^2 = (R_j R_k)^2 = 1 & (0 \leq i, j, k \leq d-1, |j-k| \geq 2) \\ (R_{i-1} R_i)^{p_i} = 1 & (1 \leq i \leq d-1) \end{cases}$$

is a presentation for $G(P)$ in terms of these generators. In particular, $G(P)$ is a finite (spherical) Coxeter group with string diagram

(see [Section 19.6](#)).

If T is a regular tessellation of $\mathbb{E}^d$, pick Φ and C as before. Now $G(T)$ is generated by the $d+1$ reflections in all walls of C giving $R_0, \dots, R_d$ (as above). The presentation for $G(T)$ carries over, but now $G(T)$ is an infinite (Euclidean) Coxeter group.

19.2 REGULAR STAR-POLYTOPES

The regular star-polyhedra and star-polytopes are obtained by allowing the faces or vertex figures to be *starry* (star-like). This leads to very beautiful figures that are closely related to the regular convex polytopes. See Coxeter [Cox73] for a comprehensive account; see also McMullen and Schulte [MS02]. In defining star-polytopes, we shall combine the approach of [Cox73] and McMullen [McM68] and introduce them via the associated starry polytope-configuration.

GLOSSARY

***d*-polytope-configuration:** A finite family Π of affine subspaces, called *elements*, of Euclidean d -space $\mathbb{E}^d$, ordered by inclusion, such that the following conditions are satisfied. Π contains the empty set $\emptyset$ and $\mathbb{E}^d$ as (*improper*) elements. The dimensions of the other (*proper*) elements can take the values $0, 1, \dots, d-1$, and the affine hull of their union is $\mathbb{E}^d$. As a partially ordered set, Π is a ranked lattice. For $F, G \in \Pi$ with $F \subseteq G$ call $G/F := \{H \in \Pi \mid F \subseteq H \subseteq G\}$ the *subconfiguration* of Π defined by F and G ; this has itself the structure of a $(\dim(G) - \dim(F) - 1)$ -polytope-configuration. As further conditions, each G/F contains at least 2 proper elements if $\dim(G) - \dim(F) = 2$, and as a partially ordered set, each G/F (including Π itself) is connected if $\dim(G) - \dim(F) \geq 3$. (See the definition of an abstract polytope in Section 19.8.) It can be proved that in $\mathbb{E}^d$ every Π satisfies the stronger condition that each G/F contains exactly 2 proper elements if $\dim(G) - \dim(F) = 2$.

Regular polytope-configuration: A polytope-configuration Π whose symmetry group $G(\Pi)$ is flag-transitive. (A flag is a maximal totally ordered subset of Π .)

Regular star-polygon: For positive integers n and k with $(n, k) = 1$ and $1 < k < \frac{n}{2}$, up to similarity the regular star-polygon $\{\frac{n}{k}\}$ is the connected plane

polygon whose consecutive vertices are $(\cos(\frac{2\pi kj}{n}), \sin(\frac{2\pi kj}{n}))$ for $j = 0, 1, \dots, n-1$. If $k = 1$, the same plane polygon bounds a (nonstarry) convex n -gon with Schläfli symbol $\{n\}$ ($= \{\frac{n}{1}\}$). With each regular (convex or star-) polygon $\{\frac{n}{k}\}$ is associated a regular 2-polytope-configuration obtained by replacing each edge by its affine hull.

Star-polytope-configuration: A d -polytope-configuration Π is **nonstarry** if it is the family of affine hulls of the faces of a convex d -polytope. It is **starry**, or a **star-polytope-configuration**, if it is not nonstarry. For instance, among the 2-polytope-configurations that are associated with a regular (convex or star-) polygon $\{\frac{n}{k}\}$ for a given n , the one with $k = 1$ is nonstarry and those for $k > 1$ are starry. In the first case the corresponding n -gon is convex, and in the second case it is genuinely star-like. In general, the starry polytope configurations are those that belong to genuinely star-like polytopes (that is, star-polytopes).

Regular star-polytope: If $d = 2$, a regular star-polytope is a regular star-polygon. Defined inductively, if $d \geq 3$, a regular d -star-polytope P is a finite family of regular convex $(d-1)$ -polytopes or regular $(d-1)$ -star-polytopes such that the family consisting of their affine hulls as well as the affine hulls of their “faces” is a regular d -star-polytope-configuration $\Pi = \Pi(P)$. Here, the faces of the polytopes can be defined in such a way that they correspond to the elements in the associated polytope-configuration. The symmetry groups of P and Π are the same.

ENUMERATION AND CONSTRUCTION

Regular star-polytopes P can only exist for $d = 2, 3$, or 4 . As regular convex polytopes, they are also uniquely determined by the Schläfli symbol $\{p_1, \dots, p_{d-1}\}$, but now at least one entry is not integral. Again the symbols for the facets and vertex figures, when superposed, give the original. If $d = 2$, $P = \{\frac{n}{k}\}$ for some k with $(n, k) = 1$ and $1 < k < \frac{n}{2}$, and $G(P) = D_n$. For $d = 3$ and 4 the star-polytopes are listed in Table 19.2.1 together with the numbers f_0 and f_{d-1} of vertices and facets, respectively.

FIGURE 19.2.1
The four
Kepler-Poinsot
polyhedra.

Every regular d -star-polytope has the same vertices and symmetry group as a regular convex d -polytope. The four regular star-polyhedra (3-star-polytopes) are also known as the **Kepler-Poinsot polyhedra** (Figure 19.2.1). They can be constructed from the icosahedron $\{3, 5\}$ or dodecahedron $\{5, 3\}$ by two kinds of operations, **stellation** or **faceting** [Cox73]. Loosely speaking, in the former operation one extends the faces of a polyhedron symmetrically until they again form a polyhedron, while in the latter operation the vertices of a polyhedron are redis-

TABLE 19.2.1 The regular star-polytopes in $\mathbb{E}^d$ ($d \geq 3$).

DIMENSION	SCHLÄFLI SYMBOL	f_0	f_{d-1}
$d = 3$	$\{3, \frac{5}{2}\}$	12	20
	$\{\frac{5}{2}, 3\}$	20	12
	$\{5, \frac{5}{2}\}$	12	12
	$\{\frac{5}{2}, 5\}$	12	12
$d = 4$	$\{3, 3, \frac{5}{2}\}$	120	600
	$\{\frac{5}{2}, 3, 3\}$	600	120
	$\{3, 5, \frac{5}{2}\}$	120	120
	$\{\frac{5}{2}, 5, 3\}$	120	120
	$\{3, \frac{5}{2}, 5\}$	120	120
	$\{5, \frac{5}{2}, 3\}$	120	120
	$\{5, 3, \frac{5}{2}\}$	120	120
	$\{\frac{5}{2}, 3, 5\}$	120	120
	$\{5, \frac{5}{2}, 5\}$	120	120
	$\{\frac{5}{2}, 5, \frac{5}{2}\}$	120	120

tributed in classes that are then the vertex sets for the faces of a new polyhedron. Regarded as regular maps on surfaces (Section 19.3), the polyhedra $\{3, \frac{5}{2}\}$ (*great icosahedron*) and $\{\frac{5}{2}, 3\}$ (*great stellated dodecahedron*) are of genus 0, while $\{5, \frac{5}{2}\}$ (*great dodecahedron*) and $\{\frac{5}{2}, 5\}$ (*small stellated dodecahedron*) are of genus 4.

The ten regular star-polytopes in $\mathbb{E}^4$ all have the same vertices and symmetry groups as the 600-cell $\{3, 3, 5\}$ or 120-cell $\{5, 3, 3\}$ and can be derived from these by 4-dimensional stellation or faceting operations [Cox73, McM68]. See also [Cox93] for their names, which describe the various relationships among the polytopes. For presentations of their symmetry groups that reflect the finer combinatorial structure of the star-polytopes, see also [MS02].

The dual of $\{p_1, \dots, p_{d-1}\}$ (which is obtained by dualizing the associated star-polytope-configuration using reciprocation with respect to a sphere) is $\{p_{d-1}, \dots, p_1\}$. Regarded as abstract polytopes (Section 19.8), the star-polytopes $\{p_1, \dots, p_{d-1}\}$ and $\{q_1, \dots, q_{d-1}\}$ are isomorphic if and only if the symbol $\{q_1, \dots, q_{d-1}\}$ is obtained from $\{p_1, \dots, p_{d-1}\}$ by replacing each entry 5 by $\frac{5}{2}$ and each $\frac{5}{2}$ by 5.

19.3 REGULAR SKEW POLYHEDRA

Regular skew polyhedra are finite or infinite polyhedra whose vertex figures are skew (antiprismatic) polygons. The standard reference is Coxeter [Cox68]. Topologically, these polyhedra are regular maps on surfaces. For general properties of regular maps see Coxeter and Moser [CM80], McMullen and Schulte [MS02], or [Chapter 21](#) of this Handbook.

GLOSSARY

(*Right*) *prism*, *antiprism (with regular bases)*: A convex 3-polytope whose

vertices are contained in two parallel planes and whose set of 2-faces consists of the two **bases** (contained in the parallel planes) and the 2-faces in the **mantle** that connects the bases. The bases are congruent regular polygons. For a (right) prism, each base is a translate of the other by a vector perpendicular to its affine hull, and the mantle 2-faces are rectangles. For a (right) antiprism, each base is a translate of a reciprocal (dual) of the other by a vector perpendicular to its affine hull, and the mantle 2-faces are isosceles triangles. (The prism or antiprism is **semiregular** if its mantle 2-faces are squares or equilateral triangles, respectively; see [Section 19.5](#).)

Map on a surface: A decomposition (tessellation) P of a closed surface S into nonoverlapping simply connected regions, the **2-faces** of P , by arcs, the **edges** of P , joining pairs of points, the **vertices** of P , such that two conditions are satisfied. First, each edge belongs to exactly two 2-faces. Second, if two distinct edges intersect, they meet in one vertex or in two vertices.

Regular map: A map P on S whose combinatorial automorphism group $\Gamma(P)$ is transitive on the flags (incident triples consisting of a vertex, an edge, and a 2-face).

Polyhedron: A map P on a closed surface S embedded (without self-intersections) into a Euclidean space, such that two conditions are satisfied. Each 2-face of P is a convex plane polygon, and any two adjacent 2-faces do not lie in the same plane. See also the more general definition in Section 19.4 below.

Skew polyhedron: A polyhedron P such that for at least one vertex x , the vertex figure of P at x is not a plane polygon; the **vertex figure** at x is the polygon whose vertices are the vertices of P adjacent to x and whose edges join consecutive vertices as one goes around x .

Regular polyhedron: A polyhedron P whose symmetry group $G(P)$ is flag-transitive. (For a regular skew polyhedron P in $\mathbb{E}^3$ or $\mathbb{E}^4$, each vertex figure must be a 3-dimensional antiprismatic polygon, meaning that it contains all edges of an antiprism that are not edges of a base. See also [Section 19.4](#).)

ENUMERATION

In $\mathbb{E}^3$ all, and in $\mathbb{E}^4$ all finite, regular skew polyhedra are known [Cox68]. In these cases the (orientable) polyhedron P is completely determined by the extended Schläfli symbol $\{p, q|r\}$, where the 2-faces of P are convex p -gons such that q meet at each vertex, and r is the number of edges in each edge path of P that leaves, at each vertex, exactly two 2-faces of P on the right. The group $G(P)$ is isomorphic to $\Gamma(P)$ and has the presentation

$$\rho_0^2 = \rho_1^2 = \rho_2^2 = (\rho_0\rho_1)^p = (\rho_1\rho_2)^q = (\rho_0\rho_2)^2 = (\rho_0\rho_1\rho_2\rho_1)^r = 1$$

(but the generators ρ_i are not all hyperplane reflections). The polyhedra $\{p, q|r\}$ and $\{q, p|r\}$ are duals, and the vertices of one can be obtained as the centers of the 2-faces of the other.

In $\mathbb{E}^3$ there are just three regular skew polyhedra: $\{4, 6|4\}$, $\{6, 4|4\}$, and $\{6, 6|3\}$. These are the (infinite) **Petrie-Coxeter polyhedra**. For example, $\{4, 6|4\}$ consists of half the square faces of the cubical tessellation $\{4, 3, 4\}$ in $\mathbb{E}^3$.

TABLE 19.3.1 The finite regular skew polyhedra in $\mathbb{E}^4$.

SCHLÄFLI SYMBOL	f_0	f_2	GROUP ORDER	GENUS
$\{4, 4 r\}$	r^2	r^2	$8r^2$	1
$\{4, 6 3\}$	20	30	240	6
$\{6, 4 3\}$	30	20	240	6
$\{4, 8 3\}$	144	288	2304	73
$\{8, 4 3\}$	288	144	2304	73

The finite regular skew polyhedra in $\mathbb{E}^4$ (or equivalently, in spherical 3-space) are listed in Table 19.3.1. There is an infinite sequence of toroidal polyhedra as well as two pairs of duals related to the (self-dual) 4-simplex $\{3, 3, 3\}$ and 24-cell $\{3, 4, 3\}$. For drawings of projections of these polyhedra into 3-space see [BW88, SW91]; Figure 19.3.1 represents $\{4, 8|3\}$.

FIGURE 19.3.1
A projection of $\{4, 8|3\}$ into $\mathbb{R}^3$.

These projections are examples of *combinatorially regular polyhedra* in ordinary 3-space; see [BW93] and [Chapter 21](#) in this Handbook. For regular polyhedra in $\mathbb{E}^4$ with planar, but not necessarily convex, 2-faces, see also [ABM00, Bra00]. For regular skew polyhedra in hyperbolic 3-space, see [Gar67].

19.4 THE GRÜNBAUM-DRESS POLYHEDRA

A new impetus to the study of regular figures came from Grünbaum [Grü77b], who generalized the regular skew polyhedra by allowing skew polygons as faces as well as vertex figures. This restored the symmetry in the definition of polyhedra. For the classification of these “new” regular polyhedra in $\mathbb{E}^3$, see [Grü77b], [Dre85], and

[MS02]. The proper setting for this subject is, strictly speaking, in the context of realizations of abstract regular polytopes (see [Section 19.8](#)).

GLOSSARY

Polygon: A figure P in Euclidean space $\mathbb{E}^d$ consisting of a (finite or infinite) sequence of distinct points, called the *vertices* of P , joined in successive pairs, and closed cyclicly if finite, by line segments, called the *edges* of P , such that each compact set in $\mathbb{E}^d$ meets only finitely many edges.

Zigzag polygon: A (zigzag-shaped) infinite plane polygon P whose vertices alternately lie on two parallel lines and whose edges are all of the same length.

Antiprismatic polygon: A closed polygon P in 3-space whose vertices are alternately vertices of each of the two (regular convex) bases of a (right) antiprism Q (Section 19.3), such that the orthogonal projection of P onto the plane of a base gives a regular star-polygon (Section 19.2). This star-polygon (and thus P) has twice as many vertices as each base, and is a convex polygon if and only if the edges of P are just those edges of Q that are not edges of a base.

Prismatic polygon: A closed polygon P in 3-space whose vertices are alternately vertices of each of the two (regular convex) bases of a (right) prism Q (Section 19.3), such that the orthogonal projection of P onto the plane of a base traverses twice a regular star-polygon in that plane (Section 19.2). Each base of Q (and thus the star-polygon) is assumed to have an odd number of vertices. The star-polygon is a convex polygon if and only if each edge of P is a diagonal in a rectangular 2-face in the mantle of Q .

Helical polygon: An infinite polygon in 3-space whose vertices lie on a helix given parametrically by $(a \cos \beta t, a \sin \beta t, bt)$, where $a, b \neq 0$ and $0 < \beta < \pi$, and are obtained as t ranges over the integers. Successive integers correspond to successive vertices.

Polyhedron: A (finite or infinite) family P of polygons in $\mathbb{E}^d$, called the *2-faces* of P , such that three conditions are satisfied. First, each edge of one of the 2-faces is an edge of exactly one other 2-face. Second, for any two edges F and F' of (2-faces of) P there exist chains $F = G_0, G_1, \dots, G_n = F'$ of edges and $H_1, \dots, H_n$ of 2-faces such that each H_i is incident with G_{i-1} and G_i . Third, each compact set in $\mathbb{E}^d$ meets only finitely many 2-faces.

Regular: A polygon or polyhedron P is regular if its symmetry group $G(P)$ is transitive on the flags.

Petrie polygon of a polyhedron: A polygonal path along the edges of a regular polyhedron P such that any two successive edges, but no three, are edges of a 2-face of P .

Petrie dual: The family of all Petrie polygons of a regular polyhedron P . This is itself a regular polyhedron, and its Petrie dual is P itself.

ENUMERATION

For a systematic discussion of regular polygons in arbitrary Euclidean spaces see [Cox93]. In light of the geometric classification scheme for the new regular polyhedra in $\mathbb{E}^3$ proposed in [Grü77b], it is useful to classify the regular polygons in $\mathbb{E}^3$

into seven groups: convex polygons, plane star-polygons (Section 19.2), apeirogons (Section 19.1), zigzag polygons, antiprismatic polygons, prismatic polygons, and helical polygons. These correspond to the four kinds of isometries in $\mathbb{E}^3$: rotation, rotatory reflection (a reflection followed by a rotation in the reflection plane), glide reflection, and twist.

The 2-faces and vertex figures of a regular polyhedron P in $\mathbb{E}^3$ are regular polygons of the above kind. (The vertex figure at a vertex x is the polygon whose vertices are the vertices of P adjacent to x and whose edges join two such vertices y and z if and only if $\{y, x\}$ and $\{x, z\}$ are edges of a 2-face in P . For a regular P , this is a single polygon.) It is convenient to group the regular polyhedra in $\mathbb{E}^3$ into 8 classes. The first four are the traditional regular polyhedra: the five Platonic solids; the three planar tessellations; the four regular star-polyhedra (Kepler-Poinsot polyhedra); and the three infinite regular skew polyhedra (Petrie-Coxeter polyhedra). The four other classes and their polyhedra can be described as follows: the class of nine finite polyhedra with finite skew (antiprismatic) polygons as faces; the class of infinite polyhedra with finite skew (prismatic or antiprismatic) polygons as faces, which includes three infinite families as well as three individual polyhedra; the class of polyhedra with zigzag polygons as faces, which contains six infinite families; and the class of polyhedra with helical polygons as faces, which has three infinite families and six individual polyhedra.

Alternatively, these forty-eight polyhedra can be described as follows [MS02]. There are eighteen finite regular polyhedra, namely the nine classical finite regular polyhedra (Platonic solids and Kepler-Poinsot polyhedra), and their Petrie duals. The regular tessellations of the plane, and their Petrie duals (with zigzag 2-faces), are the six planar polyhedra in the list. From those, twelve further polyhedra are obtained as blends (in the sense of Section 19.8) with a line segment or an apeirogon (Section 19.1). The six blends with a line segment have finite skew, or (infinite planar) zigzag, 2-faces with alternate vertices on a pair of parallel planes; the six blends with an apeirogon have helical polygons or zigzag polygons as 2-faces. Finally, there are twelve further polyhedra that are not blends; they fall into a single family and are related to the cubical tessellation of $\mathbb{E}^3$. Each polyhedron can be described by a generalized Schläfli symbol, which encodes the geometric structure of the polygonal faces and vertex figures, tells whether or not the polyhedron is a blend, and indicates a presentation of the symmetry group. For more details see [MS02] (or [Grü77b, Dre85, Joh]).

19.5 SEMIREGULAR AND UNIFORM CONVEX POLYTOPES

The very stringent requirements in the definition of regularity of polytopes can be relaxed in many different ways, yielding a great variety of weaker regularity notions. We shall only consider polytopes and polyhedra that are convex. See Johnson [Joh] for a detailed discussion, or Martini [Mar94] for a survey.

GLOSSARY

Semiregular: A convex d -polytope P is semiregular if its facets are regular and its symmetry group $G(P)$ is transitive on the vertices of P .

Uniform: A convex polygon is uniform if it is regular. Recursively, if $d \geq 3$, a convex d -polytope P is uniform if its facets are uniform and its symmetry group $G(P)$ is transitive on the vertices of P .

Regular-faced: P is regular-faced if all its facets (and lower-dimensional faces) are regular.

ENUMERATION

Each regular polytope is semiregular, and each semiregular polytope is uniform. Also, by definition each uniform 3-polytope is semiregular. For $d = 3$ the family of semiregular (uniform) convex polyhedra consists of the Platonic solids, two infinite classes of prisms and antiprisms, as well as the thirteen polyhedra known as Archimedean solids [Fej64]. The seven semiregular polyhedra whose symmetry group is edge-transitive are also called the *quasiregular* polyhedra.

Besides the regular polytopes, there are only seven semiregular polytopes in higher dimensions: three for $d = 4$, and one for each of $d = 5, 6, 7, 8$ (for a short proof, see [BB91]). However, there are many more uniform polytopes but a complete list is known only for $d = 4$ [Joh]. Except for the regular 4-polytopes and the prisms over uniform 3-polytopes, there are exactly 40 uniform 4-polytopes.

For $d = 3$ all, for $d = 4$ all save one, and for $d \geq 5$ many, uniform polytopes can be obtained by a method called **Wythoff's construction**. This method proceeds from a finite Euclidean reflection group W in $\mathbb{E}^d$, or the even (rotation) subgroup W^+ of W , and constructs the polytopes as the convex hull of the orbit under W or W^+ of a point, the initial vertex, in the fundamental region of the group, which is a d -simplex (chamber) or the union of two adjacent d -simplices in the corresponding chamber complex of W , respectively; see Sections 19.1 and 19.6.

The regular-faced polytopes have also been described for each dimension. In general, such a polytope can have different kinds of facets (and vertex figures). For $d = 3$ the complete list contains exactly 92 regular-faced convex polyhedra and includes all semiregular polyhedra. For each $d \geq 5$, there are only two regular-faced d -polytopes that are not semiregular. Except for $d = 4$, each regular-faced d -polytope has a nontrivial symmetry group.

There are many further generalizations of the notion of regularity [Mar94]. However, in most cases complete lists of the corresponding polytopes are either not known or available only for $d = 3$. The variants that have been considered include: *isogonal* polytopes (requiring vertex-transitivity of $G(P)$), or *isohedral* polytopes, the reciprocals of the isogonal polytopes, with a facet-transitive group $G(P)$; more generally, *k -face-transitive* polytopes (requiring transitivity of $G(P)$ on the k -faces), for a single value or several values of k ; *congruent-faceted*, or *monohedral*, polytopes (requiring congruence of the facets); and *equifaceted* polytopes (requiring combinatorial isomorphism of the facets). Similar problems have also been considered for nonconvex polytopes or polyhedra, and for tilings [GS87].

19.6 REFLECTION GROUPS

Symmetry properties of geometric figures are closely tied to the algebraic structure

of their symmetry groups, which are often subgroups of finite or infinite reflection groups. A classical reference for reflection groups is Coxeter [Cox73]. A more recent text is Humphreys [Hum90].

GLOSSARY

Reflection group: A group generated by (hyperplane) reflections in a finite-dimensional space V . The space can be a real or complex vector space (or affine space). A **reflection** is a linear (or affine) transformation whose eigenvalues, save one, are all equal to 1, while the remaining eigenvalue is a primitive k th root of unity for some $k \geq 2$; in the real case, it is -1 . If the space is equipped with further structure, the reflections are assumed to preserve it. For example, if V is real Euclidean, the reflections are Euclidean reflections.

Coxeter group: A group W , finite or infinite, that is generated by finitely many generators $\sigma_1, \dots, \sigma_n$ and has a presentation of the form $(\sigma_i \sigma_j)^{m_{ij}} = 1$ ($i, j = 1, \dots, n$), where the m_{ij} are positive integers or ∞ such that $m_{ii} = 1$ and $m_{ij} = m_{ji} \geq 2$ ($i \neq j$). The matrix $(m_{ij})_{ij}$ is the **Coxeter matrix** of W .

Coxeter diagram: A labeled graph $\mathcal{D}$ that represents a Coxeter group W as follows. The nodes of $\mathcal{D}$ represent the generators σ_i of W . The i th and j th node are joined by a (single) branch if and only if $m_{ij} > 2$. In this case, the branch is labeled m_{ij} if $m_{ij} \neq 3$ (and remains unlabeled if $m_{ij} = 3$).

Irreducible Coxeter group: A Coxeter group W whose Coxeter diagram is connected. (Each Coxeter group W is the direct product of irreducible Coxeter groups, with each factor corresponding to a connected component of the diagram of W .)

Root system: A finite set $\mathcal{R}$ of nonzero vectors, the **roots**, in $\mathbb{E}^d$ satisfying the following conditions. $\mathcal{R}$ spans $\mathbb{E}^d$, and $\mathcal{R} \cap \mathbb{R}e = \{\pm e\}$ for each $e \in \mathcal{R}$. For each $e \in \mathcal{R}$, the Euclidean reflection S_e in the linear hyperplane orthogonal to e maps $\mathcal{R}$ onto itself. Moreover, the numbers $2(e, e')/(e', e')$, with $e, e' \in \mathcal{R}$, are integers (**Cartan integers**); here $(\ , \)$ denotes the standard inner product on $\mathbb{E}^d$. (These conditions define **crystallographic** root systems. Sometimes the integrality condition is omitted to give a more general notion of root system.) The group W generated by the reflections S_e ($e \in \mathcal{R}$) is a finite Coxeter group, called the **Weyl group** of $\mathcal{R}$.

GENERAL PROPERTIES

Every Coxeter group $W = \langle \sigma_1, \dots, \sigma_n \rangle$ admits a faithful representation as a reflection group in the real vector space $\mathbb{R}^n$. This is obtained as follows. If W has Coxeter matrix $M = (m_{ij})_{ij}$ and $e_1, \dots, e_n$ is the standard basis of $\mathbb{R}^n$, define the symmetric bilinear form $\langle \ , \ \rangle_M$ by

$$\langle e_i, e_j \rangle_M := -\cos(\pi/m_{ij}) \quad (i, j = 1, \dots, n),$$

with appropriate interpretation if $m_{ij} = \infty$. For $i = 1, \dots, n$ the linear transforma-

tion $S_i : \mathbb{R}^n \mapsto \mathbb{R}^n$ given by

$$xS_i := x - 2\langle e_i, x \rangle_M e_i \quad (x \in \mathbb{R}^n)$$

is the orthogonal reflection in the hyperplane orthogonal to e_i . Let $O(M)$ denote the orthogonal group corresponding to $\langle \cdot, \cdot \rangle_M$. Then $\sigma_i \mapsto S_i$ ($i = 1, \dots, n$) defines a faithful representation $\rho : W \mapsto GL(\mathbb{R}^n)$, called the **canonical representation**, such that $W\rho \subseteq O(M)$.

The group W is finite if and only if the associated form $\langle \cdot, \cdot \rangle_M$ is positive definite; in this case, $\langle \cdot, \cdot \rangle_M$ determines a Euclidean geometry on $\mathbb{R}^n$. In other words, each finite Coxeter group is a finite Euclidean reflection group. Conversely, every finite Euclidean reflection group is a Coxeter group. The finite Coxeter groups have been completely classified by Coxeter and are usually listed in terms of their Coxeter diagrams.

The finite irreducible Coxeter groups with string diagrams are precisely the symmetry groups of the convex regular polytopes, with a pair of dual polytopes corresponding to a pair of groups that are related by reversing the order of the generators. See [Section 19.1](#) for an explanation about how the generators act on the polytopes. [Table 19.1.1](#) also lists the names for the corresponding Coxeter diagrams.

For $p_1, \dots, p_{n-1} \geq 2$ write $[p_1, \dots, p_{n-1}]$ for the Coxeter group with string diagram $\bullet \xrightarrow{p_1} \bullet \xrightarrow{p_2} \bullet \cdots \bullet \xrightarrow{p_{n-2}} \bullet \xrightarrow{p_{n-1}} \bullet$. Then $[p_1, \dots, p_{n-1}]$ is the automorphism group of the universal abstract regular n -polytope $\{p_1, \dots, p_{n-1}\}$; see [Section 19.8](#). The regular honeycombs $\{p_1, \dots, p_{n-1}\}$ on the sphere (convex regular polytopes) or in Euclidean or hyperbolic space are examples of such universal polytopes. The spherical honeycombs are exactly the finite universal regular polytopes (with $p_i > 2$ for all i). The Euclidean honeycombs arise exactly when $p_i > 2$ for all i and the bilinear form $\langle \cdot, \cdot \rangle_M$ for $[p_1, \dots, p_{n-1}]$ is positive semidefinite (but not positive definite). Similarly, the hyperbolic honeycombs correspond exactly to the groups $[p_1, \dots, p_{n-1}]$ that are Coxeter groups of “hyperbolic type” [MS02].

There are exactly two sources of finite Coxeter groups, to some extent overlapping: the symmetry groups of convex regular polytopes, and the Weyl groups of (crystallographic) root systems, which are important in Lie Theory. Every root system $\mathcal{R}$ has a set of **simple roots**; this is a subset $\mathcal{S}$ of $\mathcal{R}$, which is a basis of $\mathbb{E}^d$ such that every $e \in \mathcal{R}$ is a linear combination of vectors in $\mathcal{S}$ with integer coefficients that are all nonnegative or all nonpositive. The distinguished generators of the Weyl group W are given by the reflections S_e in the linear hyperplane orthogonal to e ($e \in \mathcal{S}$), for some set $\mathcal{S}$ of simple roots of $\mathcal{R}$. The irreducible Weyl groups in $\mathbb{E}^2$ are the symmetry groups of the triangle, square, or hexagon. The diagrams A_d , B_d , C_d , and F_4 of [Table 19.1.1](#) all correspond to irreducible Weyl groups and root systems (with B_d and C_d corresponding to a pair of dual root systems), but H_3 and H_4 do not (they correspond to a noncrystallographic root system [CMP98]). There is one additional series of irreducible Weyl groups in $\mathbb{E}^d$ with $d \geq 4$ (a certain subgroup of index 2 in B_d), whose diagram is denoted by D_d . The remaining irreducible Weyl groups occur in dimensions 6, 7, and 8, with diagrams E_6 , E_7 , and E_8 , respectively.

Each Weyl group W stabilizes the lattice spanned by a set $\mathcal{S}$ of simple roots, the **root lattice** of $\mathcal{R}$. These lattices have many interesting geometric properties and occur also in the context of sphere packings (see Conway and Sloane [CS99] and [Chapter 61](#) of this Handbook). The irreducible Coxeter groups W of Euclidean

type, or, equivalently, the infinite discrete irreducible Euclidean reflection groups, are intimately related to Weyl groups; they are also called *affine Weyl groups*.

The complexifications of the reflection hyperplanes for a finite Coxeter group give an example of a complex *hyperplane arrangement* (see [BLS⁺93], [OT92], and Chapter 6). The topology of the set-theoretic complement of these *Coxeter arrangements* in complex space has been extensively studied.

For hyperbolic reflection groups, see Vinberg [Vin85]. In hyperbolic space, a discrete irreducible reflection group need not have a fundamental region that is a simplex.

19.7 COMPLEX REGULAR POLYTOPES

Complex regular polytopes are subspace configurations in unitary complex space that share many properties with regular polytopes in real spaces. For a detailed account see Coxeter [Cox93]. The subject originated with Shephard [She52].

GLOSSARY

Complex d -polytope: A d -polytope-configuration as defined in Section 19.2, but now the elements, or *faces*, are subspaces in unitary complex d -space $\mathbb{C}^d$. However, unlike in real space, the subconfigurations G/F with $\dim(G) - \dim(F) = 2$ can contain more than 2 proper elements. A *complex polygon* is a complex 2-polytope.

Regular complex polytope: A complex polytope P whose (unitary) symmetry group $G(P)$ is transitive on the flags (the maximal sets of mutually incident faces).

ENUMERATION AND GROUPS

The regular complex d -polytopes P are completely known for each d . Every d -polytope can be uniquely described by a *generalized Schläfli symbol*

$$p_0\{q_1\}p_1\{q_2\}p_2 \cdots p_{d-2}\{q_{d-1}\}p_{d-1},$$

which we explain below. For $d = 1$, the regular polytopes are precisely the point sets on the complex line, which in corresponding real 2-space are the vertex sets of regular convex polygons; the Schläfli symbol is simply p if the real polygon is a p -gon. In general, the entry p_i is the Schläfli symbol for the complex 1-polytope that occurs as the 1-dimensional subconfiguration G/F of P , where F is an $(i-1)$ -face and G an $(i+1)$ -face of P such that $F \subseteq G$. As is further explained below, the p_i i -faces in this subconfiguration are cyclicly permuted by a hyperplane reflection that leaves the whole polytope invariant. Note that, unlike in real Euclidean space, a hyperplane reflection in unitary complex space need not have period 2 but can have any finite period greater than 1. The meaning of the entries q_i is also given below.

The regular complex polytopes P with $d \geq 2$ are summarized in Table 19.7.1, which includes the numbers f_0 and f_{d-1} of vertices and facets ($(d-1)$ -faces) and the group order. Listed are only the nonreal polytopes as well as only one polytope from each pair of duals. A complex polytope is **real** if, up to an affine transformation of $\mathbb{C}^d$, all its faces are subspaces that can be described by linear equations over the reals. In particular, $p_0\{q_1\}p_1 \dots p_{d-2}\{q_{d-1}\}p_{d-1}$ is real if and only if $p_i = 2$ for each i ; in this case, $\{q_1, \dots, q_{d-1}\}$ is the Schläfli symbol for the related regular polytope in real space. As in real space, each polytope $p_0\{q_1\}p_1 \dots p_{d-2}\{q_{d-1}\}p_{d-1}$ has a dual (reciprocal) and its Schläfli symbol is $p_{d-1}\{q_{d-1}\}p_{d-2} \dots p_1\{q_1\}p_0$; the symmetry groups are the same and the numbers of vertices and facets are interchanged. The polytope $p\{4\}2\{3\}2 \dots 2\{3\}2$ is the **generalized complex d -cube**, and its dual $2\{3\}2 \dots 2\{3\}2\{4\}p$ the **generalized complex d -cross-polytope**; if $p = 2$, these are the real d -cubes and d -cross-polytopes, respectively.

TABLE 19.7.1 The nonreal complex regular polytopes (up to duality).

DIMENSION	POLYTOPE	f_0	f_{d-1}	$ G(P) $
$d \geq 1$	$p\{4\}2\{3\}2 \dots 2\{3\}2$	p^d	pd	$p^d d!$
$d = 2$	$3\{3\}3$	8	8	24
	$3\{6\}2$	24	16	48
	$3\{4\}3$	24	24	72
	$4\{3\}4$	24	24	96
	$3\{8\}2$	72	48	144
	$4\{6\}2$	96	48	192
	$4\{4\}3$	96	72	288
	$3\{5\}3$	120	120	360
	$5\{3\}5$	120	120	600
	$3\{10\}2$	360	240	720
	$5\{6\}2$	600	240	1200
	$5\{4\}3$	600	360	1800
$d = 3$	$3\{3\}3\{3\}3$	27	27	648
	$3\{3\}3\{4\}2$	72	54	1296
$d = 4$	$3\{3\}3\{3\}3\{3\}3$	240	240	155 520

The symmetry group $G(P)$ of a complex regular d -polytope P is a finite unitary reflection group in $\mathbb{C}^d$; if $P = p_0\{q_1\}p_1 \dots p_{d-2}\{q_{d-1}\}p_{d-1}$, then the notation for the group $G(P)$ is $p_0[q_1]p_1 \dots p_{d-2}[q_{d-1}]p_{d-1}$. If $\Phi = \{\emptyset = F_{-1}, F_0, \dots, F_{d-1}, F_d = \mathbb{C}^d\}$ is a flag of P , then for each $i = 0, 1, \dots, d-1$ there is a unitary reflection R_i that fixes F_j for $j \neq i$ and cyclicly permutes the p_i i -faces in the subconfiguration F_{i+1}/F_{i-1} of P . These generators R_i can be chosen in such a way that in terms of $R_0, \dots, R_{d-1}$, the group $G(P)$ has a presentation of the form

$$\left\{ \begin{array}{ll} R_i^{p_i} = 1 & (0 \leq i \leq d-1), \\ R_i R_j = R_j R_i & (0 \leq i < j-1 \leq d-2), \\ R_i R_{i+1} R_i R_{i+1} R_i \dots = R_{i+1} R_i R_{i+1} R_i R_{i+1} \dots \\ \text{with } q_{i+1} \text{ generators on each side} & (0 \leq i \leq d-2). \end{array} \right.$$

This explains the entries q_i in the Schläfli symbol. Conversely, any d unitary reflections that satisfy the first two sets of relations, and generate a finite group, can be used to determine a regular complex polytope by a complex analogue of Wythoff's construction (see [Section 19.5](#)). If P is real, then $G(P)$ is conjugate, in the general linear group of $\mathbb{C}^d$, to a finite (real) Coxeter group (see [Section 19.6](#)). Complex regular polytopes are only one source for finite unitary reflection groups; there are also others [Cox93, ST54].

See Cuypers [Cuy95] for the classification of quaternionic regular polytopes (polytope-configurations in quaternionic space).

19.8 ABSTRACT REGULAR POLYTOPES

Abstract regular polytopes are combinatorial structures that generalize the familiar regular polytopes. The terminology adopted is patterned after the classical theory. Many symmetric figures discussed in earlier sections could be treated (and their structure clarified) in this more general framework. Much of the research in this area is quite recent. For a comprehensive account see McMullen and Schulte [MS02].

GLOSSARY

Abstract d -polytope: A partially ordered set P , with elements called *faces*, that satisfies the following conditions. P is equipped with a **rank function** with range $\{-1, 0, \dots, d\}$, which associates with a face F its **rank** $\text{rank } F$; if $\text{rank } F = j$, F is a **j -face**, or a **vertex**, an **edge**, or a **facet** if $j = 0, 1$, or $d - 1$, respectively. P has a unique minimal element F_{-1} of rank -1 and a unique maximal element F_d of rank d . These two elements are the **improper** faces; the others are **proper**. The **flags** (maximal totally ordered subsets) of P all contain exactly $d + 2$ faces (including F_{-1} and F_d). If $F < G$ in P , then $G/F := \{H \in P \mid F \leq H \leq G\}$ is said to be a **section** of P . All sections of P (including P itself) are **connected**, meaning that, given two proper faces H, H' of a section G/F , there is a sequence $H = H_0, H_1, \dots, H_k = H'$ of proper faces of G/F (for some k) such that H_{i-1} and H_i are incident for each $i = 1, \dots, k$. (That is, P is **strongly connected**.) Finally, if $F < G$ with $0 \leq \text{rank } F + 1 = j = \text{rank } G - 1 \leq d - 1$, there are exactly two j -faces H such that $F < H < G$. (Note that this last condition basically says that P is topologically real. The condition is violated for nonreal complex polytopes.)

Faces and co-faces: We can safely identify a face F of P with the section $F/F_{-1} = \{H \in P \mid H \leq F\}$. The section $F_d/F = \{H \in P \mid F \leq H\}$ is the **co-face** of P , or the **vertex figure** if F is a vertex.

Regular polytope: An abstract polytope P whose **automorphism group** $\Gamma(P)$ (the group of order-preserving permutations of $\mathcal{P}$) is transitive on the flags. (Then $\Gamma(P)$ must be simply flag-transitive.)

C-group: A group Γ generated by involutions $\sigma_1, \dots, \sigma_m$ (that is, a quotient of a Coxeter group) such that the **intersection property** holds:

$$\langle \sigma_i \mid i \in I \rangle \cap \langle \sigma_i \mid i \in J \rangle = \langle \sigma_i \mid i \in I \cap J \rangle \text{ for all } I, J \subset \{1, \dots, m\}.$$

The letter “C” stands for “Coxeter.” (Coxeter groups are C-groups, but not vice versa.)

String C-group: A C-group $\Gamma = \langle \sigma_1, \dots, \sigma_m \rangle$ such that $(\sigma_i \sigma_j)^2 = 1$ if $1 \leq i < j - 1 \leq m - 1$. (Then Γ is a quotient of a Coxeter group with a string Coxeter diagram.)

Realization: For a regular (abstract) d -polytope P with vertex-set $\mathcal{F}_0$, a surjection $\beta : \mathcal{F}_0 \mapsto V$ onto a set V of points in a Euclidean space, such that each automorphism of P induces an isometric permutation of V . Then V is the **vertex set** of the realization β .

Chiral polytope: An abstract polytope P whose automorphism group $\Gamma(P)$ has exactly two orbits on the flags, with adjacent flags in different orbits. (Two flags are adjacent if they differ in exactly one face.) Chiral polytopes are an important class of nearly regular polytopes.

GENERAL PROPERTIES

Abstract 2-polytopes are isomorphic to ordinary n -gons or apeirogons (Section 19.2). Except for some degenerate cases, the abstract 3-polytopes with finite faces and vertex figures are in one-to-one correspondence with the maps on surfaces (Section 19.3). Accordingly, a finite (abstract) 4-polytope P has facets and vertex figures that are isomorphic to maps on surfaces.

The group $\Gamma(P)$ of every regular d -polytope P is a string C-group. Fix a flag $\Phi := \{F_{-1}, F_0, \dots, F_d\}$, the **base flag** of P . Then $\Gamma(P)$ is generated by **distinguished generators** $\rho_0, \dots, \rho_{d-1}$ (*with respect to Φ*), where ρ_i is the unique automorphism that keeps all but the i -face of Φ fixed. These generators satisfy relations

$$(\rho_i \rho_j)^{p_{ij}} = 1 \quad (i, j = 0, \dots, d-1),$$

with $p_{ii} = 1$, $p_{ij} = p_{ji} \geq 2$ ($i \neq j$), and $p_{ij} = 2$ if $|i - j| \geq 2$; in particular, $\Gamma(P)$ is a string C-group with generators $\rho_0, \dots, \rho_{d-1}$. The numbers $p_i := p_{i-1, i}$ determine the (*Schläfli*) **type** $\{p_1, \dots, p_{d-1}\}$ of P . The group $\Gamma(P)$ is a quotient of the Coxeter group $[p_1, \dots, p_{d-1}]$ (Section 19.6), but in general the quotient is proper.

Conversely, if Γ is a string C-group with generators $\rho_0, \dots, \rho_{d-1}$, then it is the group of a regular d -polytope P , and $\rho_0, \dots, \rho_{d-1}$ are the distinguished generators with respect to some base flag of P . The i -faces of P are the right cosets of the subgroup $\Gamma_i := \langle \rho_k | k \neq i \rangle$ of Γ , and in P , $\Gamma_i \varphi \leq \Gamma_j \psi$ if and only if $i \leq j$ and $\Gamma_i \varphi \cap \Gamma_j \psi \neq \emptyset$. For any $p_1, \dots, p_{d-1} \geq 2$, $[p_1, \dots, p_{d-1}]$ is a string C-group and the corresponding d -polytope is the **universal** regular d -polytope $\{p_1, \dots, p_{d-1}\}$; every other regular d -polytope of the same type $\{p_1, \dots, p_{d-1}\}$ is derived from it by making identifications. Examples are the regular spherical, Euclidean, and hyperbolic honeycombs. The one-to-one correspondence between string C-groups and the groups of regular polytopes sets up a powerful dialogue between groups on one hand and polytopes on the other.

There is also a similar such dialogue for chiral polytopes (see Schulte and Weiss [SW94]). If P is chiral and $\Phi := \{F_{-1}, F_0, \dots, F_d\}$ is its base flag, then $\Gamma(P)$ is generated by automorphisms $\sigma_1, \dots, \sigma_{d-1}$, where σ_i fixes all the faces in $\Phi \setminus \{F_{i-1}, F_i\}$ and cyclically permutes consecutive i -faces of P in the (polygonal) section F_{i+1}/F_{i-2} of rank 2. The orientation of each σ_i can be chosen in such

a way that the resulting *distinguished generators* $\sigma_1, \dots, \sigma_{d-1}$ of $\Gamma(P)$ satisfy relations

$$\sigma_i^{p_i} = (\sigma_j \sigma_{j+1} \dots \sigma_k)^2 = 1 \quad (i, j, k = 1, \dots, d-1 \text{ and } j < k),$$

with p_i determined by the type $\{p_1, \dots, p_{d-1}\}$ of P . Moreover, a certain intersection property (resembling that for C-groups) holds for $\Gamma(P)$. Conversely, if Γ is a group generated by $\sigma_1, \dots, \sigma_{d-1}$, and if these generators satisfy the above relations and the intersection property, then Γ is the group of a chiral polytope, or the rotation subgroup of index 2 in the group of a regular polytope. Each isomorphism type of chiral polytope occurs combinatorially in two *enantiomorphic* (mirror image) forms; these correspond to two sets of generators σ_i of the group determined by a pair of adjacent base flags.

Abstract polytopes are closely related to buildings and diagram geometries [Bue95, Tit74]. They are essentially the “thin diagram geometries with a string diagram.” The universal regular polytopes $\{p_1, \dots, p_{d-1}\}$ correspond to “thin buildings.”

CLASSIFICATION BY TOPOLOGICAL TYPE

Abstract polytopes are not a priori embedded into an ambient space. Therefore for abstract polytopes, the traditional enumeration of regular polytopes is replaced by the classification by global or local topological type. On the group level, this translates into the enumeration of finite string C-groups with certain kinds of presentations.

Every *locally spherical* abstract regular polytope P of rank $d+1$ is a quotient of a regular tessellation $\{p_1, \dots, p_d\}$ in spherical, Euclidean, or hyperbolic d -space; in other words, P is a regular tessellation on the corresponding spherical, Euclidean, or hyperbolic space form. In this context, the classical regular convex polytopes are precisely the abstract regular polytopes that are locally spherical and globally spherical. The *projective regular polytopes* are the regular tessellations in real projective d -space, and are obtained as quotients of the centrally symmetric regular convex polytopes under the central inversion.

Much work has also been done in the toroidal and locally toroidal case [MS02]. A *regular toroid* of rank $d+1$ is the quotient of a regular tessellation $\{p_1, \dots, p_d\}$ in Euclidean d -space by a lattice that is invariant under all symmetries of the vertex figure of $\{p_1, \dots, p_d\}$; in other words, a regular toroid is a regular tessellation on the d -torus. If $d = 2$, these are the reflexible regular torus maps of [CM80]. For $d \geq 3$ there are three infinite sequences of *cubical toroids* of type $\{4, 3^{d-2}, 4\}$, and for $d = 4$ there are two infinite sequences of *exceptional toroids* for each of the types $\{3, 3, 4, 3\}$ and $\{3, 4, 3, 3\}$. Their groups are known in terms of generators and relations.

For $d \geq 2$, the d -torus is the only d -dimensional compact Euclidean space form that can admit a regular or chiral tessellation. Further, chirality can only occur if $d = 2$ (yielding the irreflexible torus maps of [CM80]). Little is known about regular tessellations on hyperbolic space forms (again, see [CM80] and [MS02]).

For regular d -polytopes P_1 and P_2 , let $\langle P_1, P_2 \rangle$ denote the class of all regular $(d+1)$ -polytopes with facets isomorphic to P_1 and vertex figures isomorphic to P_2 . Each nonempty class $\langle P_1, P_2 \rangle$ contains a *universal polytope* denoted by $\{P_1, P_2\}$, which “covers” all other polytopes in its class. Classification by local topological

type means enumeration of all finite universal polytopes $\{P_1, P_2\}$ where P_1 and P_2 are of the prescribed (global) topological type. There are variants of this definition. A polytope Q in $\langle P_1, P_2 \rangle$ is **locally toroidal** if P_1 and P_2 are regular convex polytopes (spheres) or regular toroids, with at least one of the latter kind.

Locally toroidal regular polytopes can only exist in ranks 4, 5, and 6 [MS02]. The enumeration is complete for rank 5, and nearly complete for rank 4. In rank 6, a list of finite polytopes is known that is conjectured to be complete. The enumeration in rank 4 involves analysis of the Schläfli types $\{4, 4, r\}$ with $r = 3, 4, \{6, 3, r\}$ with $r = 3, 4, 5, 6$, and $\{3, 6, 3\}$, and their duals. Here, complete lists of finite universal regular polytopes are known for each type except $\{4, 4, 4\}$ and $\{3, 6, 3\}$; the type $\{4, 4, 4\}$ is almost settled, and for $\{3, 6, 3\}$ partial results are known. In rank 5, only the types $\{3, 4, 3, 4\}$ and its dual occur. Finally, in rank 6, there are $\{3, 3, 3, 4, 3\}$, $\{3, 3, 4, 3, 3\}$, and $\{3, 4, 3, 3, 4\}$, and their duals. On the group level, the classification of toroidal and locally toroidal polytopes amounts to the classification of certain C-groups that are defined in terms of generators and relations. These groups are quotients of Euclidean or hyperbolic Coxeter groups and are obtained from those by either one or two extra defining relations. Very little is known about the corresponding classification for chiral polytopes.

REALIZATIONS

A good number of the geometric figures discussed in the earlier sections could be described in the general context of realizations of abstract regular polytopes. For an account of realizations see [MS02] or McMullen [McM94].

Let $\beta : \mathcal{F}_0 \mapsto V$ be a realization of a regular d -polytope P , and let $\mathcal{F}_j$ denote the set of j -faces of P ($j = -1, 0, \dots, d$). With $\beta_0 := \beta$, $V_0 := V$, then for $j = 1, \dots, d$, β recursively induces a surjection $\beta_j : \mathcal{F}_j \mapsto V_j$, with $V_j \subset 2^{V_{j-1}}$, given by

$$F\beta_j := \{G\beta_{j-1} \mid G \in \mathcal{F}_{j-1}, G \leq F\}$$

for each $F \in \mathcal{F}_j$. It is convenient to identify β and $\{\beta_j\}_{j=0}^d$ and also call the latter a realization of P . The realization is **faithful** if each β_j is a bijection; otherwise, it is **degenerate**. Its **dimension** is the dimension of the affine hull of V . Each realization corresponds to a (not necessarily faithful) representation of the automorphism group $\Gamma(P)$ as a group of Euclidean isometries.

The traditional approach in the study of regular figures starts from a Euclidean (or other) space and describes all figures of a specified kind that are regular according to some geometric definition of regularity. For example, the Grünbaum-Dress polyhedra of Section 19.4 are the realizations in $\mathbb{E}^3$ of abstract regular 3-polytopes P that are both discrete and faithful; their symmetry group is flag-transitive and is isomorphic to the automorphism group $\Gamma(P)$.

A rather new approach proceeds from a given abstract regular polytope P and describes all the realizations of P . For a finite P , each realization β is uniquely determined by its **diagonal vector** Δ , whose components are the squared lengths of the diagonals (pairs of vertices) in the diagonal classes of P modulo $\Gamma(P)$. Each orthogonal representation of $\Gamma(P)$ yields one or more (possibly degenerate) realizations of P . Then taking the sum of two representations of $\Gamma(P)$ is equivalent to an operation for the related realizations called a **blend**, which in turn amounts to adding the corresponding diagonal vectors. If we identify the realizations with their diagonal vectors, then the space of all realizations of P becomes a closed con-

vex cone $C(P)$, the **realization cone of P** , whose finer structure is given by the irreducible representations of $\Gamma(P)$. The extreme rays of $C(P)$ correspond to the **pure** (unblended) realizations, which are given by the irreducible representations of $\Gamma(P)$. Each realization of P is a blend of pure realizations.

For instance, a regular n -gon P has $\lfloor \frac{1}{2}n \rfloor$ diagonal classes, and for each $k = 1, \dots, \lfloor \frac{1}{2}n \rfloor$, there is a planar regular star-polygon $\{\frac{n}{k}\}$ if $(n, k) = 1$ (Section 19.2), or a “degenerate star-polygon $\{\frac{n}{k}\}$ ” if $(n, k) > 1$; the latter is a degenerate realization of P , which reduces to a line segment if $n = 2k$. For the regular icosahedron P there are 3 pure realizations. Apart from the usual icosahedron $\{3, 5\}$ itself, there is another 3-dimensional pure realization, namely the great icosahedron $\{3, \frac{5}{2}\}$ (Section 19.2). The final pure realization is induced by its covering of $\{3, 5\}/2$, the **hemi-icosahedron** (obtained from P by identifying antipodal vertices), all of whose diagonals are edges; thus its vertices must be those of a 5-simplex. The regular d -simplex has (up to similarity) a unique realization. The regular d -cross-polytope and d -cube have 2 and d pure realizations, respectively. For other polytopes see [BS00, MS02, MW99, MW00].

20 POLYTOPE SKELETONS AND PATHS

Gil Kalai

INTRODUCTION

The k -dimensional *skeleton* of a d -polytope P is the set of all faces of the polytope of dimension at most k . The 1-skeleton of P is called the *graph* of P and denoted by $G(P)$. $G(P)$ can be regarded as an abstract graph whose vertices are the vertices of P , with two vertices adjacent if they form the endpoints of an edge of P .

In this chapter, we will describe results and problems concerning graphs and skeletons of polytopes. In Section 20.1 we briefly describe the situation for 3-polytopes. In Section 20.2 we consider general properties of polytopal graphs—subgraphs and induced subgraphs, connectivity and separation, expansion, and other properties. In Section 20.3 we discuss problems related to diameters of polytopal graphs in connection with the simplex algorithm and the Hirsch conjecture. The short Section 20.4 is devoted to polytopal digraphs. Section 20.5 is devoted to skeletons of polytopes, connectivity, collapsibility and shellability, empty faces and polytopes with “few vertices,” and the reconstruction of polytopes from their low-dimensional skeletons; finally we consider what can be said about the collections of all k -faces of a d -polytope, first for $k = d - 1$ and then when k is fixed and d is large compared to k .

20.1 THREE-DIMENSIONAL POLYTOPES

GLOSSARY

Convex polytopes and their *faces* (and, in particular their *vertices*, *edges*, and *facets*) are defined in [Chapter 16](#) of this Handbook.

A graph is ***d-polytopal*** if it is the graph of some d -polytope.

The following standard graph-theoretic concepts are used: *subgraphs*, *induced subgraphs*, the *complete graph* K_n on n vertices, *cycles*, *trees*, a *spanning tree* of a graph, *valence* (or *degree*) of a vertex in a graph, *planar* graphs, *d-connected* graphs, *coloring* of a graph, *subdivision* of a graph, and *Hamiltonian* graphs.

We briefly discuss results on 3-polytopes. Some of the following theorems are the starting points of much research, sometimes of an entire theory. Only in a few cases are there high-dimensional analogues, and this remains an interesting goal for further research.

THEOREM 20.1.1 *Whitney* [Whi32]

Let G be the graph of a 3-polytope P . Then the graphs of faces of P are precisely the induced cycles in G that do not separate G .

THEOREM 20.1.2 *Steinitz* [Ste22]

A graph G is a graph of a 3-polytope if and only if G is planar and 3-connected.

Steinitz's theorem is the first of several theorems that describe the tame behavior of 3-polytopes. These theorems fail already in dimension four; see [Chapter 16](#).

The theory of planar graphs is a wide and rich theory. Let us quote here the fundamental theorem of Kuratowski:

THEOREM 20.1.3 *Kuratowski* [Kur22, Tho81]

A graph G is planar if and only if G does not contain a subdivision of K_5 or $K_{3,3}$.

THEOREM 20.1.4 *Lipton and Tarjan* [LT79], *strengthened by Miller* [Mil86]

The graph of every 3-polytope with n vertices can be separated, by $2\sqrt{2n}$ vertices forming a circuit in the graph, into connected components of size at most $2n/3$.

It is worth mentioning that the Koebe circle packing theorem gives a new approach to both the Steinitz and Lipton-Tarjan theorems. (See [Zie95, PA95]).

Euler's formula $V - E + F = 2$ has many applications concerning graphs of 3-polytopes; in higher dimensions, our knowledge of face numbers of polytopes (see [Chapter 18](#)) applies to the study of their graphs and skeletons. Simple applications of Euler's theorem are:

THEOREM 20.1.5

Every 3-polytopal graph has a vertex of valence at most 5. (Equivalently, every 3-polytope has a face with at most five sides.)

THEOREM 20.1.6

Every 3-polytope has either a trivalent vertex or a triangular face.

A deeper application of Euler's theorem is:

THEOREM 20.1.7 *Kotzig* [Kot55]

Every 3-polytope has two adjacent vertices the sum of whose valences is at most 13.

For a simple 3-polytope P , let $p_k = p_k(P)$ be the number of k -sized faces of P .

THEOREM 20.1.8 *Eberhard* [Ebe91]

For every finite sequence (p_k) of nonnegative integers with $\sum_{k \geq 3} (6 - k)p_k = 12$, there exists a simple 3-polytope P with $p_k(P) = p_k$ for every $k \neq 6$.

Eberhard's theorem is the starting point of a large number of results and problems, see, e.g., [Juc76, J93, GZ74]. While no high-dimensional direct analogues are known or even conjectured, the results and problems on facet-forming polytopes and nonfacets mentioned below seem related.

THEOREM 20.1.9 *Motzkin* [Mot64]

The graph of a simple 3-polytope whose facets have 0 (mod 3) vertices has, all together, an even number of edges.

THEOREM 20.1.10 *Barnette* [Bar66]

Every 3-polytopal graph contains a spanning tree of maximal valence 3.

We will now describe some results and a conjecture on colorability and Hamiltonian circuits.

THEOREM 20.1.11 *Four Color Theorem: Appel-Haken* [AH76, AH89, RSST97]
The graph of every 3-polytope is 4-colorable.

THEOREM 20.1.12 *Tutte* [Tut56]
4-connected planar graphs are Hamiltonian.

Tait conjectured in 1880, and Tutte disproved in 1946, that the graph of every simple 3-polytope is Hamiltonian. This started a rich theory of trivalent planar graphs without large paths.

CONJECTURE 20.1.13 *Barnette*
Every graph of a simple 3-polytope whose facets have an even number of vertices is Hamiltonian.

Finally, there are several exact and asymptotic formulas for the numbers of distinct graphs of 3-polytopes. A remarkable enumeration theory was developed by Tutte and was further developed by several authors. We will quote one result.

THEOREM 20.1.14 *Tutte* [Tut62]
The number of rooted simplicial 3-polytopes with v vertices is

$$\frac{2(4v-11)!}{(3v-7)!(v-2)!}.$$

Tutte's theory also provides efficient algorithms to generate random planar graphs of various types.

PROBLEM 20.1.15
What does a random 3-polytopal graph look like?

Motivation to study this problem (and high-dimensional extensions) comes also from physics (specifically, “quantum gravity”). See [ADJ97, Ang02, CS02]. One surprising property of random planar maps of various kinds is that the expected number of vertices of distance at most r from a given vertex behaves like r^4 (compared to r^2 for the planar grid).

20.2 GRAPHS OF d -POLYTOPES—GENERALITIES

GLOSSARY

For a graph G , TG denotes any *subdivision* of G , i.e., any graph obtained from G by replacing the edges of G by paths with disjoint interiors.

A d -polytope P is *simplicial* if all its proper faces are simplices. P is *simple* if every vertex belongs to d edges or, equivalently, if the polar of P is simplicial. P is *cubical* if all its proper faces are cubes.

A simplicial polytope P is **stacked** if it is obtained by the repeated operation of gluing a simplex along a facet.

For the definition of the *cyclic polytope* $C(d, n)$, see [Chapter 16](#).

For two graphs G and H (considered as having disjoint sets V and V' of vertices), $G + H$ denotes the graph on $V \cup V'$ that contains all edges of G and H together with all edges of the form $\{v, v'\}$ for $v \in V$ and $v' \in V'$.

A graph G is **d -connected** if G remains connected after the deletion of any set of at most $d - 1$ vertices.

An **empty simplex** of a polytope P is a set S of vertices such that S does not form a face but every proper subset of S forms a face.

A graph G whose vertices are embedded in $\mathbb{R}^d$ is **rigid** if every small perturbation of the vertices of G that does not change the distance of adjacent vertices in G is induced by an affine rigid motion of $\mathbb{R}^d$. G is **generically d -rigid** if it is rigid with respect to “almost all” embeddings of its vertices into $\mathbb{R}^d$. (Generic rigidity is thus a graph theoretic property, but no description of it in pure combinatorial terms is known for $d > 2$; cf. [Chapter 60](#).)

A set A of vertices of a graph G is **totally separated** by a set B of vertices, if A and B are disjoint and every path between two distinct vertices in A meets B .

A graph G is an **ϵ -expander** if, for every set A of at most half the vertices of G , there are at least $\epsilon \cdot |A|$ vertices not in A that are adjacent to vertices in A .

Neighborly polytopes and *$(0, 1)$ -polytopes* are defined in [Chapter 16](#).

The *polar dual* P^Δ of a polytope P is defined in [Chapter 16](#).

SUBGRAPHS AND INDUCED SUBGRAPHS

THEOREM 20.2.1 *Grünbaum* [Grü65]

Every d -polytopal graph contains a TK_{d+1} .

THEOREM 20.2.2 *Kalai* [Kal87]

The graph of a simplicial d -polytope P contains a TK_{d+2} if and only if P is not stacked.

One important difference between the situation for $d = 3$ and for $d > 3$ is that K_n , for every $n > 4$, is the graph of a 4-dimensional polytope (e.g., a cyclic polytope). Simple manipulations on the cyclic 4-polytope with n vertices show:

PROPOSITION 20.2.3 *Perles* (unpublished)

- (i) *Every graph G is a spanning subgraph of the graph of a 4-polytope.*
- (ii) *For every graph G , $G + K_n$ is a d -polytopal graph for some n and some d .*

This proposition extends easily to higher-dimensional skeletons in place of graphs. It is not known what the minimal dimension is for which $G + K_n$ is d -polytopal, nor even whether $G + K_n$ (for some $n = n(G)$) can be realized in some bounded dimension uniformly for all graphs G .

CONNECTIVITY AND SEPARATION

THEOREM 20.2.4 *Balinski* [Bal61]

The graph of a d -polytope is d -connected.

A set S of d vertices that separates P must form an empty simplex; in this case, P can be obtained by gluing two polytopes along a simplex facet of each.

THEOREM 20.2.5 *Larman and Mani* [LM70]

Let G be the graph of a d -polytope. Let $e = \lfloor (d+1)/3 \rfloor$. Then for every two disjoint sequences $(v_1, v_2, \dots, v_e)$ and $(w_1, w_2, \dots, w_e)$ of vertices of G , there are e vertex-disjoint paths connecting v_i to w_i , $i = 1, 2, \dots, e$.

PROBLEM 20.2.6 *Larman*

Is the last theorem true for $e = \lfloor d/2 \rfloor$?

THEOREM 20.2.7 *Cauchy, Dehn, Aleksandrov, Whiteley, ...*

- (i) *Cauchy's theorem: If P is a simplicial d -polytope, $d \geq 3$, then $G(P)$ (with its embedding in $\mathbb{R}^d$) is rigid.*
- (ii) *Whiteley's theorem [Whi84]: For a general d -polytope P , let G' be a graph (embedded in $\mathbb{R}^d$) obtained from $G(P)$ by triangulating the 2-faces of P without introducing new vertices. Then G' is rigid.*

COROLLARY 20.2.8

For a simplicial d -polytope P , $G(P)$ is generically d -rigid. For a general d -polytope P and a graph G' (considered as an abstract graph) as in the previous theorem, G' is generically d -rigid.

The main combinatorial application of the above theorem is the Lower Bound Theorem (see [Chapter 18](#)) and its extension to general polytopes.

Note that Corollary 20.2.8 can be regarded also as a strong form of Balinski's theorem. It is well known and easy to prove that a generic d -rigid graph is d -connected. Therefore, for simplicial (or even 2-simplicial) polytopes, Corollary 20.2.8 implies directly that $G(P)$ is d -connected.

For general polytopes we can derive Balinski's theorem as follows. Suppose to the contrary that the graph G of a general d -polytope P is not d -connected and therefore its vertices can be separated into two parts (say, red vertices and blue vertices) by deleting a set A of $d-1$ vertices. It is easy to see that every 2-face of P can be triangulated without introducing a blue-red edge. Therefore, the resulting triangulation is not $(d-1)$ -connected and hence it is not generically d -rigid. This contradicts the assertion of Corollary 20.2.8.

Let $\mu(n, d) = f_{d-1}(C(d, n))$ be the number of facets of a cyclic d -polytope with n vertices, which, by the Upper Bound Theorem, is the maximal number of facets possible for a d -polytope with n vertices.

THEOREM 20.2.9 *Klee* [Kle64]

The number of vertices of a d -polytope that can be totally separated by n vertices is at most $\mu(n, d)$.

Klee also showed by considering cyclic polytopes with simplices stacked to each of their facets that this bound is sharp. It follows that there are graphs of simplicial d -polytopes that are not graphs of $(d-1)$ -polytopes. (After realizing that the complete graphs are 4-polytopal, one's naive thought might be that every d -polytopal graph is 4-polytopal.)

EXPANSION

Expansion properties for the graph of the d -dimensional cube are known and important in various areas of combinatorics. By direct combinatorial methods, one can obtain expansion properties of duals to cyclic polytopes. There are a few positive results and several interesting conjectures on expansion properties of graphs of large families of polytopes.

THEOREM 20.2.10 *Kalai* [Kal91]

Graphs of duals to neighborly d -polytopes with n facets are ϵ -expanders for $\epsilon = O(n^{-4})$.

This result implies that the diameter of graphs of duals to neighborly d -polytopes with n facets is $O(d \cdot n^4 \cdot \log n)$.

CONJECTURE 20.2.11 *Mihail and Vazirani* [FM92, Kai01]

Graphs of $(0, 1)$ -polytopes P have the following expansion property: For every set A of at most half the vertices of P , the number of edges joining vertices in A to vertices not in A is at least $|A|$.

It is also conjectured that graphs of polytopes cannot have very good expansion properties:

CONJECTURE 20.2.12 *Polytope graphs are not very good expanders* [Kal91]

Let d be fixed. The graph of every simple d -polytope with n vertices can be separated into two parts, each having at least $n/3$ vertices, by removing $O(n^{1-1/(d-1)})$ vertices.

It is known that there are dual graphs to triangulations of S^3 that cannot be separated even by $O(n/\log n)$ vertices [MTTV97]. Dual graphs to cyclic $2k$ -polytopes with n vertices for n large look somewhat like graphs of grids in $\mathbf{Z}^k$ and, in particular, have no separators of size $o(n^{1-1/k})$.

CONJECTURE 20.2.13 *Expansion properties of random polytopes* [Kal91]

A random simple d -polytope with n facets is an $O(1/(n-d))$ -expander.

This conjecture is vaguely stated since there are various models for random polytopes. There are models based on geometric notions of randomness. For example consider polytopes (containing the origin) that are determined by n random hyperplanes that are tangent to the unit sphere. There is much recent interest in random Gaussian perturbations of a fixed simple polytope [ST01]. We can also consider a random combinatorial type.

CONJECTURE 20.2.14 *There are only a “few” graphs of polytopes*

The number of distinct (isomorphism types) of graphs of simple d -polytopes with n vertices is at most C_d^n , where C_d is a constant depending on d .

It is even possible that the same constant applies for all dimensions and that the conjecture holds even for graphs of general polytopes. This conjecture is of interest also for dual graphs of triangulations of spheres. Conjecture 20.2.12 (and even a much weaker separation property) would imply Conjecture 20.2.14.

OTHER PROPERTIES

CONJECTURE 20.2.15 *Barnette*

Every graph of a simple d -polytope, $d \geq 4$, is Hamiltonian.

THEOREM 20.2.16

For a simple d -polytope P , $G(P)$ is 2-colorable if and only if $G(P^\Delta)$ is d -colorable.

This theorem was proved in an equivalent form for $d = 4$ by Goodman and Onishi [GO78]. (For $d = 3$ it is a classical theorem by Ore.) For the general case, see Joswig [Jos02]. This theorem is related to seeking two-dimensional analogues of Hamiltonian cycles in skeletons of polytopes and manifolds; see [Sch94].

20.3 DIAMETERS OF POLYTOPAL GRAPHS

GLOSSARY

A **d -polyhedron** is the intersection of a finite number of halfspaces in $\mathbb{R}^d$.

$\Delta(d, n)$ denotes the maximal diameter of the graphs of d -dimensional polyhedra P with n facets.

$\Delta_b(d, n)$ denotes the maximal diameter of the graphs of d -polytopes with n vertices.

Given a d -polyhedron P and a linear functional ϕ on $\mathbb{R}^d$, we denote by $G^\rightarrow(P)$ the directed graph obtained from $G(P)$ by directing an edge $\{v, u\}$ from v to u if $\phi(v) \leq \phi(u)$. $v \in P$ is a **top vertex** if ϕ attains its maximum value in P on v .

Let $H(d, n)$ be the maximum over all d -polyhedra with n facets and all linear functionals on $\mathbb{R}^d$ of the maximum length of a minimal monotone path from any vertex to a top vertex.

Let $M(d, n)$ be the maximal number of vertices in a monotone path over all d -polyhedra with n facets and all linear functionals on $\mathbb{R}^d$.

For the notions of *simplicial complex*, *polyhedral complex*, *pure simplicial complex*, and the *boundary complex* of a polytope, see [Chapter 18](#).

Given a pure $(d-1)$ -dimensional simplicial (or polyhedral) complex K , the **dual graph** $G^\Delta(K)$ of K is the graph whose vertices are the facets $((d-1)$ -faces) of K , with two facets F, F' adjacent if $\dim(F \cap F') = d - 2$.

A pure simplicial complex K is **vertex-decomposable** if there is a vertex v of K such that $\text{lk}(v) = \{S \setminus \{v\} \mid S \in K, v \in S\}$ and $\text{ast}(v) = \{S \mid S \in K, v \notin S\}$ are both vertex-decomposable. (The complex $K = \{\emptyset\}$ consisting of the empty face alone is vertex-decomposable.)

It is a long-outstanding open problem to determine the behavior of the function $\Delta(d, n)$. In 1957, Hirsch conjectured that $\Delta(d, n) \leq n - d$. Klee and Walkup [KW67] showed that the Hirsch conjecture is false for unbounded polyhedra. The Hirsch conjecture for bounded polyhedra is still open. The special case asserting that $\Delta_b(d, 2d) = d$ is called the ***d-step conjecture***, and it was shown by Klee and Walkup to imply that $\Delta_b(d, n) \leq n - d$. Another equivalent formulation is that between any pair of vertices v and w of a polytope P there is a ***nonrevisiting path***, i.e., a path $v = v_1, v_2, \dots, v_m = w$ such that for every facet F of P , if $v_i, v_j \in F$ for $i < j$ then $v_k \in F$ for every k with $i \leq k \leq j$.

THEOREM 20.3.1 *Klee and Walkup*

$$\Delta(d, n) \geq n - d + \min\{\lfloor d/4 \rfloor, \lfloor (n - d)/4 \rfloor\}.$$

THEOREM 20.3.2 *Holt-Klee* [HK98a, HK98b, HK98c], *Fritzsche-Holt* [FH99]

For $n > d \geq 8$

$$\Delta_b(d, n) \geq n - d.$$

THEOREM 20.3.3 *Barnette* [Bar74]

$$\Delta(d, n) \leq \frac{2}{3} \cdot (n - d + 5/2) \cdot 2^{d-3}.$$

THEOREM 20.3.4 *Kalai and Kleitman* [KK92]

$$\Delta(d, n) \leq n \cdot \binom{\log n + d}{d} \leq n^{\log d + 1}.$$

The major open problem in this area is:

PROBLEM 20.3.5

Is there a polynomial upper bound for $\Delta(d, n)$? Is there a linear upper bound for $\Delta(d, n)$?

Some special classes of polytopes are known to satisfy the Hirsch bound or to have upper bounds for their diameters that are polynomial in d and n .

THEOREM 20.3.6 *Provan and Billera* [PB80]

Let G be the dual graph that corresponds to a vertex-decomposable $(d-1)$ -dimensional simplicial complex with n vertices. Then the diameter of G is at most $n - d$.

It is known that this theorem does not imply the Hirsch conjecture (for polytopes) since there are simplicial polytopes whose boundary complexes are not vertex-decomposable. Yet such examples are not so easy to come by.

THEOREM 20.3.7 *Naddef* [Nad89]

The graph of every $(0, 1)$ d -polytope has diameter at most d .

Balinski [Bal84] proved the Hirsch bound for dual transportation polytopes, Dyer and Frieze [DF94] showed a polynomial upper bound for unimodular polyhedra, Kalai [Kal92] observed that if the ratio between the number of facets and the dimension is bounded above for the polytope and all its faces then the diameter is bounded above by a polynomial in the dimension, Kleinschmidt and Onn [KO92] proved extensions of Naddef's results to integral polytopes, and Deza and

Onn [DO95] found upper bounds for the diameter in terms of lattice points in the polytope.

The value of $\Delta(d, n)$ is a lower bound for the number of iterations needed for Dantzig's simplex algorithm for linear programming with any pivot rule. However, it is still an open problem to find pivot rules where each pivot step can be computed with a polynomial number of arithmetic operations in d and n such that the number of pivot steps needed comes close to the upper bounds for $\Delta(d, n)$ given above. See Chapter 45.

The problem of routing in graphs of polytopes, i.e., finding a path between two vertices, is an interesting computational problem.

PROBLEM 20.3.8

Find an efficient routing algorithm for convex polytopes.

Using linear programming it is possible to find a path in a polytope P between two vertices that obeys the upper bounds given above such that the number of calls to the linear programming subroutine is roughly the number of edges of the path. Finding a routing algorithm for polytopes with a “small” number of arithmetic operations as a function of d and n is an interesting challenge. The subexponential simplex-type algorithms (see Chapter 45) yield subexponential routing algorithms, but improvement for routing beyond what is known for linear programming is possible.

The upper bounds for $\Delta(d, n)$ mentioned above apply even to $H(d, n)$. Klee and Minty considered a certain geometric realization of the d -cube to show that:

THEOREM 20.3.9 *Klee and Minty* [KM72]

$$M(d, 2d) \geq 2^d.$$

Recent far-reaching extensions of the Klee-Minty construction were found by Amenta and Ziegler [AZ99]. It is not known for $d > 3$ and $n \geq d + 3$ what the precise upper bound for $M(d, n)$ is and whether it coincides with the maximum number of vertices of a d -polytope with n facets given by the upper bound theorem (Chapter 18). See Pfeifle [Pfe02].

20.4 POLYTOPAL DIGRAPHS

Given a d -polytope P and a linear objective function ϕ not constant on edges, direct every edge of $G(P)$ towards the vertex with the higher value of the objective function. A directed graph obtained in this way is called a **polytopal digraph**.

The following basic result is fundamental for the simplex algorithm and also has many applications for the combinatorial theory of polytopes.

THEOREM 20.4.1 *Folklore* (see, e.g., [Wil88])

A polytopal digraph has one sink (and one source). Moreover, every induced subgraph on the vertices of any face of the polytope has one sink (and one source).

An acyclic orientation of $G(P)$ with the property that every face has a unique sink is called an **abstract objective function**. Joswig, Kaibel, and Körner [JKK02] showed that an acyclic orientation for which every 2-dimensional face has a unique

sink is already an abstract objective function.

The h -vector of a simplicial polytope P has a simple and important interpretation in terms of the directed graph that corresponds to the polar of P . The number $h_k(P)$ is the number of vertices v of P^Δ of outdegree k . (Recall that every vertex in a simple polytope has exactly d neighboring vertices.) Switching from ϕ to $-\phi$, one gets the Dehn-Sommerville relations $h_k = h_{d-k}$ (including the Euler relation for $k = 0$); see [Chapter 18](#).

Studying polytopal digraphs and digraphs obtained by abstract objective functions is very interesting in the three-dimensional case and in high dimensions.

THEOREM 20.4.2 *Mihalisin and Klee* [MK00]

Suppose that K is an orientation of a 3-polytopal graph G . Then the digraph K is 3-polytopal if and only if it is acyclic, has a unique source and a unique sink, and admits three independent monotone paths from the source to the sink.

Mihalisin and Klee write in their article “we hope that the present article will open the door to a broader study of polytopal digraphs.”

20.5 SKELETONS OF POLYTOPES

GLOSSARY

A pure polyhedral complex K is ***strongly connected*** if its dual graph is connected.

A ***shelling order*** of the facets of a polyhedral $(d-1)$ -dimensional sphere is an ordering of the set of facets $F_1, F_2, \dots, F_n$ such that the simplicial complex K_i spanned by $F_1 \cup F_2 \cup \dots \cup F_i$ is a simplicial ball for every $i < n$. A polyhedral complex is ***shellable*** if there exists a shelling order of its facets.

A simplicial polytope is ***extendably shellable*** if any way to start a shelling can be continued to a shelling.

An ***elementary collapse*** on a simplicial complex is the deletion of two faces F and G so that F is maximal and G is a codimension-1 face of F that is not included in any other maximal face. A polyhedral complex is ***collapsible*** if it can be reduced to the void complex by repeated applications of elementary collapses.

A d -dimensional polytope P is ***facet-forming*** if there is a $(d+1)$ -dimensional polytope Q such that all facets of Q are combinatorially isomorphic to P . If no such Q exists, P is called a ***nonfacet***.

A ***rational polytope*** is a polytope whose vertices have rational coordinates. (Not every polytope is combinatorially isomorphic to a rational polytope; see [Chapter 16](#).)

A d -polytope P is ***k-simplicial*** if all its faces of dimension at most k are simplices. P is ***k-simple*** if its polar dual P^Δ is k -simplicial.

Zonotopes are defined in Chapters 16 and 18.

Let K be a polyhedral complex. An ***empty simplex*** S of K is a minimal nonface of K , i.e., a subset S of the vertices of K with S itself not in K , but every proper subset of S in K .

Let K be a polyhedral complex and let U be a subset of its vertices. The **induced subcomplex** of K on U , denoted by $K[U]$, is the set of all faces in K whose vertices belong to U . An **empty face** of K is an induced polyhedral subcomplex of K that is homeomorphic to a polyhedral sphere. An empty 2-dimensional face is called an **empty polygon**. An **empty pyramid** of K is an induced subcomplex of K that consists of all the proper faces of a pyramid over a face of K .

CONNECTIVITY AND SUBCOMPLEXES

THEOREM 20.5.1 Grünbaum [Grü65]

The i -skeleton of every d -polytope contains a subdivision of $\text{skel}_i(\Delta^d)$, the i -skeleton of a d -simplex.

THEOREM 20.5.2 Folklore

- (i) *For $i > 0$, $\text{skel}_i(P)$ is strongly connected.*
- (ii) *For every face F , let $U_i(F)$ be the set of all i -faces of P containing F . Then if $i > \dim F$, $U_i(F)$ is strongly connected.*

Part (ii) follows at once from the fact that the faces of P containing F correspond to faces of the quotient polytope P/F . However, properties (i) and (ii) together are surprisingly strong, and all the known upper bounds for diameters of graphs of polytopes rely only on properties (i) and (ii) for the dual polytope.

THEOREM 20.5.3 van Kampen and Flores [vKa32, Flo32, Wu65]

For $i \geq \lfloor d/2 \rfloor$, $\text{skel}_i(\Delta^{d+1})$ is not embeddable in S^{d-1} (and hence not in the boundary complex of any d -polytope).

(This extends the fact that K_5 is not planar.)

CONJECTURE 20.5.4 Lockeberg

For every partition of $d = d_1 + d_2 + \cdots + d_k$ and two vertices v and w of P , there are k disjoint paths between v and w such that the i th path is a path of d_i -faces in which any two consecutive faces have $(d_i - 1)$ -dimensional intersection.

SHELLABILITY AND COLLAPSIBILITY

THEOREM 20.5.5 Bruggesser and Mani [BM71]

Boundary complexes of polytopes are shellable.

The proof of Bruggesser and Mani is based on starting with a point near the center of a facet and moving from this point to infinity, and back from the other direction, keeping track of the order in which facets are seen. This proves a stronger form of shellability, in which each K_i is the complex spanned by all the facets that can be seen from a particular point in $\mathbb{R}^d$. It follows from shellability that:

THEOREM 20.5.6

Polytopes are collapsible.

On the other hand,

THEOREM 20.5.7 *Ziegler* [Zie98]

There are d -polytopes, $d \geq 4$, whose boundary complexes are not extendably shellable.

THEOREM 20.5.8

There are triangulations of the $(d-1)$ -sphere that are not shellable.

Lickorish [Lic91] produced explicit examples of nonshellable triangulations of S^3 . His result was that a triangulation containing a sufficiently complicated knotted triangle was not shellable. Hachimori and Ziegler [HZ00] produced simple examples and showed that a triangulation containing any knotted triangle is not “constructible,” constructibility being a strictly weaker notion than shellability. For more on shellability, see [DK78, Bjö92].

FACET-FORMING POLYTOPES AND SMALL LOW-DIMENSIONAL FACES

THEOREM 20.5.9 *Perles and Shephard* [PS67]

Let P be a d -polytope such that the maximum number of k -faces of P on any $(d-2)$ -sphere in the skeleton of P is at most $(d-1-k)/(d+1-k)f_k(P)$. Then P is a nonfacet.

An example of a nonfacet that is simple was found by Barnette [Bar69]. Some of the proofs of Perles and Shephard use metric properties of polytopes, and for a few of the results alternative proofs using shellability were found by Barnette [Bar69].

THEOREM 20.5.10 *Schulte* [Sch85]

The cuboctahedron and the icosidodecahedron are nonfacets.

PROBLEM 20.5.11

Is the icosahedron facet-forming?

For all other regular polytopes the situation is known. The simplices and cubes in any dimension and the 3-dimensional octahedron are facet-forming. All other regular polytopes with the exception of the icosahedron are known to be nonfacets.

It is very interesting to see what can be said about metric properties of facets (or of low-dimensional faces) of a convex polytope.

THEOREM 20.5.12 *Bárány* (unpublished)

There is an $\epsilon > 0$ such that every d -polytope, $d > 2$, has a facet F for which no balls B_1 of radius R and B_2 of radius $(1+\epsilon)R$ satisfy $B_1 \subset F \subset B_2$.

The stronger statement where balls are replaced by ellipses is open.

Next, we try to understand if it is possible for all the k -faces of a d -polytope to be isomorphic to a given polytope P . The following conjecture asserts that if d is large with respect to k , this can happen only if P is either a simplex or a cube.

CONJECTURE 20.5.13 *Kalai* [Kal90]

For every k there is a $d(k)$ such that every d -polytope with $d > d(k)$ has a k -face that is either a simplex or combinatorially isomorphic to a k -dimensional cube.

Recently, Julian Pfeifle showed, on the basis of the Wythoff construction (see [Chapter 19](#)), that $d(k) > (2k - 1)(k - 1)$, for $k \geq 3$.

For simple polytopes, it follows from the next theorem that if $d > ck^2$ then every d -polytope has a k -face F such that $f_r(F) \leq f_r(C_k)$. (Here, C_k denotes the k -dimensional cube.)

THEOREM 20.5.14 *Nikulin* [Nik86]

The average number of r -dimensional faces of a k -dimensional face of a simple d -dimensional polytope is at most

$$\binom{d-r}{d-k} \cdot \left(\left(\binom{\lfloor d/2 \rfloor}{r} + \binom{\lfloor (d+1)/2 \rfloor}{r} \right) / \left(\binom{\lfloor d/2 \rfloor}{k} + \binom{\lfloor (d+1)/2 \rfloor}{k} \right) \right).$$

Nikulin's theorem appeared in his study of reflection groups in hyperbolic spaces. The existence of reflection groups of certain types implies some combinatorial conditions on their fundamental regions (which are polytopes), and Vinberg [Vin85], Nikulin [Nik86], Khovanski [Kho86], and others showed that in high dimensions these combinatorial conditions lead to a contradiction. There are still many open problems in this direction: in particular, to narrow the gap between the dimensions above for which those reflection groups cannot exist and the dimensions for which such groups can be constructed.

THEOREM 20.5.15 *Kalai* [Kal90]

Every d -polytope for $d \geq 5$ has a 2-face with at most 4 vertices.

THEOREM 20.5.16 *Meisinger, Kleinschmidt, and Kalai* [MKK00]

Every rational d -polytope for $d \geq 9$ has a 3-face with at most 150 vertices.

The previous two theorems and the next one are proved using the linear inequalities for flag numbers that are known via intersection homology of toric varieties; see [Chapter 18](#). One can also study, in a similar fashion, quotients of polytopes.

CONJECTURE 20.5.17 *Perles*

For every k there is a $d'(k)$ such that every d -polytope with $d > d'(k)$ has a k -dimensional quotient that is a simplex.

As was mentioned in the first section, $d'(2) = 3$. The 24-cell, which is a regular 4-polytope all of whose faces are octahedra, shows that $d'(3) > 4$.

THEOREM 20.5.18 *Meisinger, Kleinschmidt, and Kalai* [MKK00]

Every d -polytope with $d \geq 9$ has a 3-dimensional quotient that is a simplex.

PROBLEM 20.5.19

For which values of k and r are there d -polytopes other than the d -simplex that are both k -simplicial and r -simple?

It is known that this can happen only when $k + r \leq d$. There are infinite families of $(d-2)$ -simplicial and 2-simple polytopes, and some examples of $(d-3)$ -simplicial and 3-simple d -polytopes.

Concerning this problem Peter McMullen recently noted that the polytopes r_{st} , discussed in Coxeter's classic book on regular polytopes [Cox63] in Sections 11.8 and 11.x, are $(r+2)$ -simplicial and $(d-r-2)$ -simple, where $d = r + s + t + 1$. These so-called **Gosset-Elte polytopes** arise by the Wythoff construction from the finite reflection groups (see Chapter 19 of this Handbook); we obtain a finite polytope whenever the reflection group generated by the Coxeter diagram with r, s, t nodes on the three arms is finite, that is, when

$$1/(r+1) + 1/(s+1) + 1/(t+1) > 1.$$

The largest exceptional example, 2_{41} , is related to the Weyl group E_8 . The Gosset-Elte polytope 2_{41} is a 4-simple 4-simplicial 8-polytope with 2160 vertices. Are there 5-simplicial 5-simple 10-polytopes?

THEOREM 20.5.20

For $d > 2$, there is no cubical d -polytope P whose dual is also cubical.

I am not aware of a reference for this result but it can easily be proved by exhibiting a covering map from the standard cubical complex realizing $\mathbb{R}^{d-1}$ into the boundary complex of P .

We have considered the problem of finding very special polytopes as “subobjects” (faces, quotients) of arbitrary polytopes. What about realizing arbitrary polytopes as “subobjects” of very special polytopes? There is an old conjecture that every polytope can be realized as a subpolytope (namely the convex hull of a subset of the vertices) of a stacked polytope. Perles and Sturmfels asked whether every simplicial d -polytope can be realized as the quotient of some neighborly even-dimensional polytope. (Recall that a $2m$ -polytope is **neighborly** if every m vertices are the vertices of an $(m-1)$ -dimensional face.) Kortenkamp [Kor97] proved that this is the case for d -polytopes with at most $d+4$ vertices. For general polytopes, “neighborly polytopes” should be replaced here by “weakly neighborly” polytopes, introduced by Bayer [Bay93], which are defined by the property that every set of k vertices is contained in a face of dimension at most $2k-1$. The only theorem of this flavor I am aware of is by Billera and Sarangarajan [BS96], who proved that every $(0,1)$ -polytope is a face of a traveling salesman polytope.

RECONSTRUCTION

THEOREM 20.5.21 *An extension of Whitney's theorem [Grü67] d -polytopes are determined by their $(d-2)$ -skeletons.*

THEOREM 20.5.22 *Perles (unpublished, 1973) Simplicial d -polytopes are determined by their $\lfloor d/2 \rfloor$ -skeletons.*

This follows from the following theorem (here, $\text{ast}(F, P)$ is the complex formed by the faces of P that are disjoint to all vertices in F).

THEOREM 20.5.23 *Perles (1973)*

Let P be a simplicial d -polytope.

- (i) *If F is a k -face of P , then $\text{skel}_{d-k-2}(\text{ast}(F, P))$ is contractible in $\text{skel}_{d-k-1}(\text{ast}(F, P))$.*

- (ii) If F is an empty k -simplex, then $\text{ast}(F, P)$ is homotopically equivalent to S^{d-k} ; hence, $\text{skel}_{d-k-2}(\text{ast}(F, P))$ is not contractible in $\text{skel}_{d-k-1}(\text{ast}(F, P))$.

An extension of Perles's theorem for manifolds with vanishing middle homology was proved by Dancis [Dan84].

THEOREM 20.5.24 *Blind and Mani-Levitska* [BM87]

Simple polytopes are determined by their graphs.

Blind and Mani-Levitska described their theorem in a dual form and considered $(d-1)$ -dimensional “puzzles” whose pieces are simplices and we wish to reconstruct the puzzle based on the “local” information of which two simplices share a facet. Joswig extended their result to more general puzzles where the pieces are general $(d-1)$ -dimensional polytopes, and the way in which every two pieces sharing a facet are connected is also prescribed. A simple proof is given in [Kal88]. This proof also shows that k -dimensional skeletons of simplicial polytopes are also determined by their “puzzle.” When this is combined with Perles's theorem it follows that:

THEOREM 20.5.25 *Kalai and Perles*

Simplicial d -polytopes are determined by the incidence relations between i - and $(i+1)$ -faces for every $i > \lfloor d/2 \rfloor$.

CONJECTURE 20.5.26 *Haase and Ziegler*

Let G be the graph of a simple 4-polytope. Let H be an induced, nonseparating, 3-regular, 3-connected planar subgraph of G . Then H is the graph of a facet of P .

Haase and Ziegler [HZ02] showed that this is not the case if H is not planar. Their proof touches on the issue of embedding knots in the skeletons of 4-polytopes.

PROBLEM 20.5.27

Are simplicial spheres determined by the incidence relations between their facets and subfacets?

THEOREM 20.5.28 *Björner, Edelman, and Ziegler* [BEZ90]

Zonotopes are determined by their graphs.

THEOREM 20.5.29 *Babson, Finschi, and Fukuda* [BFF01]

Duals of cubical zonotopes are determined by their graphs.

In all instances of the above theorems except the single case of the theorem of Blind and Mani-Levitska, the proofs give reconstruction algorithms that are polynomial in the data. It is an open question if a polynomial algorithm exists to determine a simple polytope from its graph. A polynomial “certificate” for reconstruction was recently found by Joswig, Kaibel, and Körner [JKK02].

An interesting problem was whether there is an e -dimensional polytope other than the d -cube with the same graph as the d -cube.

THEOREM 20.5.30 *Joswig and Ziegler* [JZ00]

For every $d \geq e \geq 4$ there is an e -dimensional cubical polytope with 2^d vertices whose $(\lfloor e/2 \rfloor - 1)$ -skeleton is combinatorially isomorphic to the $(\lfloor e/2 \rfloor - 1)$ -skeleton of a d -dimensional cube.

Earlier, Babson, Billera, and Chan [BBC97] found such a construction for cubical spheres.

Another issue of reconstruction for polytopes that was studied extensively is the following: In which cases does the combinatorial structure of a polytope determine its geometric structure (up to projective transformations)? Such polytopes are called *projectively unique*, and the major unsolved problem is:

PROBLEM 20.5.31

Are there only finitely many projectively unique polytopes in each dimension?

McMullen [McM76] constructed projectively unique d -polytopes with $3^{d/3}$ vertices.

EMPTY FACES AND POLYTOPES WITH FEW VERTICES

THEOREM 20.5.32 *Perles* (unpublished, 1970)

Let $f(d, k, b)$ be the number of combinatorial types of k -skeletons of d -polytopes with $d + b + 1$ vertices. Then, for fixed b and k , $f(d, k, b)$ is bounded.

This follows from:

THEOREM 20.5.33 *Perles* (unpublished, 1970)

The number of empty i -pyramids for d -polytopes with $d + b$ vertices is bounded by a function of i and b .

For another proof of this theorem see [Kal94].

For a d -polytope P , let $e_i(P)$ denote the number of empty i -simplices of P .

PROBLEM 20.5.34

Characterize the sequence of numbers $(e_1(P), e_2(P), \dots, e_d(P))$ arising from simplicial d -polytopes and from general d -polytopes.

The following theorem, which was motivated by commutative-algebraic concerns, confirmed a conjecture by Kleinschmidt, Kalai, and Lee [Kal94].

THEOREM 20.5.35 *Migliore and Nagel* [MN03]

For all simplicial d -polytopes with prescribed h -vector $h = (h_0, h_1, \dots, h_d)$, the number of i -dimensional empty simplices is maximized by the Billera-Lee polytopes $P_{BL}(h)$.

$P_{BL}(h)$ is the polytope constructed by Billera and Lee [BL81] (see [Chapter 18](#)) in their proof of the sufficiency part of the g -theorem. Migliore and Nagel proved that for a prescribed f -vector, the Billera-Lee polytopes maximize even more general parameters that arise in commutative algebra: the sum of the i th Betti numbers of induced subcomplexes on j vertices for every i and j . (The case $j = i + 2$ reduces to counting missing faces.) It is quite possible that the theorem of Migliore and Nagel extends to general simplicial spheres with prescribed h -vector and to general polytopes with prescribed (toric) h -vector. (However, it is not yet known in these cases that the h -vectors are always those of Billera-Lee polytopes; see [Chapter 18](#).)

20.6 CONCLUDING REMARKS AND EXTENSIONS TO MORE GENERAL OBJECTS

The reader who compares this chapter with other chapters on convex polytopes may notice the sporadic nature of the results and problems described here. Indeed, it seems that our main limits in understanding the combinatorial structure of polytopes still lie in our ability to raise the right questions. Another feature that comes to mind (and is not unique to this area) is the lack of examples, methods of constructing them, and means of classifying them.

We have considered mainly properties of general polytopes and of simple or simplicial polytopes. There are many classes of polytopes that are either of intrinsic interest from the combinatorial theory of polytopes, or that arise in various other fields, for which the problems described in this chapter are interesting.

Most of the results of this chapter extend to much more general objects than convex polytopes. Finding combinatorial settings for which these results hold is an interesting and fruitful area. On the other hand, the results described here are not sufficient to distinguish polytopes from larger classes of polyhedral spheres, and finding delicate combinatorial properties that distinguish polytopes is an important area of research. Few of the results on skeletons of polytopes extend to skeletons of other convex bodies [LR70, LR71, GL81], and relating the combinatorial theory of polytopes with other aspects of convexity is a great challenge.

20.7 SOURCES AND RELATED MATERIAL

FURTHER READING

Grünbaum [Grü75] is a survey on polytopal graphs and many results and further references can be found there. More material on the topic of this chapter and further relevant references can also be found in [Grü67, Zie95, BMSW94, KK95, BL93]. Martini's chapter in [BMSW94] is on the regularity properties of polytopes (a topic not covered here; cf. [Chapter 19](#)), and contains further references on facet-forming polytopes and nonfacets. The original papers on facet-forming polytopes and nonfacets contain many more results, and describe relations to questions on tiling spaces with polyhedra. Other chapters of [BMSW94] are also relevant to the topic of this chapter.

RELATED CHAPTERS

[Chapter 16](#): Basic properties of convex polytopes

[Chapter 18](#): Face numbers of polytopes and complexes

[Chapter 45](#): Linear programming

[Chapters 7, 17, 19, 21, 46, and 60](#) are also related to some parts of this chapter.

21 POLYHEDRAL MAPS

Ulrich Brehm and Egon Schulte

INTRODUCTION

Historically, polyhedral maps on surfaces made their first appearance as convex polyhedra. The famous Kepler-Poinsot (star) polyhedra marked the first occurrence of maps on orientable surfaces of higher genus (namely 4), and started the branch of topology dealing with regular maps. Further impetus to the subject came from the theory of automorphic functions and from the Four-Color-Problem (Coxeter and Moser [CM80], Barnette [Bar83]).

A more systematic investigation of general polyhedral maps and nonconvex polyhedra began only around 1970, and was inspired by (the original edition of) Grünbaum's book "Convex Polytopes" [Grü67]. Since then, the subject has grown into an active field of research on the interfaces of convex and discrete geometry, graph theory, and combinatorial topology. The underlying topology is mainly elementary, and many basic concepts and constructions are inspired by convex polytope theory.

21.1 POLYHEDRA

Tessellations on surfaces are natural objects of study in topology that generalize convex polyhedra and plane tessellations. For general properties of convex polyhedra, polytopes, and tessellations, see Grünbaum [Grü67], Coxeter [Cox73], Grünbaum and Shephard [GS87], and Ziegler [Zie95], or [Chapters 3, 16, 17, 18, and 19](#) of this Handbook. For a survey on polyhedral manifolds see Brehm and Wills [BW93], which also has an extensive list of references. The long list of definitions that follows places polyhedral maps in the general context of topological and geometric complexes. For an account of 2- and 3-dimensional geometric topology, see Moise [Moi77].

GLOSSARY

Polyhedral complex: A finite set Γ of convex polytopes, the **faces** of Γ , in real n -space $\mathbb{R}^n$, such that two conditions are satisfied. First, if $Q \in \Gamma$ and F is a face of Q , then $F \in \Gamma$. Second, if $Q_1, Q_2 \in \Gamma$, then $Q_1 \cap Q_2$ is a face of Q_1 and Q_2 (possibly the empty face $\emptyset$). The subset $||\Gamma|| := \bigcup_{Q \in \Gamma} Q$ of $\mathbb{R}^n$, equipped with the induced topology, is called the **underlying space** of Γ . The **dimension** $d := \dim \Gamma$ of Γ is the maximum of the dimensions (of the affine hulls) of the elements in Γ . We also call Γ a **polyhedral d -complex**. A face of Γ of dimension 0, 1, or i is a **vertex**, an **edge**, or an **i -face** of Γ , respectively. A face that is maximal (with respect to inclusion) is called a **facet** of Γ . (In our applications, the facets are just the d -faces of Γ .)

Face poset: The set $P(\Gamma)$ of all faces of Γ , partially ordered by inclusion. As a partially ordered set, $P(\Gamma) \cup \{||\Gamma||\}$ is a ranked lattice.

(Geometric) simplicial complex: A polyhedral complex Γ all of whose nonempty faces are simplices. An **abstract simplicial complex** Δ is a family of subsets of a finite set V , the **vertex set** of Δ , such that $\{x\} \in \Delta$ for all $x \in V$, and such that $F \subseteq G \in \Delta$ implies $F \in \Delta$. Each abstract simplicial complex Δ is isomorphic (as a poset ordered by inclusion) to the face poset of a geometric simplicial complex Γ . Once such an isomorphism is fixed, we set $||\Delta|| := ||\Gamma||$, and the terminology introduced for Γ carries over to Δ . (One often omits the qualifications “geometric” or “abstract.”)

Link: The link of a vertex x in a simplicial complex Γ is the subcomplex consisting of the faces that do not contain x of all the faces of Γ containing x .

Polyhedron: A subset P of $\mathbb{R}^n$ such that $P = ||\Gamma||$ for some polyhedral complex Γ . In general, given P , there is no canonical way to associate with it the complex Γ . However, once Γ is specified, the terminology for Γ regarding $P(\Gamma)$ is also carried over to P .

Subdivision: If Γ_1 and Γ_2 are polyhedral complexes, Γ_1 is a subdivision of Γ_2 if $||\Gamma_1|| = ||\Gamma_2||$ and each face of Γ_1 is a subset of a face of Γ_2 . If Γ_1 is a simplicial complex, this is a **simplicial subdivision**.

Combinatorial d -manifold: For $d = 1$, this is a simplicial 1-complex Δ such that $||\Delta||$ is a 1-sphere. Inductively, if $d \geq 2$, it is a simplicial d -complex Δ such that $||\Delta||$ is a topological d -manifold (without boundary) and each vertex link is a **combinatorial $(d-1)$ -sphere** (that is, a combinatorial $(d-1)$ -manifold whose underlying space is a $(d-1)$ -sphere).

Polyhedral d -manifold: A polyhedral d -complex Γ having a simplicial subdivision that is a combinatorial d -manifold. If $d = 2$, this is simply a polyhedral 2-complex Γ for which $||\Gamma||$ is a compact 2-manifold (without boundary).

Triangulation: A triangulation (simplicial decomposition) of a topological space X is a simplicial complex Γ such that X and $||\Gamma||$ are homeomorphic.

Ball complex: A finite family $\mathcal{C}$ of topological balls (homeomorphic images of Euclidean unit balls) in a Hausdorff space, the **underlying space** $||\mathcal{C}||$ of $\mathcal{C}$, whose relative interiors partition $||\mathcal{C}||$ in such a way that the boundary of each ball in $\mathcal{C}$ is the union of other balls in $\mathcal{C}$. The **dimension** of $\mathcal{C}$ is the maximum of the dimensions of the balls in $\mathcal{C}$.

Embedding: For a ball complex $\mathcal{C}$, a continuous mapping $\gamma : ||\mathcal{C}|| \mapsto \mathbb{R}^n$ that is a homeomorphism of $||\mathcal{C}||$ onto its image. $\mathcal{C}$ is said to be **embedded** in $\mathbb{R}^n$.

Polyhedral embedding: For a ball complex $\mathcal{C}$, an embedding γ that maps each ball in $\mathcal{C}$ onto a convex polytope.

Immersion: For a ball complex $\mathcal{C}$, a continuous mapping $\gamma : ||\mathcal{C}|| \mapsto \mathbb{R}^n$ that is locally injective (hence the image may have self-intersections). $\mathcal{C}$ is said to be **immersed** in $\mathbb{R}^n$.

Polyhedral immersion: For a ball complex $\mathcal{C}$, an immersion γ that maps each ball in $\mathcal{C}$ onto a convex polytope.

Map on a surface: An embedded finite graph M (without loops or multiple edges) on a compact 2-manifold (surface) S such that two conditions are satisfied: The closures of the connected components of $S \setminus M$, the **faces** of M , are closed

2-cells (closed topological disks), and each vertex of M has valency at least 3. (Note that some authors use a broader definition of maps; e.g., see [CM80].)

Polyhedral map: A map M on S such that the intersection of any two distinct faces is either empty, a common vertex, or a common edge.

Figure 21.1.1 shows a polyhedral map on a surface of genus 3, known as **Dyck's regular map**. We will discuss this map further in Sections 21.4 and 21.5.

Type: A map M on S is of type $\{p, q\}$ if all its faces are topological p -gons such that q meet at each vertex. The symbol $\{p, q\}$ is the **Schläfli symbol** for M .

FIGURE 21.1.1

Dyck's regular map, of type $\{3, 8\}$.

Vertices with the same label are identified.

BASIC RESULTS

Simplicial complexes are important in topology, geometry, and combinatorics. Each abstract simplicial d -complex Δ with n vertices is isomorphic to the face poset of a geometric simplicial complex Γ in $\mathbb{R}^{2d+1}$ that is obtained as the image under a projection (Schlegel diagram—see Chapter 16) of a simplicial d -subcomplex in the boundary complex of the cyclic convex $(2d+2)$ -polytope $C(n, 2d+2)$ with n vertices; see [Grü67] or Chapter 16 of this Handbook.

Let $\mathcal{C}$ be a ball complex and $P(\mathcal{C})$ the associated poset (i.e., $\mathcal{C}$ ordered by inclusion). Let $\Delta(P(\mathcal{C}))$ denote the **order complex** of $P(\mathcal{C})$; that is, the simplicial complex whose vertex set is $\mathcal{C}$ and whose k -faces are the k -chains $x_0 < x_1 < \dots < x_k$ in $P(\mathcal{C})$. Then $\|\mathcal{C}\|$ and $\|\Delta(P(\mathcal{C}))\|$ are homeomorphic. This means that the poset $P(\mathcal{C})$ already carries complete topological information about $\|\mathcal{C}\|$. See [Bjö95] or [BW93], as well as Chapter 18, for further information.

Each polyhedral d -complex is a d -dimensional ball complex. The set $\mathcal{C}$ of vertices, edges, and faces of a map M on a 2-manifold S is a 2-dimensional ball complex. In particular, a map M is a polyhedral map if and only if the intersection of any two elements of $\mathcal{C}$ is empty or an element of $\mathcal{C}$. A map is usually identified with its poset of vertices, edges, and faces, ordered by inclusion. If M is a polyhedral map, then this poset is a lattice when augmented by $\emptyset$ and S as smallest and largest elements. The dual lattice (obtained by reversing the order) again gives a polyhedral map, the **dual map**, on the same 2-manifold S . Note that in the context of polyhedral maps, the qualification “polyhedral” does not mean that it can be realized as a polyhedral complex. However, a polyhedral 2-manifold can always be regarded as a polyhedral map.

An important problem is the following:

PROBLEM 21.1.1 *General Embeddability Problem*

When is a given finite poset isomorphic to the face poset of some polyhedral complex in a given space $\mathbb{R}^n$? When can a ball complex be polyhedrally embedded or polyhedrally immersed in $\mathbb{R}^n$?

These questions are different from the embeddability problems that are discussed in piecewise-linear topology, because simplicial subdivisions are excluded. A complete answer is available only for the face posets of spherical maps:

THEOREM 21.1.2 *Steinitz's Theorem*

Each polyhedral map M on the 2-sphere is isomorphic to the boundary complex of a convex 3-polytope. Equivalently, a finite graph is the edge graph of a convex 3-polytope if and only if it is planar and 3-connected (it has at least 4 vertices and the removal of any 2 vertices leaves a connected graph).

Very little is known about polyhedral embeddings of orientable polyhedral maps of positive genus g . There are some general necessary combinatorial conditions for the existence of polyhedral embeddings in n -space $\mathbb{R}^n$ [BGH91]. Given a simplicial polyhedral map of genus g it is generally difficult to decide whether or not it admits a polyhedral embedding in 3-space $\mathbb{R}^3$. For each $g \geq 6$, there are examples of simplicial polyhedral maps that cannot be embedded in $\mathbb{R}^3$ [BO00]. Each nonorientable closed surface can be immersed but not embedded in $\mathbb{R}^3$. However, the Möbius strip and therefore each nonorientable surface can be triangulated in such a way that the resulting simplicial polyhedral map cannot be polyhedrally immersed in $\mathbb{R}^3$ [Br83]. On the other hand, each triangulation of the torus or the real projective plane $\mathbb{RP}^2$ can be polyhedrally embedded in $\mathbb{R}^4$ [BS95].

Another important type of problem asks for topological properties of the space of all polyhedral embeddings, or of all convex d -polytopes, with a given face lattice. This is the **realization space** for this lattice. Every convex 3-polytope has an open ball as its realization space. However, the realization spaces of convex 4-polytopes can be arbitrarily complicated; see the “Universality Theorem” by Richter-Gebert [Ric96] in Chapter 16 of this Handbook.

For further embeddability results in higher dimensions, as well as for a discussion of some related problems such as the polytopality problems and isotopy problems, see [Zie95, BLS⁺99, BW93]. For a computational approach to the embeddability problem in terms of oriented matroids, see Bokowski and Sturmfels [BS89], as well as [Chapter 6](#) of this Handbook. We shall revisit the embeddability problem in Sections 21.2 and 21.5 for interesting special classes of polyhedral maps.

Many interesting maps M on compact surfaces S have a Schläfli symbol $\{p, q\}$; for examples, see [Section 21.4](#). These maps can then be obtained from the regular tessellation $\{p, q\}$ of the 2-sphere, the Euclidean plane, or the hyperbolic plane by making identifications. Trivially, $qf_0 = 2f_1 = pf_2$. Also, if the Euler characteristic χ of S is negative and m denotes the number of flags (incident triples consisting of a vertex, an edge, and a face) of M , then

$$\chi = f_0 - f_1 + f_2 = \frac{m}{2} \left(\frac{1}{q} - \frac{1}{2} + \frac{1}{p} \right) \leq -\frac{m}{84}, \quad (21.1.1)$$

and equality holds on the right-hand side if and only if M is of type $\{3, 7\}$ or $\{7, 3\}$.

21.2 EXTREMAL PROPERTIES

There is a natural interest in polyhedral maps and polyhedra defined by certain minimality properties. For relations with the famous Map Color Theorem, which gives the minimum genus of a surface on which the complete graph K_n can be embedded, see Ringel [Rin74] and Barnette [Bar83]. See also Brehm and Wills [BW93].

GLOSSARY

***f*-vector:** For a map M , the vector $f(M) = (f_0, f_1, f_2)$, where f_0, f_1, f_2 are the numbers of vertices, edges, and faces of M , respectively.

Weakly neighborly: A polyhedral map is weakly neighborly (a ***wnp map***) if any two vertices lie in a common face.

Neighborly: A map is neighborly if any two vertices are joined by an edge.

Nonconvex vertex: A vertex x of a polyhedral 2-manifold M in $\mathbb{R}^3$ is a ***convex vertex*** if at least one of the two components into which M divides a small convex neighborhood of x in $\mathbb{R}^3$ is convex; otherwise, x is nonconvex.

Tight polyhedral 2-manifold: A polyhedral 2-manifold M embedded in $\mathbb{R}^3$ such that every hyperplane strictly supporting M locally at a point supports M globally.

BASIC RESULTS

THEOREM 21.2.1

Let M be a polyhedral map of Euler characteristic χ with f -vector (f_0, f_1, f_2) . Then

$$f_0 \geq \lceil (7 + \sqrt{49 - 24\chi})/2 \rceil. \quad (21.2.1)$$

Here, $\lceil t \rceil$ denotes the smallest integer greater than or equal to t . This lower bound is known as the ***Heawood bound*** and is an easy consequence of Euler's formula $f_0 - f_1 + f_2 = \chi$ ($= 2 - 2g$ if M is orientable of genus g).

THEOREM 21.2.2

Except for the nonorientable 2-manifolds with $\chi = 0$ (Klein bottle) or $\chi = -1$ and the orientable 2-manifold of genus $g = 2$ ($\chi = -2$), each 2-manifold admits a triangulation for which the lower bound (21.2.1) is attained.

This is closely related to the Map Color Theorem. The same lower bound (21.2.1) holds for the number f_2 of faces of M , since the dual of M is a polyhedral map with the same Euler characteristic and with f -vector (f_2, f_1, f_0) .

The exact minimum for the number f_1 of edges of a polyhedral map is known for only some manifolds. Let $E_+(\chi)$ or $E_-(\chi)$, respectively, denote the smallest number f_1 such that there is a polyhedral map with f_1 edges on the orientable 2-manifold, or on the nonorientable 2-manifold, respectively, of Euler characteristic χ . The known values of $E_+(\chi)$ and $E_-(\chi)$ are listed in [Table 21.2.1](#); undecided cases

are left blank. The polyhedral maps that attain the minimal values $E_+(2)$, $E_+(-8)$, $E_-(0)$, and $E_-(-6)$ are uniquely determined.

TABLE 21.2.1 The known values of $E_+(\chi)$ and $E_-(\chi)$.

χ	2	1	0	-1	-2	-3	-4	-5	-6	-7	-8	-26
$E_+(\chi)$	6	—	18	—	27	—	33	—	38	—	40	78
$E_-(\chi)$	—	15	18	23	26	30	33	35	36	40	42	

FIGURE 21.2.1

A self-dual polyhedral map on $\mathbb{RP}^2$ with the minimum number (15) of edges.

For a map on $\mathbb{RP}^2$ with 15 edges, see Figure 21.2.1. For the unique polyhedral map with 40 edges on the orientable 2-manifold of genus 5 ($\chi = -8$), see Figure 21.2.2 (and [Br90a]). This map is weakly neighborly and self-dual, and has a cyclic group of automorphisms acting regularly on the set of vertices and on the set of faces. Maps with the latter property are currently being investigated systematically.

FIGURE 21.2.2

The unique polyhedral map of genus 5 with the minimum number (40) of edges.

A general bound for the number f_1 of edges is given by:

THEOREM 21.2.3 [Br90a]

$$f_1 \geq -\chi + \min\{y \in \mathbb{N} \mid y(\sqrt{2y} - 6) \geq -8\chi \text{ and } y \geq 8\},$$

where $\mathbb{N}$ is the set of natural numbers.

If M is a polyhedral map on a surface S , then a new polyhedral map M' on S can be obtained from M by the following operation, called **face splitting**. A new edge xy is added across a face of M , where x and y are points on edges of M that are not contained in a common edge. The new vertices x and y of M' may be vertices of M , or one or both may be relative interior points of edges of M . The dual operation is called **vertex splitting**. On the sphere S^2 , the (boundary complex of the) tetrahedron is the only polyhedral map that is minimal with respect to face splitting. On the real projective plane $\mathbb{RP}^2$, there are exactly 16 polyhedral maps that are minimal with respect to face splitting [Bar91], and exactly 7 that are minimal with respect to both face splitting and vertex splitting. These are exactly the polyhedral maps on $\mathbb{RP}^2$ with 15 edges, which is the minimum number of edges for $\mathbb{RP}^2$. For an example, see Figure 21.2.1.

For neighborly polyhedral maps we always have equality in (21.2.1). Weakly neighborly polyhedral maps (wnp maps) are a generalization of neighborly polyhedral maps. On the 2-sphere, the only wnp maps are the (boundary complexes of the) pyramids and the triangular prism. Every other 2-manifold admits only finitely many combinatorially distinct wnp maps. Moreover,

$$\limsup_{\chi \rightarrow \infty} V_{\max}(\chi) \cdot |2\chi|^{-2/3} \leq 1,$$

where $V_{\max}(\chi)$ denotes the maximum number of vertices of a wnp map of Euler characteristic χ ; see [BA86], which also discusses further equalities and inequalities for general polyhedral maps. For several 2-manifolds, all wnp maps have been determined. For example, on the torus there are exactly five wnp maps, and three of them are geometrically realizable as polyhedra in $\mathbb{R}^3$.

In some instances, the combinatorial lower bound (21.2.1) can also be attained geometrically by (necessarily orientable) polyhedra in $\mathbb{R}^3$. Trivially, the tetrahedron minimizes $f_0 (= 4)$ for $g = 0$. For $g = 1$ there is a polyhedron with $f_0 = 7$ known as the **Császár torus**; see Figure 21.2.3. A pair of congruent copies of the torus shown in Figure 21.2.3b can be linked (if the coordinates orthogonal to the plane of projection are sufficiently small). Polyhedra that have the minimum number of vertices have also been found for $g = 2$ (the exceptional case), 3, or 4, with 10, 10, or 11 vertices, respectively.

FIGURE 21.2.3
(a) The unique 7-vertex triangulation of the torus and
(b) a symmetric realization as a polyhedron.

The minimum number of vertices for polyhedral maps that admit polyhedral immersions in $\mathbb{R}^3$ is 9 for both the real projective plane $\mathbb{RP}^2$ [Br90b] and the Klein bottle. The lower bound for $\mathbb{RP}^2$ follows directly from the fact that each immersion of $\mathbb{RP}^2$ in $\mathbb{R}^3$ has (generically) a triple point (like the classical Boy surface).

There are also some surprising results for higher genus. For example, for each $q \geq 3$ there exists a polyhedral map M_q of type $\{4, q\}$ with $f_0 = 2^q$ and $g = 2^{q-3}(q-4) + 1$ such that M_q and its dual have polyhedral embeddings in $\mathbb{R}^3$ [MSW83]. These polyhedra are combinatorially regular in the sense of Section 21.5. Note that $f_0 = O(g/\log g)$. Thus for sufficiently large genus, M_q has more handles than vertices, and its dual has more handles than faces.

Every polyhedral 2-manifold in $\mathbb{R}^3$ of genus $g \geq 1$ contains at least 5 nonconvex vertices. This bound is attained for each $g \geq 1$. For tight polyhedral 2-manifolds, the lower bound for the number of nonconvex vertices is larger and depends on g . For a survey on tight polyhedral submanifolds see [Küh95].

21.3 EBERHARD'S THEOREM AND RELATED RESULTS

Eberhard's theorem is one of the oldest nontrivial results about convex polyhedra. The standard reference is Grünbaum [Grü67, Grü70]. For recent developments see also Jendrol [Jen93].

GLOSSARY

***p*-sequence:** For a polyhedral map M , the sequence $p(M) = (p_k(M))_{k \geq 3}$, where $p_k = p_k(M)$ is the number of k -gonal faces of M .

***v*-sequence:** For a polyhedral map M , the sequence $v(M) = (v_k(M))_{k \geq 3}$, where $v_k = v_k(M)$ is the number of vertices of M of degree k .

EBERHARD-TYPE RESULTS

Significant results are known for the general problem of determining what kind of polygons, and how many of each kind, may be combined to form the faces of a polyhedral map M on an orientable surface of genus g . These refine results (for $d = 3$) about the boundary complex and the number of i -dimensional faces ($i = 0, \dots, d-1$) of a convex d -polytope [Grü67, Zie95]; see [Chapter 18](#).

If M is a polyhedral map of genus g with f -vector (f_0, f_1, f_2) , then

$$\sum_{k \geq 3} p_k = f_2, \quad \sum_{k \geq 3} v_k = f_0, \quad \sum_{k \geq 3} k p_k = 2f_1 = \sum_{k \geq 3} k v_k. \quad (21.3.1)$$

Further, Euler's formula $f_0 - f_1 + f_2 = 2(1 - g)$ implies the equations

$$\sum_{k \geq 3} (6 - k) p_k + 2 \sum_{k \geq 3} (3 - k) v_k = 12(1 - g) \quad (21.3.2)$$

and

$$\sum_{k \geq 3} (4 - k)(p_k + v_k) = 8(1 - g). \quad (21.3.3)$$

These equations contain no information about p_6, v_3 and p_4, v_4 , respectively.

Eberhard-type results deal with the problem of determining which pairs $(p_k)_{k \geq 3}$ and $(v_k)_{k \geq 3}$ of sequences of nonnegative integers can occur as p -sequences $p(M)$ and v -sequences $v(M)$ of polyhedral maps M of a given genus g . The above equations yield simple necessary conditions. As a consequence of Steinitz's theorem (Section 21.1), the problem for $g = 0$ is equivalent to a similar such problem for convex 3-polytopes [Grü67, Grü70]. The classical theorem of Eberhard says the following:

THEOREM 21.3.1 *Eberhard's Theorem*

For each sequence $(p_k \mid 3 \leq k \neq 6)$ of nonnegative integers satisfying

$$\sum_{k \geq 3} (6 - k)p_k = 12,$$

there exist values of p_6 such that the sequence $(p_k)_{k \geq 3}$ is the p -sequence of a spherical polyhedral map all of whose vertices have degree 3, or, equivalently, of a convex 3-polytope that is simple (has vertices only of degree 3).

This is the case $g = 0$ and $v_3 = f_0$, $v_k = 0$ ($k \geq 4$).

More general results have been established [Jen93]. Given two sequences $p' = (p_k \mid 3 \leq k \neq 6)$ and $v' = (v_k \mid k > 3)$ of nonnegative integers such that the equation (21.3.2) is satisfied for a given genus g , let $E(p', v'; g)$ denote the set of integers $p_6 \geq 0$ such that $(p_k)_{k \geq 3}$ and $(v_k)_{k \geq 3}$, with $v_3 := (\sum_{k \geq 3} kp_k - \sum_{k \geq 4} kv_k)/3$ determined by (21.3.1), are the p -sequences and v -sequences, respectively, of a polyhedral map of genus g . For all but two admissible triples (p', v', g) , the set $E(p', v'; g)$ is known up to a finite number of elements. For example, for $g = 0$, the set $E(p', v'; 0)$ is nonempty if and only if $\sum_{k \not\equiv 0 \pmod{3}} v_k \neq 1$ or $p_k \neq 0$ for at least one odd k . In particular, for each such nonempty set, there exists a constant c depending on (p', v') such that $E(p', v'; 0) = \{j \mid c \leq j\}$, $\{j \mid c \leq j \equiv 0 \pmod{2}\}$, or $\{j \mid c \leq j \equiv 1 \pmod{2}\}$. Similarly, for each triple with $g \geq 2$, there is a constant c depending on (p', v', g) such that $E(p', v'; g) = \{j \mid c \leq j\}$. There are analogous results for sequences $(p_k \mid 3 \leq k \neq 4)$ and $(v_k \mid 3 \leq k \neq 4)$ that satisfy the equation (21.3.3) or other related equations.

For $g = 1$ there is also a more geometric Eberhard-type result available, which requires the polyhedral map M to be polyhedrally embedded in $\mathbb{R}^3$:

THEOREM 21.3.2 [Gri83]

Let s, p_k ($k \geq 3, k \neq 6$) be nonnegative integers. Then there exists a toroidal polyhedral 2-manifold M in $\mathbb{R}^3$ with $p_k(M) = p_k$ ($k \neq 6$) and $\sum_{k \geq 3} (k - 3)v_k(M) = s$ if and only if $\sum_{k \geq 3} (6 - k)p_k = 2s$ and $s \geq 6$.

Also, for toroidal polyhedral 2-manifolds in $\mathbb{R}^3$ (as well as for convex 3-polytopes), the exact range of possible f -vectors is known [Grü67, BW93].

THEOREM 21.3.3

A polyhedral embedding in $\mathbb{R}^3$ of some torus with f -vector (f_0, f_1, f_2) exists if and only if $f_0 - f_1 + f_2 = 0$, $f_2(11 - f_2)/2 \leq f_0 \leq 2f_2$, $f_0(11 - f_0)/2 \leq f_2 \leq 2f_0$, and $2f_1 - 3f_0 \geq 6$.

For generalizations of Eberhard's theorem to tilings of the Euclidean plane, see also [GS87].

21.4 REGULAR MAPS

Regular maps are topological analogues of the ordinary regular polyhedra and star-polyhedra on surfaces. Historically they became important in the context of transformations of algebraic equations and representations of algebraic curves in homogeneous complex variables. There is a large body of literature on regular maps and their groups. The classical text is Coxeter and Moser [CM80]. For a recent text see McMullen and Schulte [MS02].

GLOSSARY

(Combinatorial) automorphism: An incidence-preserving bijection (of the set of vertices, edges, and faces) of a map M on a surface S to itself. The **(combinatorial automorphism) group** $A(M)$ of M is the group of all such bijections. It can be “realized” by a group of homeomorphisms of S .

Regular map: A map M on S whose group $A(M)$ is transitive on the flags (incident triples consisting of a vertex, an edge, and a face) of M .

GENERAL RESULTS

Each regular map M is of type $\{p, q\}$ for some finite p and q . Its group $A(M)$ is transitive on the vertices, the edges, and the faces of M . In general, the Schläfli symbol $\{p, q\}$ does not determine M uniquely. The group $A(M)$ is generated by involutions ρ_0, ρ_1, ρ_2 such that the **standard relations**

$$\rho_0^2 = \rho_1^2 = \rho_2^2 = (\rho_0\rho_1)^p = (\rho_1\rho_2)^q = (\rho_0\rho_2)^2 = 1$$

hold, but in general there are also further independent relations. Any triangle in the “barycentric subdivision” (order complex) of M is a fundamental region for $A(M)$ on the underlying surface S ; see [Section 21.1](#). For any fixed such triangle, we can take for ρ_i the “combinatorial reflection” in its side opposite to the vertex that corresponds to an i -dimensional element of M . The set of standard relations gives a presentation for the symmetry group of the regular tessellation $\{p, q\}$ on the 2-sphere, in the Euclidean plane, or in the hyperbolic plane, whichever is the universal covering of M . See [Figure 21.5.1](#) (a) for a conformal (hyperbolic) drawing of the Dyck map (shown also in [Figure 21.1.1](#)) with a fundamental region shaded. The identifications on the boundary of the drawing are indicated by letters.

For orientable surfaces S , the regular maps are known for genus $g \leq 6$. Up to isomorphism, if $g = 0$, there are just the Platonic solids (or regular spherical tessellations) $\{3, 3\}$, $\{3, 4\}$, $\{4, 3\}$, $\{3, 5\}$, and $\{5, 3\}$. For $g = 1$, there are three infinite families of torus maps of type $\{3, 6\}$, $\{6, 3\}$, and $\{4, 4\}$, each a quotient of the corresponding Euclidean universal covering tessellations $\{3, 6\}$, $\{6, 3\}$, and $\{4, 4\}$, respectively. For $g \geq 2$, the universal covering tessellation $\{p, q\}$ is hyperbolic and there are only finitely many regular maps on a surface of genus g . The latter follows from the **Hurwitz formula** $|A(M)| \leq 84|\chi|$ (or from the inequality 21.1.1), where χ is the Euler characteristic of S . Each regular map on a nonorientable surface is

doubly covered by a regular map of the same type on an orientable surface, and this covering map is unique [Wil78].

Generally speaking, given M , the topology of S is reflected in the relations that have to be added to the standard relations to obtain a presentation for $A(M)$. Conversely, many interesting regular maps can be constructed by adding certain kinds of extra relations for the group. Two examples are the regular maps $\{p, q\}_r$ and $\{p, q|r\}$ obtained by adding the extra relations $(\rho_0\rho_1\rho_2)^r = 1$ or $(\rho_0\rho_1\rho_2\rho_1)^r = 1$, respectively. Often these are “infinite maps” on noncompact surfaces, but there are also many (finite) maps on compact surfaces. The Dyck map $\{3, 8\}_6$ and the famous **Klein map** $\{3, 7\}_8$ (with group $PGL(2, 7)$) are both of genus 3 and of the first kind, while the so-called regular skew polyhedra in Euclidean 3-space or 4-space are of the second kind. For more details and further interesting classes of regular maps, see [CM80, MS02] and [Chapter 19](#) of this Handbook. In Section 21.5 we shall discuss polyhedral embeddings of regular maps in ordinary 3-space.

The rotation subgroup (orientation preserving subgroup) of the group of an orientable regular map (of type $\{3, 7\}$ or $\{7, 3\}$) that achieves equality in the Hurwitz formula is also called a **Hurwitz group**. The Klein map is the regular map of smallest genus whose rotation subgroup is a Hurwitz group [Con90].

21.5 SYMMETRIC POLYHEDRA

Traditionally, much of the appeal of polyhedral 2-manifolds comes from their combinatorial or geometric symmetry properties. For surveys on symmetric polyhedra in $\mathbb{R}^3$ see Schulte and Wills [SW91], Bokowski and Wills [BW88], and Brehm and Wills [BW93].

GLOSSARY

Combinatorially regular: A polyhedral 2-manifold (or polyhedron) P is combinatorially regular if its combinatorial automorphism group $A(P)$ is flag-transitive (or, equivalently, if the underlying polyhedral map is a regular map).

Equivelar: A polyhedral 2-manifold (or polyhedron) P is equivelar of type $\{p, q\}$ if all its 2-faces are convex p -gons and all its vertices are q -valent.

GENERAL RESULTS

See Section 21.4 for results about regular maps. Up to isomorphism, the Platonic solids are the only combinatorially regular polyhedra of genus 0. For the torus, each regular map that is a polyhedral map also admits an embedding in $\mathbb{R}^3$ as a combinatorially regular polyhedron. Much less is known for maps of genus $g \geq 2$. Two infinite sequences of combinatorially regular polyhedra have been discovered, one consisting of polyhedra of type $\{4, q\}$ ($q \geq 3$) and the other of their duals of type $\{q, 4\}$. These are polyhedral embeddings of the maps M_q and their duals mentioned in Section 21.2. Several famous regular maps have also been realized as polyhedra, including Klein’s $\{3, 7\}_8$, Dyck’s $\{3, 8\}_6$, and Coxeter’s $\{4, 6|3\}$, $\{6, 4|3\}$, $\{4, 8|3\}$, and $\{8, 4|3\}$ [SW85, SW91, BS89]. However, a complete classification of

combinatorially regular polyhedra is not within reach at present. See Figure 21.5.1 for an illustration of a polyhedral realization of Dyck's regular map $\{3, 8\}_6$ shown in Figure 21.1.1. (a) shows a conformal drawing of the Dyck map, with a fundamental region shaded, while (b) shows a maximally symmetric polyhedral realization.

FIGURE 21.5.1

Dyck's regular map:

(a) a conformal drawing, with fundamental region shaded;

(b) a symmetric polyhedral realization.

For a more general concept of polyhedra in $\mathbb{R}^3$ or higher-dimensional spaces, as well as an enumeration of the corresponding regular polyhedra, see Chapter 19 of this Handbook. The latter also contains a depiction of the polyhedral realization of $\{4, 8|3\}$.

Equivelarity is a local regularity condition. Each combinatorially regular polyhedron in $\mathbb{R}^3$ is equivelar. However, there are many other equivelar polyhedra. For sufficiently large genus g , for example, there are equivelar polyhedra for each of the types $\{3, q\}$ with $q = 7, 8, 9$; $\{4, q\}$ with $q = 5, 6$; and $\{q, 4\}$ with $q = 5, 6$ [BW93].

The symmetry group of a polyhedron can be much smaller than the combinatorial automorphism group of the underlying polyhedral map. In particular, the five Platonic solids are the only polyhedra in $\mathbb{R}^3$ with a flag-transitive symmetry group. However, even for higher genus (namely, for $g = 1, 3, 5, 7, 11$, and 19), polyhedra with a vertex-transitive symmetry group are known. Such a polyhedral torus is shown in Figure 21.5.2.

FIGURE 21.5.2

A vertex-transitive polyhedral torus.

Finally, if we relax the requirement that a polyhedron be free of self-intersections and allow more general “polyhedral realizations” of maps (for instance, polyhedral

immersions), then there is much more flexibility in the construction of “polyhedra” with high symmetry properties. The most famous examples are the Kepler-Poinsot star-polyhedra, but there are also many others. For more details see [SW91, BW88, BW93, MS02] and [Chapter 19](#) of this Handbook.

ALGORITHMS AND COMPLEXITY OF FUNDAMENTAL GEOMETRIC OBJECTS

22 CONVEX HULL COMPUTATIONS

Raimund Seidel

INTRODUCTION

The “convex hull problem” is a catch-all phrase for computing various descriptions of a polytope that is either specified as the convex hull of a finite point set in $\mathbb{R}^d$ or as the intersection of a finite number of halfspaces. We first define the various problems and discuss their mutual relationships (Section 22.1). We discuss the very special case of the irredundancy problem in Section 22.2. We consider general dimension d in Section 22.3 and describe the most common general algorithmic approaches along with the best run-time bounds achieved so far. In Section 22.4 we consider separately the case of small dimensions $d = 2, 3, 4, 5$. Finally, Section 22.5 addresses various issues related to the convex hull problem.

22.1 DESCRIBING CONVEX POLYTOPES AND POLYHEDRA

“Computing the convex hull” is a phrase whose meaning varies with the context. Consequently there has been confusion regarding the applicability and efficiency of various “convex hull algorithms.” We therefore first discuss the different versions of the “convex hull problem” along with versions of the “halfspace intersection problem” and how they are related via polarity.

CONVEX HULLS

The generic convex hull problem can be stated as follows: Given a finite set $S \subset \mathbb{R}^d$, compute a description of $P = \text{conv} S$, the **polytope** formed by the convex hull of S .

A convex polytope P can be described in many ways. In our context the most important descriptions are those listed below.

GLOSSARY

(See [Chapter 16](#) for basic concepts and results of polytope theory.)

Vertex description: The set of all vertices of P (specified by their coordinates).

Facet description: The set of all facets of P (specified by their defining linear inequalities).

Double description: The set of vertices of P , the set of facets of P , and the incidence relation between the vertices and the facets (specified by an incidence matrix).

Lattice description: The face lattice of P (specified by its *Hasse diagram* (cf.

below), with vertex and facet nodes augmented by coordinates and defining linear inequalities, respectively).

Boundary description: A triangulation of the boundary of P (specified by a simplicial complex, with vertices and maximal simplices augmented by coordinates and defining normalized linear inequalities, respectively).

Hasse diagram: A directed graph of an order relation that joins nodes a to b iff $a \leq b$ and there are no elements between a and b in the sense that if $a \leq c \leq b$ then either $c = a$ or $c = b$. For the face lattice the order relation is containment.

The five descriptions above assume that P is full-dimensional. If it is not, then a specification of the smallest affine subspace containing P has to be added to all but the vertex description.

These five descriptions make explicit to varying degrees the geometric information carried by polytope P and the combinatorial information of its facial structure. The vertex description and the facet description each carry only rudimentary geometric information about P . We therefore call them *purely geometric descriptions*. The other three descriptions we call *combinatorial* since they also carry more or less complete combinatorial information about the face structure of P . As a matter of fact, these three descriptions are equivalent in the sense that one can be computed from the other by purely combinatorial means, i.e., without the use of arithmetic operations on real numbers.

Which description is to be computed depends on the application at hand. It is important to keep in mind, however, that these descriptions can differ drastically in terms of their sizes (see [Section 22.3](#)).

INTERSECTION OF HALFSAPCES

Closely related to the convex hull problem is the *halfspace intersection* problem: Given a finite set H of halfspaces in $\mathbb{R}^d$, compute a description of the *polyhedron* $Q = \bigcap H$.

Convex polyhedra are more general objects than convex polytopes in that they need not be bounded. Consequently their descriptions are slightly more complicated. Every polyhedron Q admits a “factorization” $Q = L + C + R$, where L is a linear subspace orthogonal to C and R , the set C is a convex cone, and R is a convex polytope. The “vertex description” of Q then consists of a minimal set of vectors spanning L , the set of extreme rays of C , and the set of vertices of R . Our other four description methods for convex polytopes have to be adjusted accordingly in order to apply to polyhedra. Also, the triangulations appearing in the boundary description need to allow for unbounded simplices (this concept makes sense if one views a k -simplex as an intersection of $k + 1$ halfspaces).

Because polyhedra are more general than polytopes, all statements about the size differences among the various descriptions of the latter apply also to the former.

POLARITY

The relationship between computing convex hulls and computing the intersection of halfspaces arises because of *polarity* (Section 16.1.2). Let S be a finite set in $\mathbb{R}^d$ and let H_S be the set of halfspaces $\{h_p \mid p \in S\}$, with $h_p = \{x \mid \langle x, p \rangle \leq 1\}$. Let

$P = \text{conv}S$ and let $Q = \bigcap H_S$. Polarity yields a 1-1 correspondence between the k -faces of Q and the $(d-k)$ -faces of P that admit supporting hyperplanes having P and the origin strictly on the same side. In particular, if the origin is contained in the relative interior of P , then the face lattices of P and Q are anti-isomorphic.

It is thus easy to reduce a convex hull problem to a halfspace intersection problem: First translate S by $-\sum_{p \in S} p/|S|$ to insure that the origin is contained in the relative interior of P , and compute $Q = \bigcap H_S$ for the resulting H_S . The polytope Q is then the polar P^Δ of P , and, assuming that P is full-dimensional, we have straightforward correspondences between the vertex description of Q and the facet description of P , between the facet description of Q and the vertex description of P , between the double descriptions of Q and of P (reverse the roles of vertices and facets), and between the lattice descriptions of Q and P (reverse the order of the lattice). Note that there is *no* correspondence between the boundary descriptions. If P has dimension $l < d$ then $Q = Q' \times L$, where polytope Q' has dimension l and L is a linear subspace of dimension $d-l$. The indicated correspondences then hold between P and Q' .

Reducing a halfspace intersection problem to a convex hull problem is more difficult. Polarity assumes all halfspaces to be describable as $\{x \mid \langle a, x \rangle \leq 1\}$, which means they must strictly contain the origin. In general not all halfspaces in a set H will be of such a form. In order to achieve this form the origin must be translated to a point r that is contained in the interior of $Q = \bigcap H$. Determining such a point r requires solving a linear program. Moreover, such an r does not exist if Q is empty, in which case the halfspace intersection problem has a trivial solution, or if Q is not full-dimensional, in which case one has to perform some sort of dimension reduction.

In general, halfspace intersection appears to be a slightly more general and versatile problem, especially in a homogenized formulation, which very elegantly avoids various special cases (see, e.g., [MRTT53]). Nevertheless, we will concentrate exclusively on the convex hull problem. The stated results can be translated *mutatis mutandis* to the halfspace intersection problem. In many cases the algorithms can be “dualized” to apply directly to the halfspace intersection problem, or the algorithms were originally stated for the halfspace intersection problem and were “dualized” to the convex hull problem.

22.2 THE IRREDUNDANCY PROBLEM

GLOSSARY

Irredundancy problem: Given a set S of n points in $\mathbb{R}^d$, compute the vertex description of $P = \text{conv}S$.

$\lambda(n, d)$: The time to solve a linear programming problem in d variables with n constraints. $O(n)$ for fixed d (see [Chapter 45](#)).

This problem seeks to compute all points in S that are irredundant, in the sense that they cannot be represented as a convex combination of the remaining points in S . The equivalent polar formulation requires computation of the facet

description of $Q = \bigcap H$, given a set H of n halfspaces in $\mathbb{R}^d$. We will follow the primal formulation.

The flavor of this version of the convex hull problem is very different from the other versions. Testing whether a point $p \in S$ is irredundant amounts to solving a linear programming problem in d variables with $n - 1$ constraints. The straightforward method of successively testing points for irredundancy results in an algorithm with running time $O(n\lambda(n - 1, d))$, which for fixed dimension d is $O(n^2)$.

Clarkson [Cla94] and independently Ottmann et al. [OSS95] have ingeniously improved this method so that every linear program involves only at most V constraints, where V is the number of vertices of P , i.e., the output size. The resulting running time is $O(n\lambda(V, d))$, which for fixed d is $O(nV)$.

In each of these two methods the n linear programs that occur are closely related to each other. This can be exploited, at least theoretically, by using data structures for so-called linear programming queries [Mat93, Cha96a, Ram00]. This was first done by Matoušek for the naive method [Mat93], and then by Chan for the improved method [Cha96], resulting for fixed $d > 3$ in an asymptotic time bound of

$$O(n \log^{d+2} V + (nV)^{1-1/(\lfloor d/2 \rfloor + 1)} \log^{O(1)} n).$$

Finally, note that for the small-dimensional case $d = 2, 3$ there are even algorithms with running time $O(n \log V)$ (see [Chapter 38](#)), which can be shown to be asymptotically worst-case optimal [KS86].

22.3 COMPUTING COMBINATORIAL DESCRIPTIONS

GLOSSARY

Facet enumeration problem: Compute the facet description of $P = \text{conv}S$, given S .

Vertex enumeration problem: Compute the vertex description of $Q = \bigcap H$, given H .

The facet and vertex enumeration problems are classical and were already considered as early as 1824 by Fourier (see [Sch86, pp. 209–225] for a survey). Interestingly, no *efficient* algorithm is known that solves these enumeration problems without also computing, besides the desired purely geometric description, some combinatorial description of the polyhedron involved. Consequently we now concentrate on computing combinatorial descriptions.

THE SIZES OF COMBINATORIAL DESCRIPTIONS

It is important to understand how the three combinatorial descriptions differ in terms of their sizes. Let S be a set of n points in $\mathbb{R}^d$ and let $P = \text{conv}S$. Assume that P is a d -polytope and that it has m facets. As a consequence of McMullen's Upper Bound Theorem ([Chapter 16](#)) and of polarity, the following inequalities hold

between n and m and are tight:

$$n \leq \mu(d, m) \quad \text{and} \quad m \leq \mu(d, n),$$

where

$$\mu(d, x) = f_{d-1}(C_d(x)) = \binom{x - \lceil d/2 \rceil}{\lfloor d/2 \rfloor} + \binom{x - 1 - \lceil (d-1)/2 \rceil}{\lfloor (d-1)/2 \rfloor},$$

which is $\Theta(x^{\lfloor d/2 \rfloor})$ for fixed d .

For the sake of definiteness let us define the sizes of the various descriptions as follows. For the double description of P it is the number of vertex-facet incidences, for the lattice description it is the total number of faces (of all dimensions) of P , and for the boundary description it is the number of $(d-1)$ -simplices in the boundary triangulation.

Note that for the double and the lattice descriptions the sizes are completely determined by P , whereas the size of a boundary description depends on the boundary triangulation that is actually used. The sizes of those triangulations for a given P can vary quite drastically, even if, as we assume from now on, all vertices of the triangulation must be from S .

These size measures are only crude approximations of the space required to store such descriptions in memory (in particular, in case of the lattice description the edges of the Hasse diagram are completely ignored). However, these approximations suffice to convey the possible similarities and differences between the sizes of the different descriptions.

For such a comparison between the description sizes of $P = \text{conv}S$ consider Table 22.3.1, whose columns deal with three cases. The first column lists worst-case upper bounds in terms of n and d . The second columns lists upper bounds in terms of m and d under the assumption that S is in nondegenerate position, i.e., no $d+1$ points in S lie in a common hyperplane, which means that P must be simplicial. Note that in this case there is a unique boundary description. Finally, the third column lists asymptotic bounds (d fixed) for *products of cyclic polytopes* $CC_d(n)$, a certain class of highly degenerate polytopes described in [ABS97]. (See Section 13.1 for a discussion of cyclic polytopes.) In this third table column, $\delta = \lfloor \sqrt{d/2} \rfloor$

TABLE 22.3.1 Polytope description sizes.

DESCRIPTION	WORST CASE	NONDEGENERATE	DEGENERATE CLASS $CC_d(n)$
Double	$d \cdot \mu(d, n)$	$d \cdot m$	$\Theta(n \cdot m^{1-1/\delta})$
Lattice	$2^d \cdot \mu(d, n)$	$2^d \cdot m$	$\Theta((n+m)^\delta)$
Boundary	$\mu(d, n)$	m	$\Omega((n+m)^\delta)$

The bounds in the table are based on the fact that all description sizes are maximized when P is a cyclic polytope, that each facet of a simplicial d -polytope contains 2^d faces, and that the Upper Bound Theorem also applies to simplicial spheres. The lower bound on the size of the boundary description of $CC_d(n)$ applies no matter which triangulation of the boundary is actually used.

The implication of this table is that in the worst case and also in the nondegenerate case all three combinatorial descriptions of P have approximately the same size. If d is considered constant, then the sizes are $\Theta(n^{\lfloor d/2 \rfloor})$ in the worst case, where n is the number of points in S (i.e., n is the input size), and the description sizes are $\Theta(m)$ in the nondegenerate case, where m is the number of facets of P (in a way the output size). The third column of the table, however, shows that in the general case the double description of a polytope P may be substantially more compact than the lattice description or the boundary description.

MAIN RESULTS AND OPEN PROBLEMS

The main positive results are that in the sense of asymptotic worst case complexity the convex hull problem has been solved completely, and that in the case of nondegenerate input, each of the three combinatorial descriptions can be found in time polynomial in the size of the input and the size of the output. In the case of general input this has only been shown for the lattice and for a boundary description, whereas it is unknown whether this is also possible for the double description.

In the following let $P = \text{conv}S$ be a d -polytope, and $|S| = n$.

THEOREM 22.3.1 *Chazelle* [Cha93]

If the dimension d is considered constant, then given S , each of the three combinatorial descriptions of $P = \text{conv}S$ can be computed in time $O(n \log n + n^{\lfloor d/2 \rfloor})$ using space $O(n^{\lfloor d/2 \rfloor})$. This is asymptotically worst-case optimal.

THEOREM 22.3.2 *Avis-Fukuda* [AF92]

Given S , a boundary description of $P = \text{conv}S$ can be computed in time $O(dnM)$ using space $O(dn)$, where M is the size of the boundary description produced.

If S is nondegenerate, then each of the three combinatorial descriptions of P can be computed in time $O(d^{O(1)}nM)$, where M is the size of the respective description.

THEOREM 22.3.3 *Swart* [Swa85] and *Chand-Kapur* [CK70]

Given S , the lattice description of $P = \text{conv}S$ can be computed in time and space polynomial in d , n , and the size of the output.

OPEN PROBLEM 22.3.4

Is there an algorithm that, given S , computes the double description of $P = \text{conv}S$ in time polynomial in d , n , and the size of the double description?

The algorithm in Chazelle's theorem appears to be of theoretical interest only. The algorithm of Avis-Fukuda is quite practical, the algorithms of Swart and of Chand and Kapur are less so because of the potentially large space requirements. (See [Chapter 52](#) for descriptions of available code.) The running times of the last two algorithms admit some theoretical improvements, as will be discussed in the following sections.

Almost all algorithms that have been published for solving the different versions of the convex hull problem and the halfspace intersection problem appear to be variations of three general methods: incremental, graph traversal, and divide-and-conquer. We discuss the incremental and the graph traversal methods in the next two subsections. Divide-and-conquer has proven useful only for very small

dimension, and we will discuss it in that context in Section 22.4. Methods that fall outside this threefold classification are discussed in Subsection 22.3.3.

22.3.1 THE INCREMENTAL METHOD

The incremental method puts the points in S in some order $p_1, \dots, p_n$ and then successively computes a description of $P_i = \text{conv} S_i$ from the description of P_{i-1} and p_i , where $S_i = \{p_1, \dots, p_i\}$.

Before discussing details it should be noted that no matter how the incremental method is implemented, it has a serious shortcoming in that the intermediate polytopes P_i may have many more facets than the final $P_n = P$ (see, e.g., [ABS97]). Thus the description sizes of the intermediate polytopes may be much larger than the size of the description of the final result, and hence this method cannot have running time that depends reasonably on the output size.

This is not necessarily just the result of an unfortunate choice of the insertion order, since Bremner [Bre99] has shown that if S is the vertex set of the aforementioned product of cyclic polytopes $CC_d(n)$, then P_{n-1} has $\Omega(m^{\lfloor \sqrt{d/2} \rfloor - 1})$ facets no matter which insertion order is used, where m is the number of facets of $P_n = P$.

We first present a selection of algorithms implementing the incremental method and list their asymptotic worst-case or expected running times for fixed d (Table 22.3.2). All these algorithms compute boundary descriptions, except for [Sei81] (see also [Ede87, Section 8.4]), which can also be made to compute a lattice description, and [MRTT53], which computes a double description.

TABLE 22.3.2 Sample of incremental algorithms.

ALGORITHM	TIME	BOUND TYPE
Kallay [PS85, Section 3.4.2]	$n^{\lfloor d/2 \rfloor + 1}$	worst-case
Seidel [Sei81]	$n \log n + n^{\lceil d/2 \rceil}$	worst-case
Chazelle [Cha93]	$n \log n + n^{\lfloor d/2 \rfloor}$	worst-case
Clarkson-Shor [CS89]	$n \log n + n^{\lfloor d/2 \rfloor}$	expected
Clarkson et al. [CMS93]	$n \log n + n^{\lfloor d/2 \rfloor}$	expected
Motzkin et al. [MRTT53]	$n^{3\lfloor d/2 \rfloor + 1}$	worst-case

We now concentrate on how P_{i-1} and P_i differ. For the sake of simplicity we will first assume that S is nondegenerate and hence all involved polytopes are simplicial. Moreover we will ignore how the insertion method starts and assume that P_{i-1} and P_i are full-dimensional. We say that a facet of P_{i-1} is **visible** (from p_i) if its supporting hyperplane separates P_{i-1} and p_i . Otherwise the facet is **obscured**.

The facet set of P_i consists of “old facets,” namely all obscured facets of P_{i-1} , and “new facets,” namely facets of the form $\text{conv}(R \cup \{p_i\})$, where R is a “horizon” ridge of P_{i-1} , i.e., R is contained in a visible and in an obscured facet of P_{i-1} .

Updating P_{i-1} to P_i thus requires solving three subproblems: finding (and deleting) all visible facets of P_{i-1} ; finding all horizon ridges; forming all new facets. The various incremental algorithms only differ in how they solve those subproblems, and they differ in the type of insertion order used.

Visible facets. The simplest way of finding the visible facets is simply to check each facet of P_{i-1} . This is done in Kallay’s “beneath-beyond” method [PS85, Section 3.4.2] and in the “double description method” of Motzkin et al. [MRTT53]. Since P_i may have $\Theta(i^{\lfloor d/2 \rfloor})$ facets such an approach automatically leads to a sub-optimal overall running time of $\Omega(n^{\lfloor d/2 \rfloor + 1})$ in the worst case.

Another way is to maintain “conflict lists” between facets and not yet inserted points. In the worst case this is no better than the previous method. However, if the insertion order is a random permutation of the points in S , then in expectation this method works in $O(n^{\lfloor d/2 \rfloor})$ time [CS89].

The last method requires the maintenance of a *facet graph*, whose nodes are the facets and whose arcs connect facets if they share a common ridge. The visible facets form a connected subgraph of this facet graph. Thus they can be determined by graph search, such as depth-first search. This takes time proportional to the number of visible facets, which means that in the amortized sense this takes no time since all those visible facets will be deleted. This graph search requires that one starting visible facet be known. Such an initial visible facet can be determined relatively efficiently by a special choice of the insertion order, as in [Sei81], by maintaining “canonical visible facets,” as in [CS89] and [CMS93], or by linear programming, as in [Sei91].

Horizon ridges. Determining the horizon ridges is trivial if the facet graph is used, since those ridges correspond to arcs connecting visible and obscured facets. Otherwise one has to use data structuring techniques to determine which of the ridges incident to the visible facets are incident to exactly one visible facet.

New facets. After the horizon ridges are determined, the new facets are easily constructed in time proportional to their number. Keeping this number small is one of the main difficulties of making the insertion method efficient. In the worst case there may be as many as $\mu(d-1, i-1) = \Theta(i^{\lfloor (d-1)/2 \rfloor})$ such new facets. For even d this is $\Theta(i^{\lfloor d/2 \rfloor - 1})$, which is the main reason why it was relatively easy to obtain an asymptotically worst-case optimal running time of $O(n^{\lfloor d/2 \rfloor})$ for even d [Sei81]. For general d , using a random insertion order [CS89, CMS93, Sei91] appears to be the only known way to keep this number low, at least in terms of expectation. Chazelle’s celebrated deterministic algorithm [Cha93] applies derandomization and thus in effect “simulates” random insertion order so that the number of new facets is not only small in the expected sense but also in the worst case.

Finally, if a facet graph is used, then the arcs corresponding to the ridges between the new facets need to be generated, which can be done via data structuring techniques, as in [Sei91], or by graph traversal techniques, as in [CS89, CMS93]. We should mention that if we remove the nondegeneracy assumption this problem of determining the new ridges seems to become very difficult.

Degenerate input. So far we have assumed that the input set S be nondegenerate. If this is not the case, then this can be simulated using perturbation techniques [Sei96]. This way the algorithms produce a boundary description from which a lattice description or a double description could be computed in $O(n^{\lfloor d/2 \rfloor})$ worst-case time.

The algorithm of Seidel [Sei81] (see also [Ede87, Section 8.4]) also works with degenerate input and then produces a lattice description. Most interesting, though, in the case of degeneracy is the so-called double description algorithm of Motzkin et al. [MRTT53].

THE DOUBLE DESCRIPTION METHOD

Although it is one of the oldest published incremental algorithms, this method has received little attention in the computational geometry community. This method maintains only the double descriptions of the polytopes P_i . It makes no assumptions about nondegeneracy. In fact, despite its poor worst-case complexity, empirically this method works well for degenerate inputs, where all other methods seem to fail, running out of time or space.

The algorithm determines the visible facets by simply checking all facets of P_{i-1} . The interesting point is how it determines the horizon ridges, from which the new facets are then constructed. In contrast to the other methods it does not maintain ridges, since, as we already mentioned, determining the new ridges created during an insertion is difficult. The double description method simply considers each pair of visible and obscured facets of P_{i-1} and checks whether their intersection A forms a horizon ridge. This is achieved by testing whether the vertex set in A is contained in some other facet of P_{i-1} . If it is, then A is not a ridge and hence not a horizon ridge.

A straightforward implementation of this idea will require $\Theta(i^{\lceil 3d/2 \rceil})$ time in the worst case to discover all horizon ridges of P_{i-1} , resulting in a high worst-case overall running time. Although a number of heuristics have been proposed to speed up this process (see [Zie94, p. 48]), experiments show that this method is unbearably slow in the nondegenerate case when compared to other algorithms. However, in the case of degenerate input it still appears to be the method of choice with the new primal-dual approach (Section 22.3.3) as a possible contender.

Finally, we should mention that convex hull algorithms based on so-called Fourier-Motzkin elimination are nothing but incremental algorithms dressed up in an algebraic formulation.

22.3.2 THE GRAPH TRAVERSAL METHOD

This method attempts to traverse the facet graph of polytope $P = \text{conv}S$ in an organized fashion. The basic step is: given a facet F of P and a ridge R contained in F , find the other facet F' of P that also contains R . Geometrically this amounts to determining the point $p \in S$ such that the hyperplane spanned by R and p maximizes the angle to F . In analogy to a 3D physical realization this operation is therefore known as a “gift-wrapping step,” and these algorithms are known as *gift-wrapping algorithms*. In the polar context of intersecting halfspaces, this step corresponds to moving along an edge from one vertex to another and is equivalent to a pivoting step of the simplex algorithm for linear programming. Thus these algorithms are also known as *pivoting algorithms*.

The basic outline of the graph traversal method is as follows: Find some initial facet of $P = \text{conv}S$ and the ridges that it contains. As long as there is an *open ridge* R , i.e., one for which only one containing facet F is known, perform a gift-wrapping step to discover the other facet F' containing R and determine the ridges that F' contains.

This general method faces three problems:

- (a) How does one maintain the set of open ridges?
- (b) How can the ridges of the new facet F' be quickly discovered?

- (c) How can an individual gift-wrapping step be performed quickly?

THE NONDEGENERATE CASE

Let us again first assume that the input set S is in nondegenerate position. This trivializes problem (b) since every facet is a $(d-1)$ -simplex and each of the d subsets with $d-1$ of its d vertices will span a ridge.

The most straightforward way to deal with problem (a) is to use some sort of dictionary data structure to store the set of open ridges. The most straightforward way to deal with (c) is to scan through all the points in S to find the best candidate, leading to work proportional to n per discovered facet. This straightforward method has been proposed many times (see [Sch86, p. 224] and [Chv83, p. 282] for references) and has running time $O(d^2nM)$ using $O(d(M+n))$ space, where M is the number of facets of P .

The gift-wrapping steps can be performed faster if a special data structure (for the dual of ray-shooting queries) is used. This was developed by Chan [Cha96], who achieved for fixed $d > 3$ an asymptotic time bound of

$$O(n \log M + (nM)^{1-1/(\lfloor d/2 \rfloor + 1)} \log^{O(1)} n).$$

Avis and Fukuda [AF92] proposed an ingenious way to deal with problem (a) so that no storage space is needed. They pointed out that there is a way of defining a canonical spanning tree T of the facet graph of polytope P so that the arcs of T can be recognized locally. Gift-wrapping steps are then performed only over ridges corresponding to arcs of T . Doing this in the form of a depth-first search traversal of T avoids the use of any extra storage space. Facets can be output as soon as they are discovered. Their algorithm is eminently practical and has a running time of $O(dnM)$ using only $O(dn)$ space.

In theory the gift-wrapping step improvement of Chan also could be applied to the algorithm of Avis and Fukuda. However, this appears to be of little practical relevance.

A completely different way of simultaneously addressing problems (a) and (c) was suggested by Seidel [Sei86a]. He proposed to try to discover the facets in an order corresponding to a straight-line shelling of P . In many cases gift-wrapping steps over several currently open ridges would yield the same new facet F' . However, in that case the entire vertex set of F' is known already and the expensive scan to solve problem (c) is not necessary. The facets of P for which this trick is not applicable can be discovered in advance by linear programming. This “shelling algorithm” has running time $O(n\lambda(n-1, d-1) + d^3M \log n)$, where $\lambda(n-1, d-1)$ is again the time necessary to solve a linear program with $n-1$ constraints in $d-1$ variables. From the way a shelling proceeds one can prove that the space requirement for storing the open ridges is somewhat lower than in an ordinary gift-wrapping algorithm.

The linear programs that need to be solved are similar to the ones in the irredundancy problem of Section 22.2. Again improvements can be achieved by applying linear programming queries ([Mat93]), and the $n\lambda(n-1, d-1)$ factor can be improved to $n^{2-2/(\lfloor d/2 \rfloor + 1)} \log^{O(1)} n$.

THE GENERAL CASE

There are two ways to approach the general case where P is not simplicial. The first is again to apply perturbations in order to simulate nondegeneracy of S . This

way all previously mentioned algorithms still apply, however they now compute a boundary description of P . The parameter M is now the size of the triangulation that happens to be constructed. Moreover, the perturbed computations slow down the running times by a polynomial factor in d .

The second way to deal with the general case is to generalize the algorithms so that they compute the lattice description of P . The main obstacle that must be overcome in the degenerate case is problem (b), the discovery of the ridges of a new facet F' . The obvious way to address this problem is to view the construction of F' as a recursive subproblem one dimension down. Some care must be taken however that in the many recursions small-dimensional faces are not reconstructed too often. This method was proposed by Chand and Kapur [CK70] and their algorithm was later improved and analyzed by Swart [Swa85] who showed a running time of $O(d^2 n K_1 + d^3 K_2 \log K_0)$, where K_i is the number of directed $(i+1)$ -vertex paths in the Hasse diagram of the face lattice of P .

Rote [Rot92] generalized the algorithm of Avis and Fukuda to produce the lattice description using little storage space. Its running time is $O(dK_{d+1}n)$ and it appears to be not as relevant in practice as the original algorithm.

Finally, Seidel [Sei86b] generalized his shelling algorithm to produce the lattice description in time $O(n\lambda(n-1, d-1) + K_2(d^2 + \log K_0))$. Because of the recursive nature of straight-line shellings, this generalization avoids reconstruction of small-dimensional faces. Again the improvement via linear programming queries applies.

22.3.3 OTHER METHODS

THE BRUTE-FORCE APPROACH

Let S be a set of n points in $\mathbb{R}^d$ and let $P = \text{conv}S$. Assume w.l.o.g. that the origin is contained in the interior of P (otherwise apply a translation) and assume that S is irredundant in the sense that every point in S is a vertex of P (otherwise apply the results of Section 22.2).

A set $T \subset S$ spans a face of P iff there is a halfspace that has T on its boundary and $S \setminus T$ in its interior. Algebraically this can be tested by determining

$$y_T = \max\{y \in \mathbb{R} \mid \exists x \in \mathbb{R}^d : \forall p \in T : \langle x, p \rangle = 1 \text{ and } \forall p \in S \setminus T : \langle x, p \rangle + y \leq 1\},$$

which can be computed via linear programming, and checking that $y_T > 0$.

This characterization immediately yields a straightforward algorithm with running time $O(2^n \lambda(n, d))$ for generating all faces and also the lattice description of P : Simply test each subset of S whether it spans a face of P . This brute-force approach can be substantially improved by applying backtrack-search techniques ([Bal61], [FLM97]). Fukuda et al. [FLM97] even achieve a running time of $O(nK_0 \lambda(n, d))$ this way, using just $O(dn)$ space. Unfortunately this backtrack-search approach does not seem to yield an efficient method to compute the double description of P .

THE PRIMAL-DUAL METHOD

Let S be a set of n points in $\mathbb{R}^d$, let $P = \text{conv}S$, and let $\mathcal{F}$ be the set of facets of P . Determining $\mathcal{F}$ from S is difficult if P is degenerate in the sense that it is not simplicial, i.e., its facets are not all simplices. However, in this case determining

S from $\mathcal{F}$ may not be so difficult. The primal-dual method [BFM98] of Bremner, Fukuda, and Marzetta tries to exploit this possibility, despite the fact that $\mathcal{F}$ is unknown and S is the input.

The basic idea of their algorithm is as follows: For a facet $F \in \mathcal{F}$, let H_F be the halfspace that has F on its boundary and contains P , and for $\mathcal{G} \subset \mathcal{F}$ let $H_{\mathcal{G}} = \{H_G | G \in \mathcal{G}\}$. Assume some $\mathcal{G} \subset \mathcal{F}$ is known already. Enumerate the vertices of the polyhedron $P_{\mathcal{G}} = \bigcap H_{\mathcal{G}} \supset P$. If all the vertices found are points in S and if $P_{\mathcal{G}}$ is bounded, then it must be the case that $P_{\mathcal{G}} = P$ and $\mathcal{G} = \mathcal{F}$ and all facets of P have been found, and we are done. If this is not the case (and this can be determined after at most $n+1$ vertices of $P_{\mathcal{G}}$ have been enumerated), then it is easy to find a point $v \in P_{\mathcal{G}} \setminus P$ (either a vertex not in S or a point on an extreme ray of $P_{\mathcal{G}}$). But now clearly $\mathcal{G} \neq \mathcal{F}$. Moreover it is easy to find a facet $G \in \mathcal{F} \setminus \mathcal{G}$ (or rather the halfspace H_G) that separates v from P . This amounts to performing the initial facet finding step of the gift-wrapping algorithm and can be done (without linear programming!) in $O(d^2n)$ time. Now add G to $\mathcal{G}$ and repeat.

The method suggests that the complexity of computing the facet description of a polytope P from its vertex description is related to the complexity of computing the vertex description from the facet description. It is difficult to make this theoretical statement precise without introducing assumptions about the intermediate polyhedra $P_{\mathcal{G}}$. However, on the practical side, the authors of [BFM98] present experimental evidence showing that the primal-dual method outperforms other algorithms in certain “degenerate” cases.

22.4 THE CASE OF SMALL DIMENSION

Convex hull computations in very small dimension are special. We have strong geometric intuitions about 2D and 3D space (and via Schlegel diagrams even about 4-polytopes). Moreover the situation is simpler in the case $d = 2, 3$ since our five polytope descriptions cannot differ much in terms of their sizes (they are all within a constant factor of each other), which means there is little need for keeping an exact distinction. Algorithmically, small dimensions are special in that besides the incremental and the graph traversal method, divide-and-conquer methods have also been brought to fruition.

THE 2-DIMENSIONAL CASE

The planar convex hull problem has drawn considerable attention and many different algorithmic paradigms have been tried (see textbooks such as [PS85] or [O’R98]). The graph traversal method was rediscovered and is known in the planar case as the *Jarvis march* with running time $O(nM)$, and the incremental method was rediscovered and is known in a rather different guise as the *Graham scan* with running time $O(n \log n)$ (as usual n and M are the sizes of the input and output, respectively). It was easy and natural to apply the divide-and-conquer paradigm to obtain further $O(n \log n)$ time algorithms. By giving this paradigm the extra twist of “marriage-before-conquest” it was possible even to obtain an $O(n \log M)$ algorithm, which was also shown to be worst-case optimal in the algebraic computation tree model of computation [KS86]. This algorithm required the use of

2D linear programming. Much later Chan, Snoeyink, and Yap [CSY97] showed how to avoid this and substantially simplified the algorithm in way that allowed its generalization to higher dimensions. Later Chan [Cha96] showed quite surprisingly that by using simple data structures and the method of guessing the output size by repeated squaring, the Jarvis march algorithm can be sped up to also run in time $O(n \log M)$.

THE 3-DIMENSIONAL CASE

In 3 dimensions the output size M is $O(n)$ in the worst case. However, the straightforward implementations of the standard incremental and the graph traversal methods only yield algorithms with worst-case running time $O(n^2)$. In this context the use of the divide-and-conquer paradigm was decisive in obtaining $O(n \log n)$ running time, which was achieved by Preparata and Hong (see [PS85, Section 3.4.4]; for a more detailed account, [Ede87, Section 8.5]). This running time was later matched in the expected sense by the randomized incremental algorithm of Clarkson and Shor [CS89], who also gave another randomized algorithm with expected performance $O(n \log M)$.

The question whether this optimal output-size sensitive bound could also be achieved deterministically was open for a long time. Edelsbrunner and Shi [ES91] first generalized the “marriage-before-conquest” method of [KS86] but achieved only a running time of $O(n \log^2 M)$. Eventually Chazelle and Matoušek [CM92] succeeded in derandomizing the randomized algorithm of Clarkson and Shor and obtained, at least theoretically, this optimal $O(n \log M)$ time bound. Later Chan [Cha96] showed that there is a relatively simple algorithm for achieving this bound, again by the method of speeding up the gift-wrapping method using data structures and guessing the output size by repeated squaring.

THE CASE $d = 4, 5$

In this case the sizes of the combinatorial descriptions may be as large as $\Theta(n^2)$. All the methods and bounds mentioned in Section 22.3 apply. In addition there are methods for computing a boundary description based on sophisticated divide-and-conquer and some additional pruning mechanisms. Worst-case time bounds of $O((n + M) \log^{d-2} M)$ were achieved by Chan, Snoeyink, and Yap [CSY97] for $d = 4$, and by Amato and Ramos [AR96] for $d = 4, 5$. The latter paper also states that their bound applies to computing the lattice description in the case $d = 4$.

22.5 RELATED TOPICS

There has been some work on determining the intrinsic computational complexity of versions of the convex hull problem. The strongest results at this point are:

1. For fixed $d \geq 2$ the time necessary to determine whether exactly V of n points in $\mathbb{R}^d$ are extreme is $\Omega(n \log V)$ in the algebraic computation tree model [KS86]. This is asymptotically best possible for $d = 2$.

2. For fixed $d \geq 2$ the time necessary to determine whether the convex hull of n points in $\mathbb{R}^d$ has exactly M facets is $\Omega(n^{\lceil d/2 \rceil - 1} + n \log n)$ in a specialized but realistic model of computation [E99]. This is asymptotically best possible for odd $d > 1$.

The expected sizes of convex hulls of point sets drawn according to some statistical distribution are typically much smaller than the worst-case sizes. Constructing such convex hulls has been explicitly studied by several authors (see, e.g., [DT81, Dwy91, BGJR91]). One should also mention in this context the randomized incremental algorithm [CS89]. With input set $S \subset \mathbb{R}^d$ its expected running time for constructing a boundary description is

$$O \left(\sum_{d+1 < r \leq n} df_r(S)/r + \sum_{d+1 \leq r < n} d^2 n f_r(S)/r^2 \right),$$

where $f_r(S)$ is the expected size of the boundary description of the convex hull of a random subset of S of size r . For many distributions f_r is sufficiently sublinear so that this randomized incremental algorithm has $O(n)$ expected running time.

The problem of maintaining convex hulls under insertions and deletions of points has been addressed also. In higher dimensions randomized incremental algorithms have been adapted by several authors to process updates [Mul94, Sch91, CMS93]. However, the analyses are all based on some probabilistic model of which updates actually occur. More satisfactory solutions have only been obtained in the planar case. Solutions with $O(\log n)$ update time were obtained for the insertions only case (see [PS85, Section 3.3.6]) and also for the deletions only case [HS92]. For the general dynamic case $O(\log^2 n)$ update times were achieved early on [OvL81, Gow80], and only very recently they were improved to $O(\log n)$ in [Cha01, BJ02].

For some time there was hope that additional input information might help compute convex hulls. Although this is true in the planar case, where having points presorted or having them given along a nonintersecting polygonal line [Mel87] leads to linear-time algorithms, it has been shown [Sei85] that for dimension $d \geq 3$ such additional information does not help. Having a 3D set S presorted or even knowing a nonself-intersecting polyhedral surface whose vertex set is S does not in general make it easier to find the convex hull of S .

There have been some attempts to generalize the convex hull construction problem so that the input S does not consist of points but of more general objects such as algebraically described regions in the plane [BK91, NY98], balls in $\mathbb{R}^d$ [BCD⁺92], ellipsoids in $\mathbb{R}^3$ [Wol02], or sets of polyhedra [FLL01].

Finally, parallel algorithms for the convex hull problem have been developed; see [Chapter 42](#).

23 VORONOI DIAGRAMS AND DELAUNAY TRIANGULATIONS

Steven Fortune

INTRODUCTION

The Voronoi diagram of a set of sites partitions space into regions, one per site; the region for a site s consists of all points closer to s than to any other site. The dual of the Voronoi diagram, the Delaunay triangulation, is the unique triangulation such that the circumsphere of every simplex contains no sites in its interior. Voronoi diagrams and Delaunay triangulations have been rediscovered or applied in many areas of mathematics and the natural sciences; they are central topics in computational geometry, with hundreds of papers discussing algorithms and extensions.

Section 23.1 discusses the definition and basic properties in the usual case of point sites in $\mathbb{R}^d$ with the Euclidean metric, while Section 23.2 gives basic algorithms. Some of the many extensions obtained by varying metric, sites, environment, and constraints are discussed in Section 23.3. Section 23.4 finishes with some interesting and nonobvious structural properties of Voronoi diagrams and Delaunay triangulations.

GLOSSARY

Site: A defining object for a Voronoi diagram or Delaunay triangulation. Also generator, source, Voronoi point.

Voronoi face: The set of points for which a single site is closest (or more generally a set of sites is closest). Also Voronoi region, Voronoi cell.

Voronoi diagram: The set of all Voronoi faces. Also Thiessen diagram, Wigner-Seitz diagram, Blum transform, Dirichlet tessellation.

Delaunay triangulation: The unique triangulation of a set of sites such that the circumsphere of each full-dimensional simplex has no sites in its interior.

23.1 POINT SITES IN THE EUCLIDEAN METRIC

See [Aur91, Ede87, For95] for more details and proofs of material in this section.

GLOSSARY

Sites: Points in a finite set S in $\mathbb{R}^d$.

Voronoi face of a site s : The set of all points of $\mathbb{R}^d$ strictly closer to the

FIGURE 23.1.1

Voronoi diagram and Delaunay triangulation of the same set of sites in two dimensions (a,b) and three dimensions (c,d).

site $s \in S$ than to any other site in S . The Voronoi face of a site is always a nonempty, open, convex, full-dimensional subset of $\mathbb{R}^d$.

Voronoi face $V(T)$ of a subset T : For T a nonempty subset of S , the set of points of $\mathbb{R}^d$ equidistant from all members of T and closer to any member of T than to any member of $S \setminus T$.

Voronoi diagram of S : The collection of all nonempty Voronoi faces $V(T)$, for $T \subseteq S$. The Voronoi diagram forms a cell complex partitioning $\mathbb{R}^d$. In two dimensions (Figure 23.1.1(a)), the Voronoi face of a site is the interior of a convex, possibly infinite polygon; its boundary consists of **Voronoi edges** (1-dimensional faces) equidistant from two sites and **Voronoi vertices** (0-dimensional faces) equidistant from at least three sites. Figure 23.1.1(c) shows a Voronoi diagram in three dimensions.

Delaunay face $D(T)$ of a subset T : The Delaunay face $D(T)$ is defined for a subset T of S whenever there is a sphere through all the sites of T with all other sites exterior (equivalently, whenever $V(T)$ is not empty). Then $D(T)$ is the (relative) interior of the convex hull of T . For example, in two dimensions (Figure 23.1.1(b)), a **Delaunay triangle** is formed by three sites whose circumcircle is empty and a **Delaunay edge** connects two sites that have an empty circumcircle (in fact, infinitely many empty circumcircles).

Delaunay triangulation of S : The collection of all Delaunay faces. The Delaunay triangulation forms a cell complex partitioning the convex hull of S .

There is an obvious one-one correspondence between the Voronoi diagram and the Delaunay triangulation; it maps the Voronoi face $V(T)$ to the Delaunay face $D(T)$. This correspondence has the property that the sum of the dimensions of $V(T)$ and $D(T)$ is always d . Thus, in two dimensions, $V(T)$ is a Voronoi vertex iff $D(T)$ is an open polygonal region; $V(T)$ is an edge iff $D(T)$ is; $V(T)$ is an open polygonal region iff $D(T)$ is a vertex, i.e., a site. In fact, the 1–1 correspondence is a duality between cell complexes, reversing face ordering: for subsets $T, T' \subseteq S$, $V(T')$ is a face of $V(T)$ iff $D(T)$ is a face of $D(T')$.

The set of sites $S \subseteq \mathbb{R}^d$ is in **general position** (or is **nondegenerate**) if no $d+2$ points lie on a common d -sphere and no $k+2$ points lie on a common k -flat, for $k < d$. If S is in general position, then the Delaunay triangulation of S is a simplicial complex, and every vertex of the Voronoi diagram is incident to $d+1$ edges in the Delaunay triangulation. If S is not in general position, then Delaunay faces need

not be simplices; for example, the four cocircular sites in Figure 23.1.1(b) form a Delaunay quadrilateral. A **completion** of a Delaunay triangulation is obtained by splitting nonsimplicial faces into simplices without adding new vertices.

RELATION TO CONVEXITY

There is an intimate connection between Delaunay triangulations in $\mathbb{R}^d$ and convex hulls in $\mathbb{R}^{d+1}$, and between Voronoi diagrams in $\mathbb{R}^d$ and halfspace intersections in $\mathbb{R}^{d+1}$. To see the connections, consider the special case of $d = 2$. Identify $\mathbb{R}^2$ with the plane spanned by the first two coordinate axes of $\mathbb{R}^3$, and call the third coordinate direction the *vertical* direction.

The **lifting map** $\lambda : \mathbb{R}^2 \rightarrow \mathbb{R}^3$ is defined by $\lambda(x_1, x_2) = (x_1, x_2, x_1^2 + x_2^2)$; $\Lambda = \lambda(\mathbb{R}^2)$ is a paraboloid of revolution about the vertical axis. See Figure 23.1.2(a). Let H be the convex hull of the lifted sites $\lambda(S)$.

The Delaunay triangulation of S is exactly the orthogonal projection into $\mathbb{R}^2$ of the lower faces of H (a face is **lower** if it has a supporting plane with inward normal having positive vertical coordinate). To see this informally, suppose that triangle $\lambda(s)\lambda(t)\lambda(u)$ is a lower facet of H , and that plane P passes through $\lambda(s)\lambda(t)\lambda(u)$. The intersection of P with Λ is an ellipse that projects orthogonally to a circle in $\mathbb{R}^2$ (Figure 23.1.2(a)). Since all other lifted sites are above the plane, all other unlifted sites are outside the circle, and stu is a Delaunay triangle. The opposite direction, that a Delaunay triangle is a lower facet, is similar.

For Voronoi diagrams, assign to each site $s = (s_1, s_2)$ the plane

$$P_s = \{(x_1, x_2, x_3) : x_3 = -2x_1s_1 + s_1^2 - 2x_2s_2 + s_2^2\}.$$

Let I be the intersection of the lower halfspaces of the planes P_s . The Voronoi diagram is exactly the orthogonal projection into $\mathbb{R}^2$ of the upper faces of I . To

FIGURE 23.1.2

(a) The intersection of a plane with Λ is an ellipse that projects to a circle; (b) on any vertical line, the surfaces $\{D_s\}$ appear in the same order as the planes $\{P_s\}$.

see this informally, consider the surfaces

$$D_s = \{(x_1, x_2, x_3) : x_3 = ((x_1 - s_1)^2 + (x_2 - s_2)^2)\}$$

(see Figure 23.1.2). Viewed as a function from $\mathbb{R}^2$ into R , D_s gives the squared distance to site s . Furthermore, P_s and D_s differ only by the quadratic term $x_1^2 + x_2^2$, which is independent of s . Hence a point $x \in \mathbb{R}^2$ is in the Voronoi cell of site t iff on the vertical line through x , D_t is lowest among all surfaces $\{D_s\}$. This happens exactly if, on the same line, P_t is lowest among all planes $\{P_s\}$, i.e., x is in the projection of the upper face of I formed by P_t .

COMBINATORIAL COMPLEXITY

In dimension 2, a Voronoi diagram of $n \geq 3$ sites has at most $2n - 5$ vertices and $3n - 6$ edges (and the Delaunay triangulation has at most as many triangles and edges, respectively).

In dimension $d \geq 3$ the Voronoi diagram and Delaunay triangulation can have $\Theta(n^{\lceil d/2 \rceil})$ faces. Exact bounds can be given using results from convex polytope theory (section 15). For n sites in d dimensions, the maximum number of Voronoi k -dimensional faces, $k < d$, is $f_{n-k}(C_{d+1}(n)) - \delta_{0k}$, where $C_{d+1}(n)$ is the $d+1$ -dimensional cyclic polytope, f_{n-k} gives the number of $n-k$ dimensional faces (see Section 18.3 and Theorem 18.3.4), and $\delta_{0k} = 1$ if $k = 0$ and 0 otherwise.

For a simple lower bound example in dimension 3, choose $n/2$ distinct point sites on each of two noncoplanar line segments l and l' . Then there is an empty sphere through each quadruple of sites (a, a', b, b') with a, a' adjacent on l and b, b' adjacent on l' . Since there are $\Omega(n^2)$ such quadruples, there are as many Delaunay tetrahedra (and Voronoi vertices).

If point sites are chosen uniformly at random from inside a sphere, then the expected number of faces is linear in the number of sites. In dimension 2, the expected number of Delaunay triangles is $2n$; in dimension 3, the expected number of Delaunay tetrahedra is $\sim 6.77n$; in dimension 4, the expected number of Delaunay 4-simplices is $\sim 31.78n$ [Dwy91]. Similar bounds probably hold for other distributions, but proofs are lacking.

Subquadratic bounds on the complexity of the Delaunay triangulation of point sites in R^3 can be obtained in a few cases. The **spread (of points)** of a set of points is the ratio between largest and smallest interpoint distances. A point set in R^3 of size n with spread Δ can have at most $O(\Delta^3)$ Delaunay tetrahedra, for all $\Delta = O(\sqrt{n})$ [Eri02]. Thus if the point set is dense, i.e., has spread $O(n^{1/3})$, there are only $O(n)$ tetrahedra. Points chosen on a surface can also have subquadratic complexity. For example, if the surface is sufficiently continuous and satisfies mild genericity conditions, then any (ϵ, κ) -sample of n points on the surface has complexity $O(n \log n)$ [ABL03]. A set of points is an (ϵ, κ) -sample if for any point in the set, there is at least one and at most κ other points in the set within geodesic distance ϵ measured on the surface.

23.2 BASIC ALGORITHMS

Table 23.2.1 lists basic algorithms that compute the Delaunay triangulation of n point sites in $\mathbb{R}^d$ using the Euclidean metric. Using the connection with con-

vexity, any $(d+1)$ -dimensional convex hull algorithm can be used to compute a d -dimensional Delaunay triangulation; in fact the divide-and-conquer, incremental, and gift-wrapping algorithms are specialized convex hull algorithms. Running times are given both for worst-case inputs, and for inputs chosen uniformly at random inside a sphere, with expectation taken over input distribution. The Voronoi diagram can be obtained in linear time from the Delaunay triangulation, using the one-one correspondence between their faces. See [Aur91, Ede87, For95] for more citations. [Chapter 64](#) lists available implementations of Voronoi diagram algorithms.

TABLE 23.2.1 Delaunay Triangulation algorithms in the Euclidean metric for point sites.

ALGORITHM	DIM	WORST CASE	UNIFORM
Flipping	2	$O(n^2)$	
Plane sweep	2	$O(n \log n)$	
Divide-and-conquer	2	$O(n \log n)$	$O(n)$
Randomized incremental	2	$O(n \log n)$	
Randomized incremental	≥ 3	$O(n^{\lceil d/2 \rceil})$	$O(n \log n)$
Gift-wrapping	≥ 2	$O(n^{\lceil d/2 \rceil + 1})$	$O(n)$

THE RANDOMIZED INCREMENTAL ALGORITHM

The incremental algorithm adds sites one by one, updating the Delaunay triangulation after each addition. The update consists of discovering all Delaunay faces whose circumspheres contain the new site. These faces are deleted and the empty region is partitioned into new faces, each of which has the new site as a vertex. See Figure 23.2.1. An efficient algorithm requires a good data structure for finding the faces to be deleted. Then the running time is determined by the total number of face updates, which depends upon site insertion order. The bounds given in Table 23.2.1 are the expected running time of an algorithm that makes a random choice of insertion order, with each insertion permutation equally likely; the bounds for the worst-case insertion order are about a factor of n worse. (For uniform data there is a double expectation, over both insertion order and input distribution.) With additional algorithmic complexity, it is possible to obtain deterministic algorithms with the same worst-case running times [Cha91].

FIGURE 23.2.1

The addition of site s deletes four triangles and adds six (shown dashed).

THE PLANE SWEEP ALGORITHM

The plane sweep algorithm computes a planar Delaunay triangulation using a horizontal line that sweeps upward across the plane. The algorithm discovers a Delaunay triangle when the sweepline passes through the topmost point of its circumcircle; in Figure 23.2.2, the Delaunay triangles shown have already been discovered. A sweepline data structure stores an ordered list of sites; the entry for site s corresponds to an interval I_s on the sweepline where each maximal empty circle with topmost point in I_s touches site s . The sweepline moves in discrete steps only when the ordered list changes. This happens when a new site is encountered or when a new Delaunay triangle is discovered (at the topmost point of the circumcircle of three sites that are consecutive on the sweepline list). A priority queue is needed to determine the next sweepline move. The running time of the algorithm is $O(n \log n)$ since the sweepline moves $O(n)$ times—once per site and once per triangle—and it costs time $O(\log n)$ per move to maintain the priority queue and sweepline data structure.

FIGURE 23.2.2

The sweepline list is x, s, t, u, v, w, x . The next Delaunay triangle is tuv .

OTHER ALGORITHMS

The divide-and-conquer algorithm uses a splitting line to partition the point set into two equal halves, recursively computes the Delaunay triangulation of each half, and then merges the two subtriangulations in linear time. The gift-wrapping algorithm is a specialization of the convex-hull gift-wrapping algorithm (Chapter 19) to Delaunay triangulations. Output-sensitive algorithms, with running time approximately proportional to the actual number of Delaunay facets, have remained elusive [CSY95]. If the sites form the vertices of a convex polygon, then the Voronoi diagram can be computed in linear time [AGS89].

Graphics hardware, in particular Z-buffers, allow efficient practical computation of fixed-resolution approximate Voronoi diagrams for quite general sites and distance functions [HCK99].

23.3 EXTENSIONS

GLOSSARY

Order- k Voronoi diagram: The order- k Voronoi diagram partitions $\mathbb{R}^d$ on the basis of the first k closest sites (without distinguishing order among them).

Furthest site Voronoi diagram: The furthest site Voronoi diagram partitions $\mathbb{R}^d$ on the basis of the furthest site, or equivalently, the closest $n-1$ of n sites.

Constrained Delaunay triangulation: Constrained Delaunay triangulations are defined relative to a set of **constraint facets** that restrict visibility. The constrained Delaunay triangulation of a set of sites has the property that for every simplex, the interior of the simplex circumsphere contains no site visible from the interior of the simplex.

Conforming Delaunay triangulation: Fix a set of noncrossing **constraint facets** E and a set of point sites S . A conforming Delaunay triangulation is the Delaunay triangulation of a set of sites $S' \supseteq S$ so that every facet in E is the union of Delaunay faces of S' .

Power or Laguerre diagram: A Voronoi diagram for sites s_i with weights w_i where the distance from a point x is measured along a tangent to the sphere of radius $\sqrt{w_i}$ centered on s_i .

HIGHER-ORDER VORONOI DIAGRAMS

The order- k Voronoi diagram can be obtained as an appropriate projection of the k -level of an arrangement of hyperplanes (see [Ede87, For93] and Section 24.2 of this Handbook); it can also be obtained as the orthogonal projection of an intersection polytope [AS92]. In dimension 2, the order- k Voronoi diagram has $O(k(n-k))$ faces. In dimensions $d \geq 3$, the sum of the number of faces of the order- j diagrams, $j \leq k$, is $O(n^{\lceil d/2 \rceil} k^{\lfloor d/2 \rfloor + 1})$ [CS89]; finding good bounds for fixed k remains an open problem. See Table 23.3.1 for algorithm bounds.

TABLE 23.3.1 Algorithms for order- k Voronoi diagrams of point sites in the Euclidean metric.

PROBLEM	DIM	TIME
Furthest site	2	$O(n \log n)$
Furthest site	≥ 3	$O(n^{\lceil d/2 \rceil})$
Order- k	2	$O(k(n-k) \log n + n \log^3 n)$
Order- j , $1 \leq j \leq k$	≥ 3	$O(n^{\lceil d/2 \rceil} k^{\lfloor d/2 \rfloor + 1})$

CONSTRAINED DELAUNAY TRIANGULATIONS

Let S be a set of n point sites in $\mathbb{R}^2$ and E a set of noncrossing **constraint** edges with endpoints in S . A point $p \in \mathbb{R}^2$ is **visible** from a site s if the open segment ps does not intersect any edge of E . The **constrained Delaunay triangulation** (of S with respect to E) is a triangulation of S extending the edges in E so that the circumcircle of every triangle contains no site that is visible from the interior of the triangle. In $\mathbb{R}^2$ the constrained Delaunay triangulation always exists; it is as close as possible to the true Delaunay triangulation, subject to the constraint that the edges in E must be used. See also [Section 24.2](#).

The **bounded distance** from a site to a point is Euclidean distance if the point is visible, and infinite otherwise; the **bounded Voronoi diagram** of S using E is defined using bounded distance. The bounded Voronoi diagram is dual to a subgraph of the constrained Delaunay triangulation.

Both the constrained Delaunay triangulation and the bounded Voronoi diagram can be computed in time $O(n \log n)$ using either divide-and-conquer or the sweepline paradigm. If the sites and constraint edges are the vertices and edges of a simple polygon, respectively, then the constrained Delaunay triangulation can be computed in linear time [KL93].

The constrained Delaunay triangulation can be generalized to dimension $d > 2$. Let S be a set of point sites in $\mathbb{R}^d$ and E a set of $d-1$ -dimensional closed simplicial **constraint facets** with vertices in S that are noncrossing (the intersection of two constraint simplices is either empty or a face of both). A **constrained Delaunay triangulation** (of S with respect to E) is a triangulation such that constraint facets are triangulation facets and such that, for every d -simplex, the interior of the circumsphere of the simplex contains no site visible from the interior of the simplex. In dimension $d > 2$, a constrained Delaunay triangulation does not always exist; for example, the Schönhardt polyhedron in dimension 3 cannot be triangulated without extra Steiner points (see [Section 25.5](#)). Shewchuk [She98] gives a sufficient condition for the existence of constrained Delaunay triangulations: the constraint simplices must be **ridge-protected**, that is, each j -face of a constraint simplex, $j \leq d-2$, must have a closed circumsphere not containing any sites. Shewchuk [She00] gives an algorithm that will construct the constrained Delaunay triangulation when it exists, in time $O(ns)$, where n is the number of sites and s is the number of simplices in the output. He also gives a potentially simpler algorithm [She03] that transforms an unconstrained Delaunay triangulation into a constrained Delaunay triangulation by incrementally inserting constraint facets.

CONFORMING DELAUNAY TRIANGULATIONS

Let S be a set of point sites in $\mathbb{R}^d$ and E a set of noncrossing j -dimensional **constraint simplices**, $j < d$. A **conforming Delaunay triangulation** of E is the Delaunay triangulation of a set of sites $S' \supseteq S$ so that every simplex in E is the union of faces of Delaunay simplices of S' . In $\mathbb{R}^2$, Edelsbrunner and Tan [ET93] give an algorithm for conforming Delaunay triangulations, where the cardinality of S' is $O(n^3)$, n the cardinality of S . In $\mathbb{R}^3$, algorithms that result in a finite set S' are known [CVY02], without explicit bounds on its cardinality.

OTHER DISTANCE MEASURES

Table 23.3.2 lists Voronoi diagram algorithms where “distance” is altered. The distance from a site s_i to a point x can be a function of the Euclidean distance $e(s_i, x)$ and a site-specific real weight w_i .

TABLE 23.3.2 Algorithms for point sites in $\mathbb{R}^2$, other distance measures.

PROBLEM	DISTANCE TO x	TIME
Additive weights	$w_i + e(s_i, x)$	$O(n \log n)$
Multiplicative weights	$w_i e(s_i, x)$	$O(n^2)$
Laguerre or power	$\sqrt{e(s_i, x)^2 - w_i}$	$O(n \log n)$
L_p	$\ s_i - x\ _p$	$O(n \log n)$
Skew	$e(s_i, x) + \kappa \Delta_y(s_i, x)$	$O(n \log n)$
Convex distance function		$O(n \log n)$
Abstract	axiomatic	$O(n \log n)$
Simple polygon	geodesic	$O(n \log^2 n)$
Crystal growth	$w_i \cdot SP(s_i, x)$	$O(n^3 + nS \log S)$
Anisotropic	local metric tensor	$O(n^{2+\epsilon})$

The seemingly peculiar **power distance** [Aur87] is the distance from x to the sphere of radius $\sqrt{w_i}$ about s_i along a line tangent to the sphere. Many of the basic Voronoi diagram algorithms extend immediately to the power distance, even in higher dimension.

A (**polygonal**) **convex distance function** [CD85] is defined by a convex polygon C with the origin in its interior. The distance from x to y is the real $r \geq 0$ so that the boundary of $rC + x$ contains y . Polygonal convex distance functions generalize the L_1 and L_∞ metrics (C is a diamond or square, respectively); a polygonal convex distance function is a metric exactly if C is symmetric about the origin.

The (**skew**) **distance** [Aur99] between two points is the Euclidean distance plus a constant times the difference in y -coordinate. It can be viewed as a measure of the difficulty of motion on a plane that has been rotated in three dimensions about the x -axis.

An **abstract** Voronoi diagram [KMM93] is defined by the “bisectors” between pairs of sites, which must satisfy special properties.

The **geodesic** distance inside an environment of polygonal obstacles is the length of the shortest path that avoids obstacle interiors. Recent progress using the geodesic metric appears in [HS99].

The **crystal growth** Voronoi diagram [SD91] models crystal growth where each crystal has a different growth rate. The distance from a site s_i to a point x in the Voronoi face of s_i is $w_i \cdot SP(s_i, x)$, where w_i is a weight and $SP(s_i, x)$ is the shortest path distance lying entirely within the Voronoi face of s_i . The parameter S in the running time measures the time to approximate bisectors numerically.

An **anisotropic** Voronoi diagram [LS03] requires a metric tensor at each site to specify how distance is measured from that site. The anisotropic Voronoi diagram generalizes the multiplicatively weighted diagram; both have the property that the

region of a site may be disconnected or not simply-connected.

OTHER SITES

Many classes of sites besides points have been used to define Voronoi diagram and Voronoi-diagram-like objects. For example, the Voronoi diagram of a set of disjoint circles in the plane is just an additively-weighted point-site Voronoi diagram.

The Voronoi diagram of a set of n line segment sites in R^2 can be computed in time $O(n \log n)$ using the sweepline method or the divide-and-conquer method. The divide-and-conquer algorithm extends to circular-arc segments as well. The well-known medial axis of a polygon or polygonal region can be obtained from the Voronoi diagram of its constituent line segments. The medial axis of a simple polygon can be found in linear time, using the linear-time triangulation algorithm [AGS89].

The *straight skeleton* of a simple polygon [AA⁺95] is structurally similar to the medial axis, though it is not strictly a Voronoi diagram. It is defined as the trace of the vertices of the polygon, as the polygon is shrunk by translating each edge inward at a constant rate. Unlike the medial axis, it has only polygonal edges. Several algorithms achieve time and space bounds of roughly $O(nr)$, r the number of reflex vertices; a subquadratic worst-case bound is known [EE99].

The worst-case combinatorial and algorithmic complexity of Voronoi diagrams of general sites in three dimensions is not well understood. For many sites and metrics in R^3 , roughly cubic upper bounds on the combinatorial complexity of the Voronoi diagram can be obtained using the general theory of lower envelopes of trivariate functions (see [Chapter 24](#) on arrangements). Known lower bounds are roughly quadratic, and upper bounds are conjectured to be quadratic.

A specific long-standing open problem is to give tight bounds on the combinatorial complexity of the Voronoi diagram of a set of n lines in R^3 using the Euclidean metric. Roughly quadratic upper bounds are known if the lines have only a constant number of orientations [KS03]. The boundary of the union of infinite cylinders of fixed radius is also known to have roughly quadratic complexity [AS00]; this boundary can be viewed as the level set of the line Voronoi diagram at fixed distance.

Dwyer [Dwy97] shows that the expected complexity of the Euclidean Voronoi diagram of n k -flats in R^d is $\theta(n^{d/(d-k)})$, as long as $d \geq 3$ and $0 \leq k < d$. The flats are assumed to be drawn independently from the uniform distribution on k -flats intersecting the unit ball. Thus the expected complexity of the Voronoi diagram of a set of n lines in R^3 is $O(n^{3/2})$.

Voronoi diagrams in R^3 can be defined by convex distance functions, as in the plane. If the distance function is determined by a convex polytope with a constant number of facets, then the Voronoi diagram of a set of disjoint polyhedra has combinatorial complexity roughly quadratic in the total number of vertices of all polytopes [KS04].

KINETIC VORONOI DIAGRAMS

Consider a set of n moving point sites in R^d , where the position of each site is a continuous function of a real parameter t , representing time. In general the

Voronoi diagram of the points will vary continuously with t , without any change to its combinatorial structure; however at certain discrete values t_i , $i = 1, \dots$, the combinatorial structure will change. A *kinetic Voronoi diagram algorithm* determines times that the structure changes and at each change updates a data structure representation of the Voronoi diagram. An algorithm is known [AG⁺98] that requires linear space and $O(\log n)$ time per structural change. See [Chapter 50](#).

A long-standing open problem is to give tight bounds on the total number of changes to the Voronoi diagram when each site moves along a line at unit speed. The known upper bound is roughly cubic and the lower bound is roughly quadratic. This problem is clearly related to the problem of bounding the complexity of the Voronoi diagram of lines in R^3 , just mentioned above.

OTHER SURFACES

The Delaunay triangulation of a set of points on the surface of a sphere S^d has the same combinatorial structure as the convex hull of the set of points, viewed as sitting in R^{d+1} . On a closed Riemannian manifold, the Delaunay triangulation of a set of sites exists and has properties similar to the Euclidean case, as long as the set of sites is sufficiently dense [LL00, GM01].

MOTION PLANNING

The motion planning problem is to find a collision-free path for a robot in an environment filled with obstacles. The Voronoi diagram of the obstacles is quite useful, since it gives a lower-dimensional skeleton of maximal clearance from the obstacles. In many cases the shape of the robot can be used to define an appropriate metric for the Voronoi diagram. See [Section 47.2](#) for more on the use of Voronoi diagrams in motion planning.

SURFACE RECONSTRUCTION

The *surface reconstruction problem* is to construct an approximation to a two-dimensional surface embedded in R^3 , given a set of points sampled from the surface. A whole class of surface reconstruction methods are based on the computation of Voronoi diagrams [AB99, DG03] (see [Chapters 29](#) on reconstruction and [54](#) on surface simplification).

IMPLEMENTATIONS

There are a number of available high-quality implementations of algorithms that compute Delaunay triangulations and Voronoi diagrams of point sites in the Euclidean metric. These can be obtained from the web and from the algorithms libraries CGAL and LEDA (see [Chapters 64](#) and [65](#) on implementations). It is typically challenging to implement algorithms for sites other than points or metrics other than the Euclidean metric, largely because of issues of numerical robustness. See [Bur96, Hel01, SIII00] for approaches for line segment sites in the plane.

23.4 IMPORTANT PROPERTIES

ROUNDNESS

The Delaunay triangulation is “round,” that is, skinny simplices are avoided. This can be formalized in two dimensions by Lawson’s classic result: over all possible triangulations, the Delaunay triangulation maximizes the minimum angle of any triangle. No generalization using angles is known in higher dimension. However, define the *enclosing radius* of a simplex as the minimum radius of an enclosing sphere. In any dimension and over all possible triangulations of a point set, the Delaunay triangulation minimizes the maximum enclosing radius of any simplex [Raj94]. Also see [Section 25.4](#) on mesh generation.

OPTIMALITY

Fix a set S of sites in $\mathbb{R}^d$. For a triangulation T of S with simplices $t_1, \dots, t_n$, define

$$\begin{aligned} v_i &= \text{sum of squared vertex norms of } t_i \\ c_i &= \text{squared norm of barycenter of } t_i \\ a_i &= \text{volume of } t_i \\ s_i &= \text{sum of squared edge lengths of } t_i \\ r_i &= \text{circumradius of } t_i. \end{aligned}$$

Over all triangulations T of S , the Delaunay triangulation attains the unique minimum of the following functions, where κ is any positive real [Mus97]:

$$\begin{aligned} V(T) &= \sum_i v_i a_i \\ C(T) &= \sum_i c_i a_i \\ H(T) &= \sum_i s_i / a_i && d = 2 \text{ only} \\ R(T, \kappa) &= \sum_i r_i^\kappa && d = 2 \text{ only.} \end{aligned}$$

VISIBILITY DEPTH ORDERING

Choose a viewpoint v and a family of disjoint convex objects in $\mathbb{R}^d$. Object A is *in front of* object B from v if there is a ray starting at v that intersects A and then B in that order. Though an arbitrary family can have cycles in the “in front of” relation, the relation is acyclic for the faces of the Delaunay triangulation, for any viewpoint and any dimension [Ede90].

An application comes from computer graphics. The *painter's algorithm* renders 3D objects in back to front order, with later objects simply overpainting the image space occupied by earlier objects. A valid rendering order always exists if the “in front of” relation is acyclic, as is the case if the objects are Delaunay tetrahedra, or a subset of a set of Delaunay tetrahedra.

SUBGRAPH RELATIONSHIPS

The edges of a Delaunay triangulation form a graph DT whose vertices are the sites. In any dimension, the following subgraph relations hold:

$$EMST \subseteq RNG \subseteq GG \subseteq DT$$

where $EMST$ is the Euclidean minimum spanning tree, RNG is the relative neighborhood graph, and GG is the Gabriel graph. See [Section 51.2](#) on pattern recognition.

DILATION

A geometrically embedded graph G has *dilation* c if for any two vertices, the shortest path distance along the edges of G is at most c times the Euclidean distance between the vertices. In $\mathbb{R}^2$, the edge set of the Delaunay triangulation has dilation at most ~ 2.42 ; with an equilateral-triangle convex distance function, the dilation is at most 2.

INTERPOLATION

Suppose each point site $s_i \in S \subset \mathbb{R}^d$ has an associated function value f_i . For $p \in \mathbb{R}^d$ define $\lambda_i(p)$ as the proportion of the area of s_i 's Voronoi cell that would be removed if p were added as a site. Then the *natural neighbor* interpolant $f(p) = \sum \lambda_i(p)f_i$ is C^0 , and C^1 except at sites. This construction can be generalized to give a C^k interpolant, any fixed k [HS02].

Alternatively, for a triangulation of S in $\mathbb{R}^2$, consider the piecewise linear surface defined by linear interpolation over each triangle. Over all possible triangulations, the Delaunay triangulation minimizes the roughness of the resulting surface, where *roughness* is the square of the L_2 norm of the gradient of the surface, integrated over the triangulation [Rip90].

24 ARRANGEMENTS

Dan Halperin

INTRODUCTION

Given a finite collection $\mathcal{S}$ of geometric objects such as hyperplanes or spheres in $\mathbb{R}^d$, the *arrangement* $\mathcal{A}(\mathcal{S})$ is the decomposition of $\mathbb{R}^d$ into connected open cells of dimensions $0, 1, \dots, d$ induced by $\mathcal{S}$. Besides being interesting in their own right, arrangements of hyperplanes have served as a unifying structure for many problems in discrete and computational geometry. With the recent advances in the study of arrangements of curved (algebraic) surfaces, arrangements have emerged as the underlying structure of geometric problems in a variety of “physical world” application domains such as robot motion planning and computer vision. This chapter is devoted to arrangements of hyperplanes and of curved surfaces in low-dimensional Euclidean space, with an emphasis on combinatorics and algorithms.

In the first section we introduce basic terminology and combinatorics of arrangements. In Section 24.2 we describe substructures in arrangements and their combinatorial complexity. Section 24.3 deals with data structures for representing arrangements and with special refinements of arrangements. The following two sections focus on algorithms: algorithms for constructing full arrangements are described in Section 24.4, and algorithms for constructing substructures in Section 24.5. Situations where arrangements have lower complexity than the general worst-case bounds are presented in Section 24.6. In Section 24.7 we discuss the relation between arrangements and other structures. Several applications of arrangements are reviewed in Section 24.8. Section 24.9 deals with robustness issues when implementing algorithms and data structures for arrangements and Section 24.10 surveys software implementation.

24.1 BASICS

In this section we review basic terminology and combinatorics of arrangements, first for arrangements of hyperplanes and then for arrangements of curves and surfaces.

24.1.1 ARRANGEMENTS OF HYPERPLANES

GLOSSARY

Arrangement of hyperplanes: Let $\mathcal{H}$ be a finite set of hyperplanes in $\mathbb{R}^d$. The hyperplanes in $\mathcal{H}$ induce a decomposition of $\mathbb{R}^d$ (into connected open cells), the arrangement $\mathcal{A}(\mathcal{H})$. A d -dimensional cell in $\mathcal{A}(\mathcal{H})$ is a maximal connected region

of $\mathbb{R}^d$ not intersected by any hyperplane in $\mathcal{H}$; any k -dimensional cell in $\mathcal{A}(\mathcal{H})$, for $0 \leq k \leq d-1$, is a maximal connected region in the intersection of a subset of the hyperplanes in $\mathcal{H}$ that is not intersected by any other hyperplane in $\mathcal{H}$. It follows that any cell in an arrangement of hyperplanes is convex.

Simple arrangement: An arrangement $\mathcal{A}(\mathcal{H})$ of a set $\mathcal{H}$ of n hyperplanes in $\mathbb{R}^d$, with $n \geq d$, is called simple if every d hyperplanes in $\mathcal{H}$ meet in a single point and if any $d+1$ hyperplanes have no point in common.

Vertex, edge, face, facet: 0, 1, 2, and $(d-1)$ -dimensional cell of the arrangement, respectively. (What we call *cells* here are in some texts referred to as *faces*.)

k -cell : A k -dimensional cell in the arrangement.

Combinatorial complexity of an arrangement: The overall number of cells of all dimensions in the arrangement.

EXAMPLE: AN ARRANGEMENT OF LINES

Let $\mathcal{L}$ be a finite set of lines in the plane, and let $\mathcal{A}(\mathcal{L})$ be a simple arrangement induced by $\mathcal{L}$. A 0-dimensional cell (a vertex) is the intersection point of two lines in $\mathcal{L}$; a 1-dimensional cell (an edge) is a maximal connected portion of a line in $\mathcal{L}$ that is not intersected by any other line in $\mathcal{L}$; and a 2-dimensional cell (a face) is a maximal connected region of $\mathbb{R}^2$ not intersected by any line in $\mathcal{L}$. See Figure 24.1.1.

FIGURE 24.1.1

A simple arrangement of 5 lines. It has 10 vertices, 25 edges (10 of which are unbounded), and 16 faces (10 of which are unbounded).

COUNTING CELLS

A fundamental question in the study of arrangements is how complex a certain arrangement (or portion of it) can be. Answering this question is often a prerequisite to the analysis of algorithms on arrangements.

THEOREM 24.1.1

Let $\mathcal{H}$ be a set of hyperplanes in $\mathbb{R}^d$. The maximum number of k -dimensional cells in the arrangement $\mathcal{A}(\mathcal{H})$, for $0 \leq k \leq d$, is

$$\sum_{i=0}^k \binom{d-i}{k-i} \binom{n}{d-i}.$$

The maximum is attained exactly when $\mathcal{A}(\mathcal{H})$ is simple.

We assume henceforth that the dimension d is a (small) constant. With few exceptions, we will not discuss *exact* combinatorial complexity bounds, as in the theorem above, but rather use the big-O notation. Theorem 24.1.1 implies the following:

COROLLARY 24.1.2

The maximum combinatorial complexity of an arrangement of n hyperplanes in $\mathbb{R}^d$ is $O(n^d)$. If the arrangement is simple its complexity is $\Theta(n^d)$. In these bounds the constant of proportionality depends on d .

24.1.2 ARRANGEMENTS OF CURVES AND SURFACES

We now introduce more general arrangements, allowing for objects that are non-linear and/or bounded. We distinguish between planar arrangements and arrangements in three or higher dimensions. For planar arrangements we require only that the objects defining the arrangement be x -monotone Jordan arcs with a constant maximum number of intersections per pair. For arrangements of surfaces in three or higher dimensions we require that the surfaces be algebraic of constant maximum degree (a more precise definition is given below). This requirement simplifies the analysis and computation of such arrangements, and it does not seem to be too restrictive, as in most applications the arrangements that arise are of low-degree algebraic surfaces.

In both cases we typically assume that the objects (curves or surfaces) are in general position. This is a generalization to the current setting of the simplicity assumption for hyperplanes made above. (This assumption is reconsidered in Section 24.9.) All the other definitions in the Glossary carry over to arrangements of curves and surfaces.

PLANAR ARRANGEMENTS

Let $\mathcal{C} = \{c_1, c_2, \dots, c_n\}$ be a collection of Jordan arcs in the xy -plane, such that each arc is **x -monotone** (i.e., every line parallel to the y -axis intersects an arc in at most one point) and each pair of arcs in $\mathcal{C}$ intersect in at most s points for some fixed constant s . The arrangement $\mathcal{A}(\mathcal{C})$ is the decomposition of the plane into open cells of dimensions 0, 1, and 2 induced by the arcs in $\mathcal{C}$. Here, a 0-dimensional cell (a vertex) is either an endpoint of one arc or an intersection point of two arcs. See Figure 24.1.2.

FIGURE 24.1.2

A simple arrangement of 5 bounded arcs, where $s = 2$. It has 17 vertices (10 of which are arc endpoints), 19 edges, and 4 faces (one of which is unbounded).

We assume that the arcs in $\mathcal{C}$ are in **general position**, namely, that each intersection of a pair of arcs in $\mathcal{C}$ is either a common endpoint or a transversal

intersection at a point in the relative interior of both arcs, and that no three arcs intersect at a common point.

THEOREM 24.1.3

If $\mathcal{C}$ is a collection of n Jordan arcs as defined above, then the maximum combinatorial complexity of the arrangement $\mathcal{A}(\mathcal{C})$ is $O(n^2)$. There are such arrangements whose complexity is $\Theta(n^2)$. In these bounds the constant of proportionality depends linearly on s .

THREE AND HIGHER DIMENSIONS

We denote the coordinate axes of $\mathbb{R}^d$ by $x_1, x_2, \dots, x_d$. For a collection $\mathcal{S} = \{s_1, s_2, \dots, s_n\}$ of (hyper)surface patches in $\mathbb{R}^d$ we make the following assumptions:

1. Each surface patch is contained in an algebraic surface of constant maximum degree.
2. The boundary of each surface patch is determined by at most some constant number of algebraic surface patches of constant maximum degree each. (Formally, each surface patch is a semialgebraic set of $\mathbb{R}^d$ defined by a Boolean combination of a constant number of d -variate polynomial equalities or inequalities of constant maximum degree each.)
3. Every d surface patches in $\mathcal{S}$ meet in at most s points.
4. Each surface patch is *monotone* in $x_1, \dots, x_{d-1}$, namely every line parallel to the x_d -axis intersects the surface patch in at most one point.
5. The surface patches in $\mathcal{S}$ are in *general position*.

We use the simplified term *arrangement of surfaces* to refer to arrangements whose defining objects satisfy the assumptions above. A few remarks regarding these assumptions (see [AS00a, Section 2], [Mat02, Section 7.7], [Sha94], for detailed discussions of the required assumptions):

- Assumptions (1) and (2), together with the general position assumption (5), imply that every d -tuple of surfaces meet in at most some constant number of points. One can bound this number using Bézout's Theorem (see [Chapter 33](#)). The bound s on the number of d -tuple intersection points turns out to be a crucial parameter in the combinatorial analysis of substructures in arrangements. Often, one can get a better estimate for s than the bound implied by Bézout's theorem.
- Assumption (4) is used in results cited below. It can however be easily relaxed without affecting these results: If a surface patch does not satisfy this assumption, it can be decomposed into pieces that satisfy the assumption, and by assumptions (1) and (2) the number of these pieces will be bounded by a constant and their boundaries will satisfy assumption (2).
- Assumption (5) often does not affect the worst-case combinatorial bounds obtained for arrangements or their substructures, because it can be shown that the asymptotically highest complexity is obtained when the surfaces are in general position [Sha94]. For algorithms, this assumption is more problematic. There are general relaxation methods but these seem to introduce new difficulties [Sei98] (see also [Section 24.9](#)).

THEOREM 24.1.4

Given a collection $\mathcal{S}$ of n surfaces in $\mathbb{R}^d$, as defined above, the maximum combinatorial complexity of the arrangement $\mathcal{A}(\mathcal{S})$ is $O(n^d)$. There are such arrangements whose complexity is $\Theta(n^d)$. The constant of proportionality in these bounds depends on d and on the maximum algebraic degree of the surfaces and of the polynomials defining their boundaries.

ARRANGEMENTS ON CURVED SURFACES

Although we do not discuss such arrangements directly in this chapter, many of the combinatorial and algorithmic results that we survey carry over to arrangements on curved surfaces with only slight adjustments. Arrangements on spheres are especially prevalent in applications. The ability to analyze or construct arrangements on curved surfaces is implicitly assumed and exploited in the results for arrangements of surfaces in Euclidean space, since we often need to consider the lower-dimensional arrangement induced on a surface by its intersections with all the other surfaces that define the arrangement.

ADDITIONAL TOPICS

We focus in this chapter on simple arrangements. We note, however, that non-simple arrangements raise interesting questions; see, for example, [Szé97]. Another noteworthy topic that we will not cover here is *combinatorial equivalence* of arrangements; see Chapter 6 and [BLW⁺93].

24.2 SUBSTRUCTURES IN ARRANGEMENTS

A substructure in an arrangement (i.e., a portion of an arrangement), rather than the entire arrangement, may be sufficient to solve a problem at hand. Also, the analysis of several algorithms for constructing arrangements relies on combinatorial bounds for substructures. We survey substructures that are known in general to have significantly smaller complexity than that of the entire arrangement. For simplicity, some of the substructures are defined below only for the planar case.

GLOSSARY

Let $\mathcal{C}$ be a collection of n x -monotone Jordan arcs as defined in Section 24.1.

Lower (upper) envelope: For this definition we regard each curve c_i in $\mathcal{C}$ as the graph of a continuous univariate function $c_i(x)$ defined on an interval. The lower envelope Ψ of the collection $\mathcal{C}$ is the pointwise minimum of these functions: $\Psi(x) = \min c_i(x)$, where the minimum is taken over all functions defined at x . (The lower envelope is the 0-level of the arrangement $\mathcal{A}(\mathcal{C})$; see below.) Similarly, the upper envelope of the collection $\mathcal{C}$ is defined as the pointwise maximum of these functions. Lower and upper envelopes are completely symmetric structures, and from this point on we will discuss only lower envelopes.

Minimization diagram of $\mathcal{C}$: The subdivision of the x -axis into maximal intervals so that on each interval the same subset of functions attains the minimum. In $\mathbb{R}^d$ we regard the surface patches in $\mathcal{S}$ as graphs of functions in the variables $x_1, \dots, x_{d-1}$, the lower envelope is the pointwise minimum of these functions, and the minimization diagram is the subdivision of $\mathbb{R}^{d-1}$ into maximal connected cells such that over the interior of each cell the lower envelope is attained by a fixed subset of $\mathcal{S}$.

Zone: For an additional curve γ , the collection of faces of the arrangement $\mathcal{A}(\mathcal{C})$ intersected by γ . See Figure 24.4.1. In earlier works, the zone is sometimes called the *horizon*.

Single cell: In this section, a d -cell in an arrangement in $\mathbb{R}^d$.

Many cells (m cells): Any m distinct d -cells in an arrangement in $\mathbb{R}^d$.

Sides and borders: Let e be an edge in an arrangement of lines, and let l be the line containing e . The line l divides the plane into two halfplanes h_1, h_2 . We regard e as two-sided, and denote the two sides by (e, h_1) and (e, h_2) . The edge e is on the boundary of two faces f_1 and f_2 in the arrangement. e is said to be a **1-border** of either face, marked (e, f_1) and (e, f_2) , respectively. Similarly a vertex in a simple arrangement of lines has four sides, and it is a **0-border** of four faces. The definition extends to arrangements of hyperplanes in higher dimensions and to arrangements of curved surfaces.

k -level: We assume here, for simplicity, that the curves are unbounded; the definition can be extended to the case of bounded curves. A point p in the plane is said to be at level k , if there are exactly k curves in $\mathcal{C}$ lying strictly below p (i.e., a relatively open ray emanating from p in the negative y direction intersects exactly k curves in $\mathcal{C}$). The level of an (open) edge e in $\mathcal{A}(\mathcal{C})$ is the level of any point of e . The k -level of $\mathcal{A}(\mathcal{C})$ is the closure of the union of edges of $\mathcal{A}(\mathcal{C})$ that are at level k ; see Figure 24.2.1. The **at-most- k -level** of $\mathcal{A}(\mathcal{C})$, denoted $(\leq k)$ -**level**, is the union of points in the plane at level j , for $0 \leq j \leq k$. Different texts use slight variations of the above definitions. In particular, in some texts the ray is directed upwards thus counting the levels from top to bottom. k -levels in arrangements of hyperplanes are closely related (through *duality*, see Section 24.7) to k -sets in point configurations; see Chapter 1.

FIGURE 24.2.1

The bold polygonal line is the 2-level of the arrangement of four lines.

The shaded region is the (≤ 2) -level of the arrangement.

Union boundary: If each surface s in an arrangement in $\mathbb{R}^d$ is the boundary of a d -dimensional object, then the boundary of the union of the objects is another interesting substructure. The study of the union boundary has largely been motivated by robot motion planning problems; for details see Chapter 47.

$\alpha(n)$: The extremely slowly growing functional inverse of Ackermann’s function.
See [Section 47.4](#).

MEASURING THE COMPLEXITY OF A SUBSTRUCTURE

For an arrangement in $\mathbb{R}^d$, if a substructure consists of a collection C of d -cells, its combinatorial complexity is defined to be the overall number of cells of any dimension on the boundary of each of the d -cells in C . This means that we count certain cells of the arrangement with multiplicity (as *borders* of the corresponding d -cells). For example, for the zone of a line l in an arrangement of lines, each edge of the arrangement that intersects l will be counted twice. However, since we assume that our arrangements reside in a fixed (low) dimensional space, this only implies a constant multiplicative factor in our count.

The complexity of the lower envelope of an arrangement is defined to be the complexity of its minimization diagram. In three or higher dimensions, this means that we count features that do not appear in the original arrangement. For example, in the lower envelope of a collection of triangles in 3-space, the projection of the edges of two distinct triangles may intersect in the minimization diagram although the two triangles are disjoint in 3-space.

The complexity of a k -level in an arrangement is defined in a similar way to the complexity of an envelope. The complexity of the $(\leq k)$ -level is defined as the overall number of cells of the arrangement that lie in the region of space whose points are at level at-most- k .

COMBINATORIAL COMPLEXITY BOUNDS FOR SUBSTRUCTURES

In the rest of this section we list bounds on the maximum combinatorial complexity of substructures. For lines, hyperplanes, Jordan arcs, and surfaces, these are arranged in Tables 24.2.1, [24.2.2](#), [24.2.3](#), and [24.2.4](#), respectively. Bounds in the tables using ϵ should read “for any $\epsilon > 0$ ” (with the implied constant of proportionality depending on ϵ). In the bounds for k -levels and $(\leq k)$ -levels we assume that $k \geq 1$ (otherwise one should use $k + 1$ instead of k). For each substructure, many special cases of arrangements have been considered and the results are too numerous to cover here. For an extensive recent review of results for k -levels see [Mat02, Chapter 11], for other substructures see [AS00a], [Mat02, Chapter 7].

TABLE 24.2.1 Substructures in arrangements of n lines in the plane.

SUBSTRUCTURE	BOUND	NOTES
Envelope	n edges	See [Ede87] for an exact bound on the number of 0- and 1-borders
Single face	n edges	
Zone of a line	$\Theta(n)$	
m faces	$\Theta(m^{2/3}n^{2/3} + m + n)$	Upper bound [CEG ⁺ 90]; lower bound [Ede87]
k -level	$O(nk^{1/3})$	[Dey98]
	$n2^{\Omega(\sqrt{\log k})}$	[Tot01]
$(\leq k)$ -level	$\Theta(nk)$	[AG86]

TABLE 24.2.2 Substructures in arrangements of n hyperplanes in $\mathbb{R}^d$.

SUBSTRUCTURE	BOUND	NOTES
Envelope	$\Theta(n^{\lfloor \frac{d}{2} \rfloor})$	Upper bound theorem [McM70]
Single cell	$\Theta(n^{\lfloor \frac{d}{2} \rfloor})$	Upper bound theorem [McM70]
Zone of a hyperplane	$\Theta(n^{d-1})$	[ESS93]
Zone of p -dimensional algebraic surface (const max deg)	$O(n^{\lfloor (d+p)/2 \rfloor} \log^\gamma n)$	$\gamma = d + p \pmod{2}$ [APS93], the bound is almost tight in the worst case
m cells	$O(m^{1/2} n^{d/2} \log^{\lfloor \frac{d}{2} \rfloor - 1} n)$	Bound is almost tight [AMS94]; see [AA92] for bounds on no. of facets
k -level, $d = 3$	$O(nk^{3/2})$	[SST01]
k -level, $d \geq 4$	$O(n^{\lfloor d/2 \rfloor} k^{\lfloor d/2 \rfloor - \epsilon_d})$	[AACS98], constant $\epsilon_d > 0$
$(\leq k)$ -level	$\Theta(n^{\lfloor d/2 \rfloor} k^{\lfloor d/2 \rfloor})$	[CS89]

CURVES

For a collection $\mathcal{C}$ of n well-behaved curves as defined in Section 24.1, the complexity bounds for certain substructures involve functions related to *Davenport-Schinzel sequences*. The function $\lambda_s(n)$ is defined as the maximum length of a Davenport-Schinzel sequence of order s on n symbols, and it is almost linear in n for any fixed s . Davenport-Schinzel sequences play a central role in the analysis of substructures of arrangements of curves and surfaces. See [Section 47.4](#) for more details.

THEOREM 24.2.1

For a set $\mathcal{C}$ of n x -monotone Jordan arcs such that each pair intersects in at most s points, the maximum number of intervals in the minimization diagram of $\mathcal{C}$ is $\lambda_{s+2}(n)$. If the curves are unbounded, then the maximum number of intervals is $\lambda_s(n)$.

The connection between a zone and a single cell. As observed in [EGP⁺92], a bound on the complexity of a single cell in general arrangements of arcs implies the same asymptotic bound on the complexity of the zone of an additional well-behaved curve γ in the arrangement; “well-behaved” meaning that γ does not intersect any curve in $\mathcal{C}$ more than some constant number of times. This observation extends to higher dimensions and is exploited in the result for zones in arrangements of surfaces [HS95a].

The results in [Table 24.2.3](#) are for Jordan arcs (bounded curves). There are slightly better bounds in the case of unbounded curves. For subquadratic bounds on k -levels in special arrangements of curves see [TT98], [Cha03], [NPP⁺02]. Improved bounds on the complexity of m faces in special arrangements of curves are given in [AEGS92] for segments, [AAS03] for circles, and [NPP⁺02] for pseudo circles and some other types of curves.

UNION BOUNDARY

For a collection of n Jordan regions (regions bounded by closed Jordan curves) such that each pair of bounding curves intersects at most twice, there are at most $6n - 12$

TABLE 24.2.3 Substructures in arrangements of n Jordan arcs.

SUBSTRUCTURE	BOUND	NOTES
Envelope	$\Theta(\lambda_{s+2}(n))$	See Theorem 24.2.1
Single face, zone	$\Theta(\lambda_{s+2}(n))$	[GSS89]
m cells	$O(m^{1/2}\lambda_{s+2}(n))$	[EGP ⁺ 92]
	$\Omega(m^{2/3}n^{2/3})$	Lower bound for lines
$(\leq k)$ -level	$\Theta(k^2\lambda_{s+2}(\lfloor \frac{n}{k} \rfloor))$	[Sha91]

TABLE 24.2.4 Substructures in arrangements of n surfaces.

OBJECTS	SUBSTRUCTURE	BOUND	NOTES
Surfaces in $\mathbb{R}^d$	Lower envelope	$O(n^{d-1+\epsilon})$	[HS94],[Sha94]
	Single cell, zone	$O(n^{d-1+\epsilon})$	[Bas98],[HS95a]
	$(\leq k)$ -level	$O(n^{d-1+\epsilon}k^{1-\epsilon})$	Combining [CS89] and Lower envelopes bound
$(d-1)$ -simplices in $\mathbb{R}^d$	Lower envelope	$\Theta(n^{d-1}\alpha(n))$	[Ede89]
	Single cell, zone	$O(n^{d-1} \log n)$	[AS94]
$(d-1)$ -spheres in $\mathbb{R}^d$	Lower envelope, single cell	$\Theta(n^{\lceil \frac{d}{2} \rceil})$	Linearization

intersection points (for $n \geq 3$) between curves on the union boundary [KLPS86]. This bound is tight in the worst case. For variants and extensions of this result see [EGH⁺89], [PS99], [AEHS01].

Many of the interesting results in this area are for Minkowski sums where one of the operands is convex, motivated primarily by motion planning problems. These results are reviewed in [Chapter 47](#). We mention one exemplary result that (almost) settles a long-standing open problem: the complexity of the union boundary of n congruent infinite cylinders (namely, each cylinder is the Minkowski sum of a line in 3-space and a unit ball) is $O(n^{2+\epsilon})$ [AS00b].

Another family of results is for so-called *fat* objects. For example, a triangle is considered fat if all its angles are at least some fixed constant $\delta > 0$. For such triangles it is shown [MPS⁺94] that they determine at most a linear number of *holes* (namely connected components of the complement of the union) and that their union boundary has near-linear complexity. Typically (but not always) fatness precludes constructions with high union complexity, such as grid-like patterns with complexity $\Omega(n^d)$ in $\mathbb{R}^d$. For more results in the plane see [AFK⁺92], [ES00], [vK98]. For results in $\mathbb{R}^3$ and in higher dimensions consult [BSTY98], [PSS03].

ADDITIONAL COMBINATORIAL BOUNDS

The following bounds, while not bounds on the complexity of substructures, are useful in the analysis of algorithms for computing substructures and in obtaining other combinatorial bounds on arrangements.

Sum of squares. Let $\mathcal{H}$ be a collection of n hyperplanes in $\mathbb{R}^d$. For each d -cell c of the arrangement $\mathcal{A}(\mathcal{H})$, let $f(c)$ denote the number of cells of any dimension on the boundary of c . Aronov et al. [AMS94] show that $\sum_c f^2(c) = O(n^d \log^{\lfloor \frac{d}{2} \rfloor - 1} n)$, where the sum extends over all d -cells of the arrangement. They use it to obtain bounds on the complexity of m cells in the arrangement. An application of the zone theorem [ESS93] implies a related bound: If we denote the number of hyperplanes appearing on the boundary of the cell c by $g(c)$, then $\sum_c f(c)g(c) = O(n^d)$, where the sum extends over all d -cells of the arrangement.

Overlay of envelopes. For two sets A and B of objects in $\mathbb{R}^d$, the complexity of the *overlay of envelopes* is defined as the complexity of the subdivision of $\mathbb{R}^{d-1}$ induced by superposing the minimization diagram of A on that of B . Given two sets $\mathcal{C}_1$ and $\mathcal{C}_2$, each of n x -monotone Jordan arcs, such that no pair of (the collection of $2n$) arcs intersects more than s times, the complexity of the overlay is easily seen to be $\Theta(\lambda_{s+2}(n))$. In 3-space, given two sets each of n well-behaved surfaces, the complexity of the overlay is $O(n^{2+\epsilon})$ [ASS96] (a simpler proof of the bound appears in [KS02]). The bound is applied to obtain a simple divide-and-conquer algorithm for computing the envelope in 3-space, and for obtaining bounds on the complexity of *transversals* (see Chapter 4). The bound in $\mathbb{R}^4$ is $O(n^{3+\epsilon})$ [KS02].

OPEN PROBLEMS

1. What is the complexity of the k -level in an arrangement of lines in the plane? For the gap between the known lower and upper bounds see Table 24.2.1. This is a long-standing open problem in combinatorial geometry.
2. What is the complexity of m faces in an arrangement of well-behaved Jordan arcs? For lines a tight bound is known, whereas for curves a considerable gap still exists—see Table 24.2.3.
3. What is the complexity of the boundary of the union of n infinite cylinders of different radii in 3-space? If all the radii are the same then the bound is $O(n^{2+\epsilon})$ [AS00b]. Also, what is the complexity of the union of n arbitrary cubes in 3-space? A near-quadratic bound is known only when the cubes are nearly equal [PSS03].

24.3 REPRESENTATIONS AND DECOMPOSITIONS

Before describing algorithms for arrangements in the next sections, we discuss how to represent an arrangement. The appropriate data structure for representing an arrangement depends on its intended use. Two typical ways of using arrangements are: (i) traversing the entire arrangement cell by cell; and (ii) directly accessing certain cells of the arrangement. We will present three structures, each providing a method for traversing the entire arrangement: the *incidence graph*, the *cell-tuple structure*, and the *complete skeleton*. We will then discuss refined representations that further subdivide an arrangement into subcells. These refinements are essential to allow for efficient access to cells of the arrangement. For algebraic geometry-oriented representations and decompositions see Chapters 33 and 47.

GLOSSARY

Let $\mathcal{S}$ be a collection of surfaces in $\mathbb{R}^d$ (or curves in $\mathbb{R}^2$) as defined in Section 24.1, and $\mathcal{A}(\mathcal{S})$ the arrangement induced by $\mathcal{S}$. Let c_1 be a k_1 -dimensional cell of $\mathcal{A}(\mathcal{S})$ and c_2 a k_2 -dimensional cell of $\mathcal{A}(\mathcal{S})$.

Subcell, supercell: If $k_2 = k_1 + 1$ and c_1 is on the boundary of c_2 , then c_1 is a subcell of c_2 , and c_2 is a supercell of c_1 .

(-1) -dimensional cell, $(d+1)$ -dimensional cell: Some representations assume the existence of two additional cells in an arrangement. The unique (-1) -dimensional cell is a subcell of every vertex (0-dimensional cell) in the arrangement, and the unique $(d+1)$ -dimensional cell is a supercell of all the d -dimensional cells in the arrangement.

Incidence: If c_1 is a subcell of c_2 , then c_1 and c_2 are *incident* to one another. We say that c_1 and c_2 define an *incidence*.

24.3.1 REPRESENTATIONS

INCIDENCE GRAPH

The incidence graph (sometimes called the *facial lattice*) of the arrangement $\mathcal{A}(\mathcal{S})$ is a graph $G = (V, E)$ where there is a node in V for every k -cell of $\mathcal{A}(\mathcal{S})$, $-1 \leq k \leq d + 1$, and an arc between two nodes if the corresponding cells are incident to one another (cf. Figure 16.1.3). For an arrangement of n surfaces in $\mathbb{R}^d$ the number of nodes in V is $O(n^d)$ by Theorem 24.1.4. This is also a bound on the number of arcs in E : every cell (besides the (-1) -dimensional cell) in an arrangement $\mathcal{A}(\mathcal{S})$ in general position has at most a constant number of supercells. For an exact bound in the case of hyperplanes, see [Ede87, Section 1.2].

CELL-TUPLE STRUCTURE

While the incidence graph captures all the cells in an arrangement and (as its name implies) their incidence relation, it misses *order* information between cells. For example, there is a natural order among the edges that appear along the boundary of a face in a planar arrangement. This leads to the *cell-tuple structure* [Bri93] which is a generalization to any dimension of the two-dimensional doubly-connected-edge-list (DCEL) [dBvK⁺00] or the similar *quad-edge structure* of Guibas and Stolfi [GS85] and the 3D *facet-edge structure* of Dobkin and Laszlo [DL89]. The cell-tuple structure gives a simple and uniform representation of the incidence and ordering information in the arrangement.

SKELETON

Let $\mathcal{H}$ be a finite set of hyperplanes in $\mathbb{R}^d$. A *skeleton* in the arrangement $\mathcal{A}(\mathcal{H})$ is a connected subset of edges and vertices of the arrangement. The *complete*

skeleton is the union of all the edges and vertices of the arrangement. Edelsbrunner [Ede87] proposes a representation of the skeleton as a digraph, which allows for a systematic traversal of the entire arrangement (in the case of a complete skeleton) or a substructure of the arrangement. Using a one-dimensional skeleton to represent an arrangement in an arbitrary-dimensional space is a notion that appears also in algebro-geometric representations. There, however, the skeleton, or **roadmap**, is far more complicated (indeed it represents more general arrangements); see [BPR00] and [Chapter 47](#).

24.3.2 DECOMPOSITIONS

A raw arrangement may still be an unwieldy structure as cells may have complicated shapes and many bounding subcells. It is often desirable to decompose the cells of the arrangement into subcomponents so that each subcomponent has a constant descriptive complexity and is homeomorphic to a ball. Besides the obvious convenience that such a decomposition offers (just like a triangulation of a simple polygon), it turns out to be crucial to the design and analysis of randomized algorithms for arrangements, as well as to combinatorial analysis of arrangements.

For a decomposition to be useful, we aim to add as few extra features as possible. The three decompositions described in this section have the property that the complexity of the decomposed arrangement is asymptotically close to (sometimes the same as) that of the original arrangement. (This is still not known for the *vertical decomposition* in higher dimensions—see the open problem below.)

BOTTOM VERTEX DECOMPOSITION OF HYPERPLANE ARRANGEMENTS

Consider an arrangement of lines $\mathcal{A}(\mathcal{L})$ in the plane. For a face f let $v_b = v_b(f)$ be the bottommost vertex of f (the vertex with lowest y coordinate, ties can be broken by the lexicographic ordering of the coordinate vectors of the vertices). Extend an edge from v_b to each vertex on the boundary of f that is not incident to an edge incident to v_b ; see Figure 24.3.1. Repeat for all faces of $\mathcal{A}(\mathcal{L})$ (unbounded faces require special care). The original arrangement, together with the added edges, constitutes the **bottom vertex decomposition** of $\mathcal{A}(\mathcal{L})$, which is a decomposition of $\mathcal{A}(\mathcal{L})$ into triangles. The notion extends to arrangements of hyperplanes in higher dimensions, and it is carried out recursively [Cla88]. The combinatorial complexity of the decomposition is asymptotically the same as that of the original arrangement.

FIGURE 24.3.1

The bottom vertex decomposition of a face in an arrangement of lines.

VERTICAL DECOMPOSITION

The bottom vertex decomposition does not in general extend to arrangements of nonlinear objects. Fortunately there is an alternative, rather simple, decomposition method that applies to almost any reasonable arrangement. This is the **vertical decomposition** or **trapezoidal decomposition**. See Figure 24.3.2. It is optimal for two-dimensional arrangements, namely its complexity is asymptotically the same as that of the underlying arrangement. It is near-optimal in three and four dimensions. In higher dimensions it is still the general decomposition method that is known to have the best (lowest) complexity.

FIGURE 24.3.2

The vertical decomposition of an arrangement of segments: a vertical line segment is extended upward and downward from each vertex of the arrangement until it either hits another segment or extends to infinity.

The extension to higher dimensions is defined recursively and is presented in full generality in [CEGS91]. For details of the extension to three dimensions, see [CEG⁺90] for the case of spheres, and [DBGH96] for the case of triangles. The four-dimensional case is studied in [Kol01a], [Kol01b]. Table 24.3.1 summarizes the bounds on the maximum combinatorial complexity of the vertical decomposition for several types of arrangements and substructures. Certain assumptions that curves and surfaces are “well-behaved” are not detailed.

TABLE 24.3.1 Combinatorial bounds on the maximum complexity of the vertical decomposition of n objects.

OBJECTS	BOUND	NOTES
Curves in $\mathbb{R}^2$	$\Theta(K)$	K is the complexity of $\mathcal{A}$
Surfaces in $\mathbb{R}^d$	$O(n^{2d-4+\epsilon})$	[CEGS91], [Kol01a]
Triangles in $\mathbb{R}^3$	$\Theta(n^3)$	[DBGH96]
Triangles in $\mathbb{R}^3$	$O(n^2\alpha(n)\log n + K)$	K is the complexity of $\mathcal{A}$ [Tag96]
Surfaces in $\mathbb{R}^3$, single cell	$O(n^{2+\epsilon})$	[SS97]
Surfaces in $\mathbb{R}^3$, $(\leq k)$ -level	$O(n^{2+\epsilon}k)$	See [AES99] for refined bounds
Hyperplanes in $\mathbb{R}^4$	$\Theta(n^4)$	[Kol01b]
Simplices in $\mathbb{R}^4$	$O(n^4\alpha(n)\log n)$	[Kol01b]

OTHER DECOMPOSITION SCHEMES

Aronov and Sharir devised alternative decomposition methods for arrangements of simplices [AS90], [AS94]. These are more involved than the decompositions described above and we omit their description here. These methods were instrumental in obtaining improved combinatorial bounds and efficient algorithms for arrangements of simplices. A sparse variant of the vertical decomposition is proposed in [SH02] for the case of triangles in 3-space: it produces fewer 3D cells (which are convex but may have many bounding facets) and its computation requires simpler geometric primitives than the standard vertical decomposition—this is advantageous from a practical (implementation) point of view. Yet another decomposition scheme has been devised for surfaces arising in the study of polygonal motion planning in translation and rotation [HS96].

CUTTINGS

All the decompositions described so far have the property that each cell of the decomposition lies fully in a single cell of the arrangement. In various applications this property is not required and other decomposition schemes may be applied, such as *cuttings* (Chapter 36). Cuttings are the basis of efficient divide-and-conquer algorithms for numerous geometric problems on arrangements and otherwise.

STRUCTURES FOR POINT LOCATION AND RAY SHOOTING

To access certain cells of an arrangement without traversing the entire arrangement, we need more elaborate structures than those described above. See Chapters 34 and 37 for details.

OPEN PROBLEMS

1. Obtain an improved combinatorial bound on the complexity of the vertical decomposition of arrangements of surfaces in five and higher dimensions. Such a result would have a wide-ranging effect on other combinatorial bounds, on algorithms, and on a variety of applications of arrangements.
2. The decompositions described above are asymptotically efficient. However it has been observed that the constant factors in the complexity bounds are highly noticeable in practice. It is desirable to devise alternative *sparser* decompositions, namely decompositions that add fewer extra features such that they will still have some of the favorable properties of say the vertical decomposition. For steps in this direction, cf. [HP00], [SH02].

24.4 ALGORITHMS FOR ARRANGEMENTS

This section covers constructing an arrangement: producing a representation of an arrangement in one of the forms described in the previous section (or in a similar

form). We distinguish between algorithms for the construction of the entire arrangement (surveyed in this section), and algorithms for constructing substructures of an arrangement (in the next section). We start with deterministic algorithms and then describe randomized ones.

MODEL OF COMPUTATION

We assume the standard model in computational geometry: infinite precision real arithmetic [PS85]. For algorithms computing arrangements of curves or surfaces, we further assume that certain operations on a small number of curves or surfaces each take unit time. For algebraic curves or surfaces, the unit cost assumption for these operations is theoretically justified by results on the solution of sets of polynomial equations; see [Chapter 33](#). When implementing algorithms for arrangements some of these assumptions need to be reconsidered—see [Sections 24.9](#) and [24.10](#).

24.4.1 DETERMINISTIC ALGORITHMS

Incremental construction. The incremental algorithm proceeds by adding one object after the other to the arrangement while maintaining (a representation of) the arrangement of the objects added so far. This approach yields an optimal-time algorithm for arrangements of hyperplanes. The analysis of the running time is based on the zone result [ESS93] (Section 24.2). We describe it next for a collection $\mathcal{L} = \{l_1, \dots, l_n\}$ of n lines in the plane, assuming that the arrangement $\mathcal{A}(\mathcal{L})$ is simple.

FIGURE 24.4.1

Adding the line l_{i+1} to the arrangement $\mathcal{A}(\mathcal{L}_i)$.

The shaded region is the zone of l_{i+1} in the arrangement of the other four lines.

Let $\mathcal{L}_i$ denote the set $\{l_1, \dots, l_i\}$. At stage $i+1$ we add l_{i+1} to the arrangement $\mathcal{A}(\mathcal{L}_i)$. We maintain the DCEL representation (Section 24.3.1) for $\mathcal{A}(\mathcal{L}_i)$, so that in addition to the incidence information, we also have the order of edges along the boundary of each face. The addition of l_{i+1} is carried out in two steps: (i) we find a point p of intersection between l_{i+1} and an edge of $\mathcal{A}(\mathcal{L}_i)$ and split that edge into

two, and (ii) we walk along l_{i+1} from p to the left (assuming l_{i+1} is not vertical) updating $\mathcal{A}(\mathcal{L}_i)$ as we go; we then walk along l_{i+1} from p to the right completing the construction of $\mathcal{A}(\mathcal{L}_{i+1})$. See Figure 24.4.1.

Finding an edge of $\mathcal{A}(\mathcal{L}_i)$ that l_{i+1} intersects can be done in $O(i)$ time by choosing one line l_j from $\mathcal{L}_i$ and checking all the edges of $\mathcal{A}(\mathcal{L}_i)$ that lie on l_j for intersection with l_{i+1} . This intersection point p lies on an edge e that borders two faces of $\mathcal{A}(\mathcal{L}_i)$. We split e into two edges at p . Next, consider the face f intersected by the part of l_{i+1} to the left of p . Using the order information, we walk along the edges of f away from p and we check for another intersection p' of l_{i+1} with an edge e' on the boundary of f . At the intersection we split e' into two edges, we add an edge to the arrangement for the portion $\overline{pp'}$ of l_{i+1} , and we move to the face on the other (left) side of e' . Once we are done with the faces of $\mathcal{A}(\mathcal{L}_i)$ crossed by l_{i+1} to the left of p , we go back to p and walk to the other side. This way we visit all the faces of the zone of l_{i+1} in $\mathcal{A}(\mathcal{L}_i)$, as well as some of its edges. The amount of time spent is proportional to the number of edges we visit, and hence bounded by the complexity of the zone. The space required for the algorithm is the space to maintain the DCEL structure. The same approach extends to higher dimensions. For details see [Ede87, Chapter 7] (note that the algorithm as described in [Ede87] uses the incidence graph for maintaining the arrangement).

THEOREM 24.4.1

If $\mathcal{H}$ is a set of n hyperplanes in $\mathbb{R}^d$ such that $\mathcal{A}(\mathcal{H})$ is a simple arrangement, then $\mathcal{A}(\mathcal{H})$ can be constructed in $\Theta(n^d)$ time and space.

The time and space required by the algorithm are clearly optimal. However, it turns out that for arrangements of lines one can do better in terms of *working space*. This is explained below in the subsection *topological sweep*. See [Goo93], [HJW90] for parallel algorithms for arrangements of hyperplanes.

The incremental approach can be applied to constructing arrangements of curves, using the vertical decomposition of the arrangement [EGP⁺92]:

THEOREM 24.4.2

Let $\mathcal{C}$ be a set of n Jordan arcs as defined in Section 24.1. The arrangement $\mathcal{A}(\mathcal{C})$ can be constructed in $O(n\lambda_{s+2}(n))$ time using $O(n^2)$ space.

Sweeping over the arrangement. The sweep paradigm, a fundamental paradigm in computational geometry, is also applicable to constructing arrangements. For planar arrangements, its worst-case running time is slightly inferior to that of the incremental construction described above. It is, however, output sensitive.

THEOREM 24.4.3

Let $\mathcal{C}$ be a set of n Jordan arcs as defined in Section 24.1. The arrangement $\mathcal{A}(\mathcal{C})$ can be constructed in $O((n+k)\log n)$ time and $O(n+k)$ space, where k is the number of intersection points in the arrangement.

One can similarly sweep a plane over an arrangement of surfaces in $\mathbb{R}^3$. There is an output-sensitive algorithm for constructing the vertical decomposition of an arrangement of n surfaces that runs in time $O(n\log^2 n + V\log n)$, where V is the combinatorial complexity of the vertical decomposition. For details see [SH02].

Topological sweep. Edelsbrunner and Guibas [EG89] devised an algorithm for

constructing an arrangement of lines that requires only linear working storage and still runs in optimal $O(n^2)$ time. Instead of sweeping the arrangement with a straight line, they sweep it with a pseudoline that serves as a “topological wave-front.”

The most efficient deterministic algorithm for computing the intersections in a collection of well-behaved curves is due to Balaban [Bal95]. It runs in $O(n \log n + k)$ time and requires $O(n)$ working storage. The algorithm does *not* construct the arrangement; it only finds the intersection points, unsorted.

24.4.2 RANDOMIZED ALGORITHMS

Most randomized algorithms for arrangements follow one of two paradigms: (i) incremental construction or (ii) divide-and-conquer using random sampling. The randomization in these algorithms is in choices made by the algorithm; for example, the order in which the objects are handled in an incremental construction. In the expected performance bounds, the expectation is with respect to the random choices made by the algorithm. We do not make any assumptions about the distribution of the objects in space. See also [Chapter 40](#).

In constructing a full arrangement, these two paradigms are rather straightforward to apply. Most of these algorithms use an efficient decomposition as discussed in Section 24.3.

Incremental construction. Here the randomization is in the order that the objects defining the arrangement are inserted. For the construction of an arrangement of curves, the algorithm is similar to the deterministic construction mentioned above.

THEOREM 24.4.4 [Mul93]

Let $\mathcal{C}$ be a set of n Jordan arcs as defined in Section 24.1. The arrangement $\mathcal{A}(\mathcal{C})$ can be constructed by a randomized incremental algorithm in $O(n \log n + k)$ expected time and $O(n + k)$ expected space, where k is the number of intersection points in the arrangement.

Divide-and-conquer by random sampling. For a set $\mathcal{V}$ of n objects in $\mathbb{R}^d$ the paradigm is: choose a subset $\mathcal{R}$ of the objects at random, construct the arrangement $\mathcal{A}(\mathcal{R})$, decompose it further into constant complexity components (using, for example, one of the methods described in Section 24.3), and recursively construct the portion of the arrangement in each of the resulting components. Then glue all the substructures together into the full arrangement. The theory of random sampling is then used to show that with high probability the size of each subproblem is considerably smaller than that of the original problem, and thus efficient resource bounds can be proved.

The divide-and-conquer counterpart of Theorem 24.4.4 is due to Amato et al. [AGR00]. It has the same running time, and uses slightly more space (or exactly the same space for the case of segments).

The result stated in the following theorem is obtained by applying this paradigm to arrangements of algebraic surfaces and it is based on the vertical decomposition of the arrangement.

THEOREM 24.4.5 [CEGS91], [Kol01a]

Given a collection $\mathcal{S}$ of n algebraic surfaces in $\mathbb{R}^d$ as defined in Section 24.1, a data structure of size $O(n^{2d-4+\epsilon})$ for the arrangement $\mathcal{A}(\mathcal{S})$ can be constructed in $O(n^{2d-4+\epsilon})$ time for any $\epsilon > 0$, so that a point-location query can be answered in $O(\log n)$ time. In these bounds the constant of proportionality depends on ϵ , the dimension d , and the maximum algebraic degree of the surfaces and their boundaries.

If only traversal of the entire arrangement is needed, it is plausible that a simpler structure such as the incidence graph could be constructed using less time and storage space, close to $O(n^d)$ for both. See [Can93],[BPR00] for algebro-geometric methods.

Derandomization. Techniques have been proposed to derandomize many randomized geometric algorithms, often without increase in their asymptotic running time; see Chapter 40. However, in most cases the randomized versions are conceptually much simpler and hence may be better candidates for efficient implementation.

24.4.3 OTHER ALGORITHMIC ISSUES

For algebro-geometric tools, see Chapter 33. See Chapter 41 (and Section 24.9) for a discussion of precision and degeneracies. Parallel algorithms are discussed in Chapter 42.

24.5 CONSTRUCTING SUBSTRUCTURES**ENVELOPE AND SINGLE CELL IN ARRANGEMENTS OF HYPERPLANES**

Computing a single cell or an envelope in an arrangement of hyperplanes is equivalent (through duality) to computing the convex hull of a set of points in $\mathbb{R}^d$ (Chapter 22).

Using linearization [AM94], we can solve these problems for arrangements of spheres in $\mathbb{R}^d$. We first transform the spheres into hyperplanes in $\mathbb{R}^{d+1}$, and then solve the corresponding problems in $\mathbb{R}^{d+1}$.

LOWER ENVELOPE

The lower envelope of a collection of n well-behaved curves (where each pair intersect in at most s points) can be computed by a simple divide-and-conquer algorithm that runs in time $O(\lambda_{s+2}(n) \log n)$ and requires $O(\lambda_{s+2}(n))$ storage. Hersherberger [Her89] devised an improved algorithm that runs in time $O(\lambda_{s+1}(n) \log n)$; in particular, for the case of line segments, it runs in optimal $O(n \log n)$ time. In 3-space, Agarwal et al. [ASS96] showed that a simple divide-and-conquer scheme can be used to compute the envelope of n surfaces in time $O(n^{2+\epsilon})$. This is an application of the bound on the complexity of the overlay of envelopes cited in Section 24.2. Boissonnat and Dobrindt give a randomized incremental algorithm for computing the envelope [BD96]. There are efficient algorithms for computing the envelope of $(d-1)$ -simplices in $\mathbb{R}^d$ (see [EGS89] for the algorithm in 3D which can be efficiently extended to higher dimensions), and an efficient data structure

for point location in the minimization diagram of surfaces in $\mathbb{R}^4$. Output-sensitive construction of the envelope of triangles in $\mathbb{R}^3$ has been mainly studied in relation to hidden-surface-removal (see [dB93]). Partial information of the minimization diagram (vertices, edges and 2-cells) can be computed efficiently for arrangements of surfaces in any fixed dimension [AAS97].

SINGLE CELL AND ZONE

All the results cited below for a single cell in arrangements of bounded objects hold for the zone problem as well (see the remark in Section 24.2 on the connection between the problems).

Computing a single face in an arrangement of n Jordan arcs as defined in Section 24.1 can be accomplished in worst-case near-optimal time: deterministically in $O(\lambda_{s+2}(n) \log^2 n)$ time, and using randomization in $O(\lambda_{s+2}(n) \log n)$ time [SA95].

In three dimensions, Schwarzkopf and Sharir [SS97] give an algorithm with running time $O(n^{2+\epsilon})$ for any $\epsilon > 0$ to compute a single cell in an arrangement of n well-behaved surfaces. Algorithms with improved running time to compute a single cell in 3D arrangements are known for arrangements of surfaces induced by certain motion planning problems [Hal92], [Hal94], and for arrangements of triangles [dBDS95].

LEVELS

In an arrangement of n lines in the plane, the k -level can be computed in $O((n + f) \log n)$ time, where f is the combinatorial complexity of the k -level—the bound is for the algorithm described in [EW86] while using the data structure in [BJ02] which in turn builds on ideas in [Cha01]. For computing the k -level in an arrangement of hyperplanes in $\mathbb{R}^d$ see [AM95],[Cha96].

The $(\leq k)$ -level in arrangements of lines can be computed in worst-case optimal time $O(n \log n + kn)$ [ERvK96]. Algorithms for computing the $(\leq k)$ -level in arrangements of Jordan arcs are described in [AdB⁺98], the $(\leq k)$ -level in arrangements of planes in $\mathbb{R}^3$ (in optimal $O(n \log n + k^2 n)$ expected time) in [Cha00], and in arrangements of surfaces in $\mathbb{R}^3$ in [AES99].

UNION BOUNDARY

For a given family of planar regions bounded by well-behaved curves, let $f(m)$ be the maximum complexity of the union boundary of a collection of m objects of the family. Then the union of n such objects can be constructed deterministically in $O(f(n) \log^2 n)$ time or by a randomized incremental algorithm in expected $O(f(n) \log n)$ time [dBDS95]. A slightly faster algorithm for the case of fat triangles is given in [MMP⁺91]. An efficient randomized algorithm for computing the union of convex polytopes in $\mathbb{R}^3$ is given in [AST97].

MANY CELLS

There are efficient algorithms (deterministic and randomized) for computing a set

of selected faces in arrangements of lines or segments in the plane. These algorithms are nearly worst-case optimal [AMS98]. Algorithms for arrangements of planes are described in [EGS90], and for arrangements of triangles in 3-space in [AS90].

The related issue of computing the incidences between a set of objects (lines, unit circles) and a set of points is dealt with in [Mat93], with results that extend to higher dimensions [AS00a]. Generally, the bounds for the running time are roughly the same as those for the number of incidences. For lower bounds for the related *Hopcroft's problem* see [Eri96], [BK03].

OPEN PROBLEMS

Devise efficient algorithms for computing:

1. The lower envelope of an arrangement of surfaces in five and higher dimensions; for an algorithm that computes partial information see [AAS97].
2. A single cell in an arrangement of surfaces in four and higher dimensions; for a worst-case near-optimal algorithm in three dimensions see [SS97].

24.6 SPARSE ARRANGEMENTS

So far we have discussed arrangements of n objects in $\mathbb{R}^d$ where each object has constant descriptive complexity and the total complexity of the entire arrangement can be $\Omega(n^d)$ in the worst case. In many situations arrangements do not achieve this worst-case complexity, or there are additional parameters that control the complexity of the arrangement. In this section we survey several such situations.

Let $\mathcal{C}$ be a collection of n Jordan arcs, where each pair of arcs in $\mathcal{C}$ intersects at most a constant number of times, and with the additional condition that any vertical line intersects at most k of the curves in $\mathcal{C}$. In this case the maximum combinatorial complexity of the arrangement $\mathcal{A}(\mathcal{C})$ is $\Theta(nk)$. For an application of this result and for more results on arrangements with low **vertical stabbing number** (the number of objects stabbed by any vertical line) see [dBH⁺97].

A general way to take advantage of reduced complexity of an arrangement is to construct the arrangement using an output-sensitive algorithm. However, by understanding the source of the reduced complexity it may be possible to devise algorithms that perform better than general-purpose output-sensitive algorithms. In several cases this has indeed been achieved. The collection of atom spheres in the geometric model of molecules exhibits sparseness properties that have led to improved combinatorial bounds and relatively simple algorithms. These algorithms have been implemented and perform well in practice [HO98], [HS98]. Another area where results of this nature have been obtained is robot motion planning among *fat obstacles*; see Section 47.3.

ARRANGEMENTS OF CONVEX POLYTOPES

Consider the subdivision of 3-space induced by k convex polytopes with a total of n vertices. To bound the complexity of this arrangement we can regard this

as an arrangement of $O(n)$ triangles in 3-space, implying an upper bound $O(n^3)$. However, the complexity of such an arrangement is shown in [dBH⁺97] to be only $O(nk^2)$. More generally Aronov et al. [ABE91] showed that the complexity of an arrangement of k convex polytopes in $\mathbb{R}^d$ with a total of n facets is $\Theta(n^{\lfloor \frac{d}{2} \rfloor} k^{\lceil \frac{d}{2} \rceil})$.

A useful substructure in an arrangement of convex polytopes is the collection of *maximally covered cells*, namely cells of the arrangement that are covered by more polytopes than any other cell in their immediate neighborhood [GHH⁺98]. The ability to access these cells efficiently has led to an efficient and practical algorithm to test whether an object consisting of polyhedral parts is interlocked (i.e., cannot be taken apart with two hands).

24.7 RELATION TO OTHER STRUCTURES

Arrangements relate to a variety of additional structures. Since the machinery for analyzing and computing arrangements is rather well developed, problems on related structures are often solved by first constructing (or reasoning about) the corresponding arrangement.

Using *duality* one can transform a set (or *configuration*) of points in $\mathbb{R}^d$ (the primal space) into a set of hyperplanes in $\mathbb{R}^d$ (the dual space) and vice versa. Different duality transforms are advantageous in different situations [O'R98]. Edelsbrunner [Ede87, Chapter 12] describes a collection of problems stated for point configurations and solved by operating on their corresponding dual arrangements. An example is given in the next section. See also [Chapter 1](#).

Plücker coordinates are a tool that enables one to treat k -flats in $\mathbb{R}^d$ as points or hyperplanes in a possibly different (higher) dimensional space. This has been taken advantage of in the study of families of lines in 3-space—see [Chapter 37](#).

Lower envelopes (or more generally k -levels in arrangements) relate to Voronoi diagrams—see [Chapter 23](#).

For the connection of arrangements to polytopes and zonotopes see [Ede87] and Section 16.1.4 of this Handbook. For the connection to oriented matroids see [Chapter 6](#).

24.8 APPLICATIONS

A typical application of arrangements is for solving a problem on related structures. We first transform the original structure (e.g., a point configuration) into an arrangement and then solve the problem on the resulting arrangement. See Section 24.7 above and [Chapters 1, 23, and 37](#).

EXAMPLE: MINIMUM AREA TRIANGLE

Let P be a set of n points in the plane. We wish to find three points of P such that the triangle that they define has minimum area. We use the duality transform that maps a point $p := (a, b)$ to the line $p^* := (y = ax - b)$, and maps a line $l := (y = cx + d)$ to the point $l^* := (c, -d)$. One can show that if we fix two points

$p_i, p_j \in P$, and the line p_k^* has the smallest vertical distance to the intersection point $p_i^* \cap p_j^*$ among all other lines in $P^* = \{p^* | p \in P\}$, then the point p_k defines the minimum area triangle with the fixed points p_i, p_j over all points in $P \setminus \{p_i, p_j\}$. Finding the triple of lines as above (an intersecting pair and the other line closest to the intersection) is easy after constructing the arrangement $\mathcal{A}(P^*)$ (Section 24.4), and can be done in $\Theta(n^2)$ time in total. This is the most efficient algorithm known for this problem [GO95]. The minimum volume simplex defined by $d + 1$ points in a set of n points in $\mathbb{R}^d$ can be found using arrangements of hyperplanes in $\Theta(n^d)$ time.

OTHER APPLICATIONS

Another strand of applications consists of the “robotic” or “physical world” applications [HS95b]. In these problems a continuous space is decomposed into a finite number of cells so that in each cell a certain invariant is maintained. Here, arrangements are used to discretize a continuous space without giving up the completeness or exactness of the solution. An example of an application of this kind solves the following problem: Given a convex polyhedron in 3-space, determine how many combinatorially distinct orthographic and perspective views it induces; see Table 25.6.3. The answer is given using an arrangement of circles on the sphere (for orthographic views) and an arrangement of planes in 3-space (for perspective views) [BD90].

Many developments in the study of arrangements of curves and surfaces have been primarily motivated by problems in robot motion planning (Chapter 47) and several of its variants (Chapter 48). For example, the most efficient algorithm known for computing a collision-free path for an arbitrary polygonal robot (not necessarily convex) moving by translation and rotation among polygonal obstacles in the plane is based on computing a single connected component in an arrangement of surfaces in 3-space. The problem of planning a collision-free motion for a robot among obstacles is typically studied in the *configuration space* where every point represents a possible configuration of the robot. The related arrangements are of surfaces that represent all the contact configurations between the boundary of the robot and the boundaries of obstacles and thus partition configuration space into free cells (describing configurations where the robot does not intersect any obstacle) and forbidden cells. Given the initial (free placement) of the robot, we need only explore the cell that contains this initial configuration in the arrangement.

A concept similar to configuration space of motion planning has been applied in assembly planning (Section 48.3). The assembly planning problem is converted into a problem in *motion space* where every point represents an allowed path (motion) of a subcollection of the assembly relative the rest of the assembly [HLW00]. The motion space is partitioned by a collection of constraint surfaces such that for all possible motions inside a cell of the arrangement, the collection of movable subsets of the assembly is invariant.

As mentioned earlier, arrangements on spheres are prevalent in applications. Aside from vision applications, they also occur in: computer-assisted radio-surgery [SAL93], molecular modeling [HS98], assembly planning (Section 48.3), manufacturing [AdB⁺02], and more.

Arrangements have been used to solve problems in many other areas including geometric optimization [AS98], range searching (Chapter 36), statistical analysis

(Chapter 57), and micro robotics [BDH99], to name a few. More applications can be found in the sources cited below and in several other chapters in this book.

24.9 ROBUSTNESS

Transforming the data structures and algorithms described above into effective computer programs is a difficult task. The typical assumptions of (i) the real RAM model of computation and (ii) general position, are not realistic in practice. This is not only a problem for implementing software for arrangements but rather a general problem in computational geometry (see Chapter 65). However, it is especially acute in the case of arrangements since here one needs to compute *intersection points* of curves and surfaces and use the computed values in further operations (to distinguish from say convex hull algorithms that only select a subset of the input points).

EXACT COMPUTING

A general paradigm to overcome robustness problems is to compute exactly. For arrangements of linear objects, namely, arrangements of hyperplanes or of simplices, there is a fairly straightforward solution: using arbitrary precision rational arithmetic. This is regularly done by keeping arbitrary long integers for the numerator and denominator of each number. Of course the basic numerical operations now become costly, and a method was devised to reduce the cost of rational arithmetic predicates through the use of *floating point filters* (Chapter 41) which turn out to be very effective in practice, especially when the input is nondegenerate.

So far filtering has been applied to predicates but not to constructions. Notice that, if one has to produce the *exact* coordinates of an intersection point in an arrangement, there are no shortcuts and exact arithmetic needs to be used.

Matters are more complicated when the objects are not linear, namely when we deal with higher-degree curves and surfaces. First, there is the issue of representation. Consider the following simplest planar arrangement of the line $y = x$ and the circle $x^2 + y^2 = 1$ (both described by equations with integer coefficients). The upper vertex (intersection point) v_1 has coordinates $(\sqrt{2}/2, \sqrt{2}/2)$. This means that we cannot have a simple numerical representation of the vertices of the arrangement. An elegant solution to this problem is provided by special number types (so-called *algebraic number types*; notice though that only a subset of the algebraic numbers is currently supported). The approach is transparent to the user who just has to substitute the standard machine type (e.g., double) for the corresponding novel number type (which is a C++ class). Two software libraries support such number types (called *real* in both): LEDA [MN00] (Chapter 65) and Core [KLPY99] (Chapter 41). The ideas behind the solution proposed by both are similar and rely on separation bounds. In terms of arrangements the power that these number types provide is that we can determine the exact topology of the arrangement in all cases including degenerate cases. For example, if another circle passes through the point v_1 we can definitively determine this fact (which in general we cannot with standard machine arithmetic like the C++ double).

While exact computing may seem to be the solution to all problems, the sit-

uation is far from being satisfactory for several reasons: (i) The existing number types considerably slow down the computation compared with standard machine arithmetic. (ii) It is difficult to implement the full fledged number types required for arrangements of curves and surfaces. The state-of-the-art libraries offer the necessary types for arrangements of circles but not even for arrangements of conic arcs. Recently, an alternative approach has been taken to enable the exact construction of arrangements of conic arcs. It is based on using the GCD of the defining polynomials of arrangement vertices [BEH⁺02], [Wei02]. (iii) It still leaves open the question of handling degeneracies (see PERTURBATION below).

The high cost of exact predicates has led researchers to look for alternative algorithmic solutions (for problems where good solutions, in the standard measures of computational geometry, have been known), solutions that use less costly predicates; see, e.g., [BP00].

ROUNDING

In rounding we transform an arbitrary precision arrangement into fixed precision representation. The most intensively studied case is that of planar arrangements of segments. A solution proposed independently by Hobby [Hob99] and by Greene (improving on an earlier method in [GY86]), snaps vertices of the arrangement to centers of pixels in a prespecified grid. The method preserves several topological properties of the original arrangement and indeed expresses the vertices of the arrangement with limited precision numbers (say bounded bit-length integers). A dynamic algorithm is described in [GM98], and an improved algorithm for the case where there are many intersections within a pixel is given in [GGHT97]. Snap rounding has several drawbacks though: a line is substituted by a polyline possibly with many links (a “shortest-path” rounding scheme is proposed in [Mil00] that sometimes introduces fewer links than snap rounding), and a vertex of the arrangement can become very close to a non-incident edge (the latter problem has been overcome in an alternative scheme *iterated snap rounding* which guarantees a large separation between such features of the arrangement but pays in the quality of approximation [HP02]). Furthermore, a pair of input segments may intersect an arbitrarily large number of times in the rounded arrangements. Finally, the 3D version seems to produce a huge number of extra features [For99]: a polyhedral subdivision of complexity n turns into a snapped subdivision of complexity $O(n^4)$.

Effective and consistent rounding of arrangements remains an important and largely open problem. The importance of rounding arrangements stems not only from its being a means to overcome robustness issues, but, not less significantly, from being a way to express the arrangement numerically with reasonable bit-size numbers. Even if highly efficient exact number types are developed, there will still remain the question of numerical representation of the output.

APPROXIMATE ARITHMETIC IN PREDICATE EVALUATION

The behavior of fundamental algorithms for computing line arrangements (both sweep line and incremental) while using limited precision arithmetic is studied in [FM91]. It is shown that the two algorithms can be implemented such that for n lines the maximum error of the coordinates of vertices is $O(n\epsilon)$ where ϵ is the relative

error of the approximate arithmetic used (e.g., floating point). An algorithm for constructing curve arrangements with rounded arithmetic is presented in [Mil89].

PERTURBATION

An arrangement of lines is considered degenerate if it is not simple (Section 24.1). A degeneracy occurs for example when three lines meet at a common point. Intuitively this is a degeneracy since moving the lines slightly will result in a topologically different arrangement. Degeneracies in arrangements pose difficulties for two reasons. First and foremost they incredibly complicate programming (similar reasons led to the general position assumption—developing a theoretical algorithm that handles all possible degenerate cases is also a technically cumbersome and error-prone process). Although it has been proposed that handling degeneracies could be the solution in practice to relax the general position assumption [BMS94], in three and higher dimensions handling all degeneracies in arrangements seems an extremely difficult task. The second difficulty posed by degeneracies is that the numerical computation at or near degeneracies typically requires higher precision and will for example cause floating point filters to fail and resort to exact computing resulting in longer running time.

To overcome the first difficulty, symbolic perturbation schemes have been proposed. They enable a consistent perturbation of the input objects so that all degeneracies are removed. These schemes modify the objects only symbolically and a limiting process is used to define the perturbed objects (corresponding to infinitesimal perturbations) such that all predicates will have non-zero results. They require the usage of exact arithmetic, and a postprocessing stage to determine the structure of the output. For a unifying view of these schemes and a discussion of their properties, see [Sei98].

An alternative approach is to *actually* perturb the objects from their original placement. One would like to perturb the input objects as little as possible so that precision problems are resolved. This approach is viable in situations where the exact placement of the input can be compromised, as is the case in many engineering and scientific applications where the input is inexact due to measurement or modeling errors. An efficient such scheme for arrangements of spheres that model molecules is described in [HS98]; it has been adapted and extended to arrangements of polyhedral surfaces in [Raa99]. It is referred to as *controlled* perturbation since it guarantees that the final arrangement is degeneracy free (and predicates can be safely computed with limited precision arithmetic), to distinguish from heuristic perturbation methods. An in-depth study of the parameters that govern the scheme in the case of planar arrangements of circles is given in [HL03].

OPEN PROBLEM

Devise efficient and consistent rounding schemes for arrangements of curves in the plane and for arrangements in three and higher dimensions.

24.10 SOFTWARE

In spite of the numerous applications of arrangements, robust software for computing and manipulating arrangements is scarce. The reason for this is the difficulties outlined in the previous section. The situation is starting to change, with the increased understanding of the underlying difficulties, the research on overcoming these difficulties that has intensified during the last several years (Chapter 41), and the appearance of infrastructure for developing such software in the form of computational geometry libraries that emphasize robustness (Chapter 65).

24.10.1 2D ARRANGEMENTS

LEDA enables the construction of arrangements of segments via a sweep line algorithm. The resulting subdivision is represented as a LEDA graph. Point location based on persistent search trees is supported. The construction is robust through the use of arbitrary precision rationals.

A stand-alone package by Goldwasser supports arrangements of segments (or polygons), and the closely related arrangements of arcs of great circles on a sphere [Gol95]. Although care has been taken to handle degenerate polygons, the software uses standard floating point arithmetic and not exact number types.

Keyser et al. [KCMK99] describe a library for exact manipulation of algebraic curves, one application of which is computing the arrangement induced by such curves. Their method does not however handle degeneracies.

Arrangements of segments as well as of more general types of curves are supported by CGAL as we describe next.

2D ARRANGEMENTS IN CGAL

The most generic arrangement package at the time of the writing is the CGAL 2D arrangements package. The genericity is obtained through the separation of the combinatorial part of the algorithms and the numerical part [FHH⁺00]. (The overall design follows [Ket99].) The combinatorial algorithms are coded assuming that a small set of numerical/geometric operations (predicates and constructions) is supplied by the user for the desired type of curves. These operations are packed in a traits class (Chapter 65) that is passed as a parameter to the algorithms. The algorithms include the dynamic construction of the arrangement, represented as a doubly-connected-edge-list (DCEL), allowing for insertion and deletion of curves. Alternatively one can construct the arrangement using a sweep line algorithm. Then three algorithms for point location are supported. All algorithms handle arbitrary input, namely they do not assume general position. Several traits classes are supplied with the package for: line segments, circular arcs, canonical parabolas, polylines, and recently a unifying class for conic arcs [Wei02]. The CGAL arrangement package has been used to implement motion planning algorithms [AFH02], [HH02], a rounding scheme [HP02] and more.

An alternative algorithm for constructing arrangements of conic arcs (a static version using a sweep-line algorithm) was developed by Berberich et al. [BEH⁺02]. The more involved case of cubics is treated by Eigenwillig et al. [ESW02].

24.10.2 3D ARRANGEMENTS

Software to construct arrangements of triangles in 3-space exactly, assuming general position, is described in [SH02]. The implementation uses a space sweep algorithm and exact rational arithmetic. The arrangement is represented by its vertical decomposition or a sparser variant called the *partial vertical decomposition*. Several projects are underway whose goal is the construction of arrangements of algebraic surfaces in 3-space.

24.11 SOURCES AND RELATED MATERIAL

FURTHER READING

The study of arrangements through the early 1970s is covered by Grünbaum in [Grü67, Chapter 18], [Grü71], and [Grü72]. See also the monograph by Zaslavsky [Zas75].

In this chapter we have concentrated on more recent results. Details of many of these results can be found in the following books. The book by Edelsbrunner [Ede87] takes the view of “arrangements of hyperplanes” as a unifying theme for a large part of discrete and computational geometry until 1987. Sharir and Agarwal’s book [SA95] is an extensive report on results for arrangements of curves and surfaces. See also the more recent survey [AS00a].

Chapters dedicated to arrangements of hyperplanes in books: Mulmuley emphasizes randomized algorithms [Mul93], O’Rourke discusses basic combinatorics, relations to other structures and applications [O’R98], and Pach and Agarwal [PA95] discuss problems involving arrangements in discrete geometry. Boissonnat and Yvinec [BY98] discuss, in addition to arrangements of hyperplanes, arrangements of segments and of triangles.

Arrangements of hyperplanes and of surfaces are also the topics of chapters in the recently published book by Matoušek [Mat02].

25 TRIANGULATIONS AND MESH GENERATION

Marshall Bern

INTRODUCTION

A triangulation is a partition of a geometric domain, such as a point set, polygon, or polyhedron, into simplices that meet only at shared faces. (For point sets, the partition stops at the convex hull.) Triangulations are important for representing complicated geometry by piecewise simple geometry. The first four sections of this chapter discuss two-dimensional triangulations: Delaunay triangulation of point sets (Section 25.1); triangulations of polygons, including constrained Delaunay triangulation (Section 25.2); other optimal triangulations (Section 25.3); and mesh generation (Section 25.4). The next section treats the important practical case of polyhedra in $\mathbb{R}^3$ (Section 25.5). The last section discusses triangulations in arbitrary dimension $\mathbb{R}^d$ (Section 25.6).

FIGURE 25.0.1

Triangulations of a point set, a simple polygon, and a polyhedron.

25.1 DELAUNAY TRIANGULATION

The Delaunay triangulation is the most famous and useful triangulation of a point set. [Chapter 23](#) discusses this construction in conjunction with the Voronoi diagram.

GLOSSARY

- Empty circle:** No input points in the interior.
- Delaunay triangulation (DT):** Triangles have empty circumcircles.
- Completion:** Four or more cocircular points must be further triangulated.
- Edge flipping:** Local improvement move, used to compute DT.

BASIC FACTS

Let $S = \{s_1, s_2, \dots, s_n\}$ be a set of points in the Euclidean plane $\mathbb{R}^2$. The Delaunay triangulation (DT) is defined by the **empty circle condition**: a triangle $s_i s_j s_k$ appears in the DT if and only if its circumcircle neither encloses nor passes through any other points of S .

The DT always includes the convex hull of S . If no four points of S are cocircular, the Delaunay triangulation is indeed a triangulation of S . If four or more points are cocircular, there may be faces with more than three sides, which can be triangulated to **complete** the triangulation of S . The DT is the planar dual of the Voronoi diagram, meaning that an edge $s_i s_j$ appears in the DT if and only if the Voronoi cells of s_i and s_j share a boundary edge.

There is a connection between a Delaunay triangulation in $\mathbb{R}^2$ and a convex polytope in $\mathbb{R}^3$. If we **lift** S onto the paraboloid with equation $z = x^2 + y^2$ by mapping $s_i = (x_i, y_i)$ to $(x_i, y_i, x_i^2 + y_i^2)$, then the DT turns out to be the projection of the lower convex hull of the lifted points. See [Figure 23.1.2](#).

ALGORITHMS

There are a number of practical planar DT algorithms [For95], including edge flipping, incremental construction, sweep-line, and divide-and-conquer. We describe only the edge flipping algorithm, even though its worst-case running time of $O(n^2)$ is not optimal, because it is most relevant to our subsequent discussion.

The edge flipping algorithm starts from any triangulation of S and then locally optimizes each edge. Let e be an internal (nonconvex-hull) edge and Q_e be the triangulated quadrilateral formed by the triangles sharing e . Q_e is *reversed* if the two angles without the diagonal sum to more than 180° , or equivalently, if each triangle circumcircle contains the opposite vertex. If Q_e is reversed, we “flip” it by exchanging e for the other diagonal.

```

Compute an initial triangulation of  $S$ 
Place all internal edges into a queue
while the queue is not empty do
    Remove the first edge  $e$ 
    if quadrilateral  $Q_e$  is reversed then flip it fi
    Add outside edges of  $Q_e$  to the queue od
  
```

FIGURE 25.1.1

A generic step in computing the initial triangulation.

An initial triangulation can be computed by a sweep-line algorithm, as shown in Figure 25.1.1. This algorithm adds the points of S by x -coordinate order. Upon each addition, the algorithm walks around the convex hull of the already-added points, adding edges until the slope reverses.

The following theorem guarantees the success of edge flipping: a triangulation in which no quadrilateral is reversed must be a completion of the DT. This theorem can be proved using the lifting map; a reversed quadrilateral lifts to a reflex edge, and a surface without reflex edges must be the lower convex hull.

OPTIMALITY PROPERTIES

Certain quality measures [BE95] are improved by flipping a reversed quadrilateral. For example, the minimum angle in a triangle of Q_e must increase. Hence, a triangulation that maximizes the minimum angle cannot have a reversed quadrilateral, implying that it is a completion of the DT. Some completion of the DT:

- minimizes the maximum radius of a circumcircle;
- maximizes the minimum angle (in fact, lexicographically maximizes the angles from smallest to largest);
- minimizes the maximum radius of an enclosing circle;
- maximizes the sum of inscribed circle radii;
- minimizes the “potential energy” of a piecewise-linear surface; and
- minimizes the surface area of a piecewise-linear surface for elevations scaled sufficiently small.

Two additional properties of the DT: Delaunay triangles are acyclically ordered by distance from any fixed reference point, and the distance along edges of the DT between any pair of vertices is at most a constant (at most 2.42) times the Euclidean distance between them.

FIGURE 25.1.2

Power diagram and weighted Delaunay triangulation. The dashed circle is the orthogonal circle for triangle $s_i s_j s_k$.

REGULAR TRIANGULATIONS

Delaunay triangulations and Voronoi diagrams may be defined for various distance measures (Section 23.3); here we mention one generalization that retains most of the rich mathematical structure. Suppose each point $s_i = (x_i, y_i)$ in S has a weight w_i . The **regular triangulation** of S (sometimes called **weighted Delaunay triangulation**) is the projection of the lower convex hull of the points $(x_i, y_i, x_i^2 + y_i^2 - w_i)$. With a small (perhaps negative) weight, a site can drop out of the regular triangulation, so in general the regular triangulation is a graph on a subset of the sites S . In the special case that all weights are zero, the regular triangulation is exactly the DT. Because the w_i weights are arbitrary, regular triangulations in $\mathbb{R}^2$ are exactly the projections of lower convex hulls of polytopes in $\mathbb{R}^3$. Not all triangulations are regular; see Section 17.3 for a counterexample.

The planar dual of the regular triangulation is the **power diagram**, a Voronoi diagram in which the distance to s_i is the square of the Euclidean distance minus w_i . We can regard the sites in a power diagram as circles, with the radius of site i being $\sqrt{w_i}$. See Figure 25.1.2. The analogue of the empty circle condition for regular triangulations is the **orthogonal circle condition**: a triangle $s_i s_j s_k$ appears in the triangulation if and only if the circle that crosses circles i, j and k at right angles penetrates no other site circle more deeply.

25.2 TRIANGULATIONS OF POLYGONS

We now discuss triangulations of more complicated inputs: polygons and planar straight-line graphs. We start with the problem of simply computing any triangulation and then progress to constrained Delaunay triangulation.

GLOSSARY

Simple polygon: Connected boundary without self-intersections.

Monotone polygon: Intersection with any vertical line is one segment.

Constrained Delaunay triangulation: Allows input edges as well as vertices. Triangles have empty circumcircles, meaning no visible input vertices.

SIMPLE POLYGONS

Triangulating a simple polygon is both an interesting problem in its own right and an important preprocessing step in other computations. For example, the following problems are known to be solvable in linear time once the input polygon P is triangulated: computing link distances from a given source, finding a monotone path within P between two given points, and computing the portion of P illuminated by a given line segment,

How much time does it take to triangulate a simple polygon? For practical purposes, one should use either an $O(n \log n)$ deterministic algorithm (such as the one given below for the more general case of planar straight-line graphs) or a slightly

faster randomized algorithm (such as one with running time $O(n \log^* n)$) included in [Mul94]).

However, for theoretical purposes, achieving the ultimate running time was for several years an outstanding open problem. After a sequence of interim results, Chazelle [Cha91] devised a linear-time algorithm. Chazelle's algorithm, like previous algorithms, reduces the problem to that of computing the **horizontal visibility map** of P —the partition obtained by shooting horizontal rays left and right from each of the vertices. The “up-phase” of this algorithm recursively merges coarse visibility maps for halves of the polygon (polygonal chains); the “down-phase” refines the coarse map into the complete horizontal visibility map.

PLANAR STRAIGHT-LINE GRAPHS

Let G be a planar straight-line graph (PSLG). We describe an $O(n \log n)$ algorithm [PS85] that triangulates G in two stages, called regularization and triangulation. Regularization adds edges to G so that each vertex, except the first and last, has at least one edge extending to the left and one extending to the right. Conceptually, we sweep a vertical line ℓ from left to right across G while maintaining the list of intervals of ℓ between successive edges of G . For each interval I , we remember a vertex $v(I)$ visible to all points of I ; this vertex will be either an endpoint of one of the two edges bounding I or a vertex between these edges, lacking a right edge. When we hit a vertex u with no left edge, we add the edge $\{u, v(I)\}$, where I is the interval containing u , as shown in Figure 25.2.1(a). After the left-to-right sweep, we sweep from right to left, adding right edges to vertices lacking them.

```

Start  $\ell$  at left with  $v(\text{interval}(u)) = (-\infty, 0)$ 
for each vertex  $u$  from left to right do
    if  $u$  has no left edges then add edge  $\{u, v(\text{interval}(u))\}$  fi
    Delete  $u$ 's left edges from interval list
    Insert  $u$ 's right edges with  $v()$  set to  $u$  od
Repeat the steps above for vertices from right to left

```

FIGURE 25.2.1

(a) Sweep-line algorithm for regularization. (b) Stack-based triangulation algorithm.

After the regularization stage, each bounded face of G is *monotone*, meaning that a vertical line intersects the face in at most one segment. We consider the vertices $u_1, u_2, \dots, u_n$ of a face in left-to-right order, using a stack to store the not-yet-triangulated vertices (a reflex chain) to the left of the current vertex u_i . If u_i is adjacent to u_{i-1} , the topmost vertex on the stack, as shown in the upper picture of Figure 25.2.1(b), then we pop vertices off the stack and add diagonals from these vertices to u_i , until the vertices on the stack— u_i on top—again form a reflex chain. If u_i is instead adjacent to the leftmost vertex on the stack, as shown in the lower picture, then we can add a diagonal from each vertex on the stack, and clear the stack of all vertices except u_i and u_{i-1} .

CONSTRAINED DELAUNAY TRIANGULATION

Constrained Delaunay triangulation [LL86] provides a way to force the edges of a planar straight-line graph into the DT. A point p is *visible* to point q if line segment pq does not intersect any edge or vertex in G , except maybe at its endpoints. A triangle abc with vertices from G appears in the *constrained Delaunay triangulation* (CDT) if its circumcircle neither contains nor passes through any other vertex of G visible to some point in abc . If G is a graph with vertices but not edges, then this definition generalizes ordinary, unconstrained Delaunay triangulation. If G is a polygon or polygon with holes, as in Figure 25.2.2(b), then the CDT retains only the triangles interior to G .

FIGURE 25.2.2

Constrained Delaunay triangulations of (a) a PSLG and (b) a polygon with a hole.

The edge flipping algorithm generalizes to the constrained case, with the modification that edges of G are never placed on the queue. There are also $O(n \log n)$ -time algorithms for the CDT, and even a randomized $O(n)$ algorithm for the case that G is just a simple polygon [KL93]. See [Section 64.2](#) for pointers to software for computing the constrained Delaunay triangulation.

25.3 OPTIMAL TRIANGULATIONS

We have already seen two types of optimal triangulations: the DT and the CDT. Some applications, however, demand triangulations with properties other than

those optimized by these two triangulations. Table 25.3.1 gives a summary of results; each result holds for arbitrary PSLGs, except the fourth, which applies only to polygons.

GLOSSARY

Edge insertion: Local improvement operation, more general than edge flipping.

Local optimum: A solution that cannot be improved by local moves.

Greedy triangulation: At each step, add the shortest valid edge.

Steiner triangulation: Extra—noninput—points are allowed.

TABLE 25.3.1 Optimal triangulation results.

PROPERTY	ALGORITHMS	TIME
Delaunay	Various algorithms [For95]	$O(n \log n)$
Minmax angle	Fast edge insertion [ETW92]	$O(n^2 \log n)$
Minmax slope terrain	Edge insertion [BEE ⁺ 93]	$O(n^3)$
Min total edge length	Approx'n algorithms [Epp94, LK96]	$O(n \log n)$
Minmax edge length	MST induces polygons [ET91]	$O(n^2)$
Greedy edge length	Dynamic Voronoi diagram [LL92]	$O(n^2)$

EDGE FLIPPING AND EDGE INSERTION

The edge flipping DT algorithm can be modified to compute many other optimal triangulations. For example, if we redefine “reversed” to mean a quadrilateral triangulated with the diagonal that forms the larger maximum angle, then edge flipping can be used to minimize the maximum angle. For minmax angle, however, edge flipping computes only a local optimum, not necessarily the true global optimum.

Although edge flipping seems to work well in practice [ETW92], its theoretical guarantees are very weak: the running time is not known to be polynomially bounded and the local optimum it finds may be greatly inferior to the true optimum.

A more general local improvement method, called **edge insertion** [BEE⁺93, ETW92] exactly solves certain minmax optimization problems, including minmax angle and minmax slope of a piecewise-linear interpolating surface.

Assume that the input is a planar straight-line graph G , and we are trying to minimize the maximum angle. Starting from some initial triangulation of G , edge insertion repeatedly adds a candidate edge e that subdivides the maximum angle. (In general, edge insertion always breaks up a worst triangle by adding an edge incident to its “worst vertex.”) The algorithm then removes the edges that are crossed by e , forming two polygonal holes alongside e . Holes are retriangulated by repeatedly removing **ears** (triangles with two sides on the boundary, as shown in Figure 25.3.1) with maximum angle smaller than the old worst angle $\angle cab$. If retriangulation succeeds, then the overall triangulation improves and edge bc is eliminated as a future candidate. If retriangulation fails, then the overall triangulation is returned to its state before the insertion of e , and e is eliminated as a future candidate. Each candidate insertion takes time $O(n)$, giving a total running time of $O(n^3)$.

```

Compute an initial triangulation with all  $\binom{n}{2}$  edge slots unmarked
while  $\exists$  an unmarked edge  $e$  cutting the worst vertex of worst triangle  $abc$  do
    Add  $e$  and remove all edges crossed by  $e$ 
    Try to retriangulate by removing ears better than  $abc$ 
    if retriangulation succeeds then
        mark  $bc$ 
    else mark  $e$  and undo  $e$ 's insertion fi od

```

FIGURE 25.3.1

Edge insertion retriangulates holes by removing sufficiently good ears. (From [BE95], with permission.)

Edge insertion can compute the minmax “eccentricity” triangulation or the minmax slope surface [BEE⁺93] in time $O(n^3)$. By inserting candidate edges in a certain order, one can improve the running time to $O(n^2 \log n)$ for minmax angle [ETW92] and maxmin triangle height.

MINIMUM WEIGHT TRIANGULATION

Several natural optimization criteria can be defined using edge lengths [BE95]. The most famous such criterion—called *minimum weight triangulation*—asks for a triangulation of a planar point set minimizing the total edge length. No polynomial-time algorithm is known for this problem, nor is it known to be NP-complete. There is, however, a recently developed algorithm that is quite fast in practice. This algorithm [DKM97] uses a local criterion to find edges sure to be in the minimum weight triangulation. These edges break the convex hull of the point set into regions, such as simple polygons or polygons with one or two disconnected interior points, that can be triangulated optimally using dynamic programming.

The best approximation algorithm for minimum weight triangulation, by Levcopoulos and Krznaric [LK96], gives a solution within a constant multiplicative factor of the optimal length. Eppstein gave a constant-factor approximation ratio for minimum weight Steiner triangulation, in which extra vertices are allowed.

A commonly used heuristic for minimum weight triangulation is *greedy triangulation*. This algorithm adds edges one at a time, each time choosing the shortest edge that is not already crossed. Greedy triangulation can be viewed as an optimal triangulation in its own right, because it lexicographically minimizes the sorted vector of edge lengths. For arbitrary planar point sets, the greedy triangulation can be computed in time $O(n^2)$ by dynamic maintenance of a bounded Voronoi diagram [LL92].

Another natural criterion asks for a triangulation minimizing the maximum

edge length. Edelsbrunner and Tan [ET91] showed that such a triangulation—like the DT—must contain the edges of the minimum spanning tree (MST). This geometric lemma gives the following polynomial-time algorithm: compute the MST and then triangulate the resulting simple polygons optimally using dynamic programming.

OPEN PROBLEMS

1. Explain the empirical success of edge flipping for non-Delaunay optimization criteria, both solution quality and running time.
2. Settle the complexity of min weight triangulation—in P or NP-complete?
3. Show that the min weight Steiner triangulation exists, that is, rule out the possibility that more and more Steiner points decrease the total edge length forever.

25.4 PLANAR MESH GENERATION

A *mesh* is a decomposition of a geometric domain into *elements*, usually triangles or quadrilaterals in $\mathbb{R}^2$. Meshes are used to discretize continuous functions, especially solutions to partial differential equations. Practical mesh generation problems tend to be application-specific: one desires small elements where the function changes rapidly and larger elements elsewhere. However, certain goals apply fairly generally, and computational geometers have formulated problems incorporating these considerations. [Table 25.4.1](#) summarizes these results, and below we discuss some of them in detail.

GLOSSARY

Steiner point: An extra vertex, not an input point.

Conforming mesh: Elements exactly fill out the input domain.

Quadtree: A recursive subdivision of the plane with squares.

NO SMALL ANGLES

Sharp angles can degrade appearance and accuracy, so most mesh generation methods attempt to avoid small angles. (There is an exception: properly aligned sharp triangles prove quite useful in simulations of viscous flow.)

Baker et al. [BGR88] gave a grid-based algorithm for triangulating a PSLG so that all *new* angles—a sharp angle in the input cannot be erased—measure at least 14° . Bern et al. [BEG94] used quadtrees instead of a uniform grid and proved the following efficiency guarantee: the number of triangles is $O(1)$ times the minimum number in any no-small-angle triangulation of the input. The number of triangles required depends not just on the number of input vertices n , but also on the

TABLE 25.4.1 Mesh generation results.

PROPERTY	INPUTS	ALGORITHMS	SIZE
No small angles	polygons	Quadtrees [BEG94], circles [Rup93]	$O(1) \cdot \text{Optimal}$
No small solid angles	polyhedra	Octrees [MV92]	$O(1) \cdot \text{Optimal}$
No small or obtuse	polygons	Grids [BGR88], quadtrees	$O(1) \cdot \text{Optimal}$
No obtuse angles	polygons	Disk packing [BMR94]	$O(n)$
No obtuse angles	some PSLGs	Grids [BE92]	$O(n^4)$
No large angles	PSLGs	Propagating horns [Mit93, Tan94]	$O(n^2)$
Conforming Delaunay	PSLGs	Blocking & propagation [ET93]	$O(n^3)$

geometry of the input. The simple example of a long skinny rectangle shows why the number of triangles depends upon the geometry. Ruppert [Rup93], building on work of Chew, devised a *Delaunay refinement* algorithm with the same guarantee. The main loop of Ruppert’s algorithm attempts to add the circumcenter of a too-sharp triangle. If the circumcenter “encroaches” upon a boundary edge, meaning that it falls within the edge’s diameter circle and is visible to that edge, then the algorithm subdivides the boundary edge instead of adding the triangle circumcenter. Edelsbrunner and Guoy [EG01] proposed a more selective—and empirically more efficient—form of Delaunay refinement called *sink insertion*; this method does not add the circumcenter of the too-sharp triangle, but rather follows a chain of triangles until reaching one that contains its own circumcenter.

The efficiency guarantees for these Delaunay refinement algorithms follow from a stronger guarantee: at each point p of the domain the mesh triangle will be within a constant factor of the “local feature size,” which for polygons can be simply stated as the distance from p to the second-closest polygon vertex (see also Chapter 30). Miller et al. [MT⁺95] expanded Ruppert’s algorithm to a sort of paradigm, randomizable and parallelizable: pack the domain with a maximal set of non-overlapping disks with radii within a constant factor of the local feature size, and then compute the Delaunay triangulation of the disk centers. This approach is also related to “bubble meshing,” which simulates physical forces in order to place mesh vertices. Disk packing and placement, and in three dimensions ball placement, has proved to be a powerful and flexible approach to mesh generation, that can handle difficult practical issues such as multilevel meshes and solution adaptation, without sacrificing provable guarantees [Ber02].

NO LARGE ANGLES

A weaker condition than avoiding sharp angles is to avoid large angles (close to 180°). The strictest bound on large angles that does not also imply a bound on small angles is to ask for no obtuse angles, that is, all angles at most 90°. Surprisingly, it is possible to triangulate any polygon (possibly with holes) with only $O(n)$ nonobtuse triangles [BMR94]. Figure 25.4.1 illustrates the algorithm: the domain is packed with nonoverlapping disks until each uncovered region has either 3 or 4 sides; radii to tangencies are added in order to split the domain into small polygons; and finally these polygons are triangulated with right triangles, without adding any new subdivision points (vertices embedded within edges).

FIGURE 25.4.1

Nonobtuse triangulation steps. (From [BMR94], [BE95], with permission.)

By relaxing the bound on the largest angle from 90° to something larger, researchers have obtained results for arbitrary PSLGs. Mitchell [Mit93] gave an algorithm that uses $O(n^2 \log n)$ triangles to guarantee that all angles measure less than $\frac{7}{8}\pi$. The algorithm traces a cone of possible angle-breaking edges, called a *horn*, from each vertex—including subdivision points—with a larger angle. Horns propagate around the PSLG until meeting an exterior edge or another horn. By adding some more horn-stopping “traps,” Tan [Tan94] improved the angle bound to $\frac{11}{15}\pi$ and the complexity bound to $O(n^2)$, matching a lower bound.

CONFORMING DELAUNAY TRIANGULATION

A convenient mesh generation approach adds extra vertices—**Steiner points**—to the input, until the Delaunay triangulation of the vertices “conforms” to the input, meaning that each input edge is a union of Delaunay edges.

There are a number of algorithms for this problem in the plane; all take the basic approach of covering the input edges by disks that do not enclose any input vertices. Edelsbrunner and Tan [ET93] gave an algorithm that uses $O(n^3)$ triangles, currently the only polynomial algorithm.

SURFACE MESHES

A topic that sits between two and three dimensions is surface meshes for 3D solids. Key problems include **surface reconstruction**, that is, fitting a triangulated surface to a set of sample points, **mesh simplification**, reducing the number of triangles while preserving essential topology and geometry, and **geometry compression**, encoding the geometry efficiently.

Recent papers on surface reconstruction [ABK98, ACDL00, ACK01] assume that the input points satisfy a **sampling condition**: at any location on a smooth surface the closest sample point is no farther away than some constant times the distance to the surface’s **medial axis**. Under this condition—which in some sense captures both surface curvature and thickness of the solid—the 3D Delaunay triangulation of the sample points contains a set of triangles conforming to the surface, and algorithms based on the shapes of Voronoi cells can pick out such a set. See

Chapter 30 for further details.

For mesh simplification, surface curvature is more relevant than thickness of the solid, because the topology of the surface is already known. A smart simplification algorithm [GH97] repeatedly contracts an edge and repositions the coalesced vertex to the location in space that minimizes the sum of squared distances (“quadric error”) to all the planes supporting original faces incident to vertices that have gone into the coalesced vertex.

Geometry compression (cf. Chapter 54) can be either lossless or lossy. The key to lossless compression [TR98] is good prediction of vertex coordinates based on neighboring vertices. Lossy compression can simplify the mesh or otherwise change its connectivity for still more compact encoding. One very effective lossy method [GSS99] remeshes the surface into a *semiregular mesh*, in which all but the largest triangles are obtained by repeated subdivision of a triangle into four congruent copies of itself; the resulting hierarchical encoding is related to wavelet-based image compression.

OPEN PROBLEMS

1. Does every PSLG have a polynomial-size nonobtuse triangulation?
2. Does every PSLG have a conforming Delaunay triangulation of size $O(n^2)$?
3. What sampling condition is necessary and sufficient to reconstruct surfaces with corners and creases?

25.5 THREE-DIMENSIONAL POLYHEDRA

In this section we discuss the triangulation (or *tetrahedralization*) of 3D polyhedra. A polyhedron P is a flat-sided (connected) solid, usually assumed to satisfy the following nondegeneracy condition: around any point on the boundary of P , a sufficiently small ball contains one connected component of each of the interior and exterior of P . With this assumption, the numbers of vertices, edges, and faces (facets) of P are all linearly related.

GLOSSARY

Reflex edge: An edge with interior dihedral angle greater than 180° . (The dihedral angle between faces is measured on a plane normal to the shared edge.)

Convex polyhedron: A polyhedron without reflex edges.

Simple polyhedron: Topologically equivalent to a ball; edge skeleton forms a planar graph.

General polyhedron: May be topologically equivalent to a solid torus or higher-genus object, and may have more than one boundary component (i.e., cavities).

BAD EXAMPLES

Three dimensions is not as nice as two. Triangulations of the same input may contain different numbers of tetrahedra. For example, a triangulation of an n -vertex convex polyhedron may have as few as $n - 3$ or as many as $\binom{n-2}{2}$ tetrahedra. Below et al. [BLR00] recently proved that finding the minimum number of tetrahedra needed to triangulate (without Steiner points) a convex polyhedron is NP-complete. And when we move to nonconvex polyhedra, we get an even worse surprise: some inputs cannot even be triangulated without Steiner points.

FIGURE 25.5.1

A twisted prism cannot be triangulated without Steiner points.

Schönhardt's polyhedron, shown in Figure 25.5.1, is the simplest example of a polyhedron that cannot be triangulated. Ruppert and Seidel [RS92] proved the NP-completeness of determining whether a polyhedron can be triangulated without Steiner points, and of testing whether k Steiner points suffice.

Chazelle [Cha84] gave an n -vertex polyhedron that requires $\Omega(n^2)$ Steiner points. This polyhedron is a box with thin wedges removed from the top and bottom faces (Figure 25.5.2). The tips of the wedges nearly meet at the hyperbolic surface $z = xy$ and divide this surface into $\Omega(n^2)$ small squares, no pair of which can lie in the same tetrahedron in a triangulation.

FIGURE 25.5.2

A polyhedron that requires $\Omega(n^2)$ tetrahedra. (From [BE95], with permission.)

GENERAL POLYHEDRA

Any polyhedron can be triangulated with $O(n^2)$ tetrahedra, matching the lower bound. One algorithm shoots vertical walls up and down from each edge of the polyhedron boundary; walls stop when they reach some other part of the boundary. The tops and bottoms of the resulting “cylinders” are then triangulated to produce $O(n^2)$ triangular prisms, which can each be triangulated with a single interior Steiner point. An improvement first plucks off “pointed vertices” with unhindered “caps.” Such a vertex, together with its incident faces, forms an empty convex cone.

The improved algorithm uses $O(n + r^2)$ tetrahedra, where r is the number of reflex edges on the original polyhedron [CP90].

An alternative algorithm [Cha84] divides the polyhedron into convex solids by incrementally bisecting each reflex angle with a plane that extends away from the reflex angle in all directions until it first contacts the polyhedron boundary. This algorithm produces at most $O(nr + r^{7/3})$ tetrahedra [HS92].

SPECIAL POLYHEDRA

Any strictly convex polyhedron can be triangulated with at most $2n - 7$ tetrahedra by “starring” from a vertex. The region between two convex polyhedra (the convex hull of the union, minus the polyhedra), with a total of n vertices, can be triangulated without any Steiner points. If Steiner points are allowed, $O(n)$ tetrahedra suffice. The union of three convex polyhedra can also be tetrahedralized without Steiner points. The region between a convex polyhedron and a terrain can be triangulated with $O(n \log n)$ tetrahedra, and in fact, some such regions require $\Omega(n \log n)$ tetrahedra [CS94].

THREE-DIMENSIONAL MESH GENERATION

Mesh generation for 3D solids is an important, largely open, practical problem. Current approaches include octrees (the generalization of quadtrees), advancing front, bubble meshing, and Delaunay refinement, but no one method gives satisfactory results for all applications. Some of the practical issues include types of elements (tetrahedral or cubical or perhaps a mix), shapes of elements (solid and dihedral angles bounded away from extremes), anisotropy (stretched elements for accurate discretization of laminar flows), and solution adaptation (refinement and derefinement in regions where it is needed).

On the theoretical side, Mitchell and Vavasis [MV92] gave an octree method that guarantees well-shaped tetrahedra (equivalently, no small solid angles) and efficiency within a constant factor of optimal, the generalization of [BEG94] to $\mathbb{R}^3$. Miller et al. [MT⁺95] used maximal ball packing and Delaunay triangulation to guarantee well-shaped tetrahedra with the exception of *slivers*, the unique type of bad tetrahedron that can occur in a DT of a well-spaced point set. A sliver is a flat tetrahedron whose projection onto a plane that passes near all its vertices is fairly square; this is the only type of bad tetrahedron that has a small ratio of circumsphere radius to shortest edge. Luckily slivers are relatively fragile and can be removed (with weak but provable guarantees) by perturbing the point set [Ber02, Ede01]. One such perturbation, called *sliver exudation*, has the advantage that it does not actually move the points, but rather changes vertex weights in a weighted Delaunay triangulation; key to the success of sliver exudation is the result that a mild change in vertex weights dramatically changes the size of the orthogonal sphere [Ede01].

Constrained Delaunay triangulation does not extend to $\mathbb{R}^3$, because not every polyhedron has a triangulation without Steiner points, and even “easy” polyhedra may not have triangulations that use only tetrahedra with empty circumspheres. Shewchuk [She98] devised the closest thing to a 3D constrained Delaunay triangulation. Call a segment of a polyhedron X *strongly Delaunay* if it has a circumsphere

that neither encloses nor passes through any other vertex of X . Call a simplex (line, triangle, tetrahedron) *constrained Delaunay* if it has a circumsphere that encloses no vertex of X visible to any point in the relative interior of the simplex. If each of X 's segments is strongly Delaunay, then X has a triangulation in which each simplex is constrained Delaunay. In the nondegenerate case of no five cospherical vertices, the constrained Delaunay triangulation of X is unique. Shewchuk has used this notion of constrained Delaunay triangulation in a Delaunay refinement mesh generator that generalizes Ruppert's 2D generator: input edges are subdivided until their diametral spheres are empty, input faces (assumed triangles) are subdivided until their equatorial spheres are empty, and finally badly shaped tetrahedra are fixed by adding their circumcenters. This generator eliminates all types of bad tetrahedra except slivers.

OPEN PROBLEMS

1. Can the region between k convex polytopes, with n vertices in total, be (Steiner) triangulated with $O(n + k^2)$ tetrahedra?
2. Give an *input-sensitive* tetrahedralization algorithm, for example, one that uses only $O(1)$ times the smallest number of tetrahedra.
3. Give a polynomial bound (or even a simple-to-state bound depending upon geometry) on the number of Steiner points needed to make all segments of a polyhedron strongly Delaunay.
4. (Üngör) Can a cube be triangulated such that all tetrahedra have only acute dihedral angles? The corresponding question in two dimensions—triangulate a square with acute triangles—is a well-known, and fairly easy, puzzle.
5. Give an algorithm for computing tetrahedralizations of point sets or polyhedra, such that each tetrahedron contains its own circumcenter. This condition guarantees a desirable matrix property for a finite-volume formulation of an elliptic partial differential equation [Ber02].

25.6 ARBITRARY DIMENSION

We now discuss triangulation algorithms for arbitrary dimension $\mathbb{R}^d$. In our big-O expressions, we consider the dimension d to be fixed.

GLOSSARY

Polytope: A bounded intersection of halfspaces in $\mathbb{R}^d$.

Face: A subpolytope such as a vertex, edge, or 2D face.

Simplex: The convex hull of $d + 1$ affinely independent points in $\mathbb{R}^d$.

Circumsphere: The sphere through the vertices of a simplex.

Flip: A local operation, sometimes called a geometric bistellar operation, that exchanges two different triangulations of $d + 2$ points in $\mathbb{R}^d$.

POINT SETS

Delaunay triangulation—and more generally regular triangulation—extends to $\mathbb{R}^d$. The DT contains a simplex if and only if its circumsphere neither encloses nor passes through any other input points. The lifting map generalizes as well, and can be used to show that the DT includes at most $O(n^{\lceil d/2 \rceil})$ simplices. For practical applications such as interpolation, surface reconstruction and mesh generation, however, the DT rarely attains its worst-case complexity. The DT of random points within a volume or on a convex surface in $\mathbb{R}^3$ has linear expected complexity, but on a nonconvex surface can have near-quadratic complexity [Eri03]. DT complexity can also be bounded by geometric parameters such as the ratio between longest and shortest pairwise distances [Eri03].

Due to the lifting relation, any convex hull algorithm can be used to compute DTs. Many of the two-dimensional algorithms mentioned above also generalize to $\mathbb{R}^d$; however, the generalization of the edge flipping algorithm is not entirely straightforward. A flip in $\mathbb{R}^d$ exchanges two triangulations of $d + 2$ points in convex position. For example, 5 points in $\mathbb{R}^3$ can be triangulated by two tetrahedra sharing a face or by three tetrahedra sharing an edge. Flipping from an arbitrary triangulation in $\mathbb{R}^3$ can get stuck before reaching the DT [Joe89], but incrementally adding a point, splitting a simplex, and then flipping cannot. In fact, randomized incremental insertion is the most popular algorithm for computing DTs in $\mathbb{R}^3$.

Most DT optimality properties do not generalize to higher dimensions. One exception: the DT minimizes the maximum radius of a simplex enclosing sphere. The *enclosing sphere* is the smallest sphere containing a simplex, either the circumsphere, or the circumsphere of some face.

Of interest in algebraic geometry as well as computational geometry is the *flip graph* or *triangulation space*, which has a vertex for each distinct triangulation and an edge for each flip. Using the lifting relation, we can view flipping as exchanging the lower and upper convex hulls of $d + 2$ lifted points. For the flip graph we do not require the $d + 2$ points to be in convex position, and thus we allow a flip that inserts a new vertex, for example, splitting a tetrahedron in $\mathbb{R}^3$ into four by inserting an interior vertex. The flip graph of regular triangulations has the structure of a high-dimensional polytope [BFS90, GKZ90], but the flip graph including nonregular triangulations is not well understood. Santos [San98] recently showed that for points in $\mathbb{R}^5$ the flip graph including nonregular triangulations may not be connected, and in $\mathbb{R}^6$ may even have an isolated vertex.

The following is known about Steiner triangulations of point sets in $\mathbb{R}^d$. It is always possible to add $O(n)$ Steiner points, so that the DT of the augmented point set has size only $O(n)$, and there is always a nonobtuse Steiner triangulation containing at most $O(n^{\lceil d/2 \rceil})$ path simplices [BCER95]. A path simplex is one containing a path of d pairwise orthogonal edges.

POLYTOPES

Triangulations of polytopes in $\mathbb{R}^d$ arise in combinatorics and algebra [GKZ90, Sta80]. Several algorithms are known for triangulating the hypercube, but there is a gap between the most efficient algorithm (least number of simplices) and the best lower bound [OS02]; see [Section 17.5.2](#). It is known that the region between

two convex polytopes—a nonconvex polytope—can always be triangulated without Steiner points [GP88]; see [Section 17.3.1](#). Below et al. [BBLR00] have shown that there can be significant differences (linear in the number of vertices) in the minimum numbers of simplices in a triangulation and a *dissection* of a 3D polytope, which is a partition of a polytope into simplices whose faces may meet only partially (for example, a triangle bordering two other triangles along one of its sides).

OPEN PROBLEMS

1. Is the flip graph of the triangulations of a point set or polytope in $\mathbb{R}^3$ or $\mathbb{R}^4$ necessarily connected?
2. What is the asymptotic complexity of the maximum number of triangulations of a set of n points in $\mathbb{R}^d$? See [SS02] for results in $\mathbb{R}^2$.
3. Narrow the gap between the upper and lower bounds on the minimum number of simplices in a triangulation of the d -cube.

26 POLYGONS

Joseph O'Rourke and Subhash Suri

INTRODUCTION

Polygons are among the fundamental building blocks in geometric modeling, and they are used to represent a wide variety of shapes and figures in computer graphics, vision, pattern recognition, robotics, and other computational fields. By a polygon we will mean a region of the plane enclosed by a simple cycle of straight line segments; a *simple cycle* means that nonadjacent segments do not intersect and two adjacent segments intersect only at their common endpoint. This chapter describes a collection of results on polygons with both combinatorial and algorithmic flavors. After classifying polygons in the opening section, Section 26.2 covers polygon decomposition, and Section 26.3 polygon intersection. Sections 26.4 and 26.5, respectively, discuss path finding problems and polygon containment problems. Section 26.6 touches upon a few miscellaneous problems and results.

26.1 POLYGON CLASSIFICATION

Polygons can be classified in several different ways depending on their domain of application. In VLSI applications, for instance, the most commonly used polygons have their sides parallel to the coordinate axes.

GLOSSARY

- Simple polygon:*** A closed region of the plane enclosed by a simple cycle of straight line segments.
- Convex polygon:*** The line segment joining any two points of the polygon lies within the polygon.
- Monotone polygon:*** Any line parallel to some fixed direction intersects the polygon in a single connected piece.
- Monotone mountain:*** A monotone polygon one of whose two monotone chains is a single segment.
- Star-shaped polygon:*** The entire polygon is visible from some point inside the polygon.
- Orthogonal polygon:*** A polygon with sides parallel to the (orthogonal) coordinate axes. Sometimes called a *rectilinear polygon*.

POLYGON TYPES

FIGURE 26.1.1

A classification of polygons.

Before starting our discussion on problems and results concerning polygons, we clarify a few technical issues. The qualifier “simple” in the definition of a simple polygon states a *topological* property, meaning “nonself-intersection.” Not to be confused with “uncomplicated polygons,” in fact, these polygons include the most complex among polygons that are topologically equivalent to a disk (see the classification below). Finally, we will make a standard **general position** assumption throughout this chapter that no three vertices of a polygon are collinear.

The following *hierarchical* classification of polygons is one of the most commonly used (see Figure 26.1.1):

This hierarchy is best explained using the concept of visibility (see [Chapter 25](#)). We say that two points x and y in a polygon P are mutually **visible** if the line segment $\overline{xy}$ does not intersect the complement of P ; thus the segment $\overline{xy}$ is allowed to graze the polygon boundary but not cross it. We call a set of points $K \subset P$ the **kernel** of P if all points of P are visible from every point in the kernel (see Figure 33.4.4). Then, a polygon P is convex if $K = P$; the polygon is star-shaped if $K \neq \emptyset$; otherwise, the polygon is merely a simple polygon. Speaking somewhat loosely, a monotone polygon can be viewed as a special case of a star-shaped polygon with the exterior kernel at infinity—that is, a monotone polygon can be decomposed into two polygonal chains, each of which is entirely visible from the (same) point at infinity in the extended plane. Notice that the star-shaped polygon in Figure 26.1.1 is also a monotone polygon. The more specialized *monotone mountains* have also proved to be useful intermediate shapes, for, e.g., triangulation [O’R98, Sec. 2.3].

By definition, a simple polygon P is a polygon *without holes*—that is, the interior of the polygon is topologically equivalent to a disk. A **polygon with holes** is a higher-genus variant of a simple polygon, obtained by removing a nonoverlapping

set of strictly interior, simple subpolygons from P . Figure 26.1.2 illustrates the distinction between a simple polygon and a polygon with holes.

An important class of polygons are the *orthogonal polygons*, where all edges are parallel to the coordinate axes. These polygons arise quite naturally in certain applications such as VLSI design, and often algorithms are faster on these more structured polygons.

It would be useful to have a clear notion of a “random polygon” so that algorithms could be tested for typical rather than worst-case behavior. This leads to the issue of generating the *simple polygonalizations* of a fixed point set, a simple polygon whose vertices are the points. This has been solved only in special cases, e.g., for computing the number of monotone simple polygonalizations [ZSSM96], or via heuristic methods [AH96]. One impediment is the following unresolved question.

OPEN PROBLEM

Simple polygonalization: Can the number of simple polygonalizations of a set of n points in the plane be computed in polynomial time?

26.2 POLYGON DECOMPOSITION

Many computational geometry algorithms that operate on polygons first decompose them into more elementary pieces, such as triangles or quadrilaterals. There is a substantial body of literature in computational geometry on this subject. The most celebrated problem in this category is the “polygon triangulation problem.”

GLOSSARY

Steiner point: A vertex not part of the input set.

Diagonal: A line segment connecting two polygon nonadjacent vertices and contained in the polygon. An *edge* connects adjacent vertices.

Polygon cover: A collection of subpolygons whose union is exactly the input polygon.

FIGURE 26.1.2

Examples of a simple polygon and a polygon with holes.

Polygon partition: A collection of subpolygons with *pairwise disjoint* interiors whose union is exactly the input polygon.

Dissection: A dissection of one polygon P to another Q is a partition of P into a finite number of pieces that may be reassembled to form Q .

TRIANGULATION

The polygon triangulation problem is to dissect a polygon into triangles by drawing a maximal number of noncrossing diagonals. Only the vertices of the polygon are used as triangle vertices, and no additional (Steiner) vertices are allowed. It is an easy and well-known result that every simple polygon can be triangulated, and that the number of triangles is invariant over all triangulations. More precisely:

THEOREM 26.2.1

Every simple polygon admits a triangulation, and every triangulation of an n -vertex polygon has $n - 3$ diagonals and $n - 2$ triangles.

The number of possible diagonals in a polygon may vary from linear (e.g., a spiral polygon) to quadratic (e.g., a convex polygon). A diagonal that breaks the polygon into two roughly equal halves is called a **balanced** diagonal. In designing his $O(n \log n)$ time algorithm for triangulating a polygon, Chazelle [Cha82] proved the following fact, which has found numerous applications in divide-and-conquer based algorithms for polygons:

THEOREM 26.2.2

Every n -vertex simple polygon admits a diagonal that breaks the polygon into two subpolygons, neither one with more than $\lceil 2n/3 \rceil + 1$ vertices.

By recursively dividing the polygon using balanced diagonals, we get a balanced decomposition of P , which can be modeled by a tree of height $O(\log n)$. The existence of a balanced diagonal follows easily once we consider the graph-theoretic dual of a triangulation. This dual graph of a polygon triangulation is a tree, with maximum node degree three. Diagonals of the triangulation correspond to the edges of the dual tree, and thus a balanced diagonal corresponds to an edge whose removal breaks the tree into two subtrees, each with at most $\lceil 2n/3 \rceil + 1$ nodes.

The problem of computing a triangulation of a polygon has had a long and distinguished history [O'R87], culminating in Chazelle's linear-time algorithm [Cha91]. Table 26.2.1 lists some of the best-known algorithms for this problem. The algorithm in [Sei91] is a randomized Las Vegas algorithm (see Chapter 34). All others are deterministic algorithms, with worst-case time bounds as shown.

Chazelle's deterministic linear-time algorithm is formidably complex, but has led to a simpler randomized algorithm that runs in linear expected time [AGR01].

Finally, if the polygon contains holes, then it has been shown that $\Theta(n \log n)$ time is both necessary and sufficient for triangulating the region [HM85]. See Table 26.2.2.

TABLE 26.2.1 Results on triangulating a simple polygon.

TIME COMPLEXITY	ALGORITHM	SOURCE
$O(n \log n)$	monotone pieces	[GJPT78]
$O(n \log n)$	divide-and-conquer	[Cha82]
$O(n \log n)$	plane sweep	[HM85]
$O(n \log^* n)$	randomized	[Sei91]
$O(n)$	polygon cutting	[Cha91]

TABLE 26.2.2 Results on triangulating a polygon with holes.

TIME COMPLEXITY	ALGORITHM	SOURCES
$O(n \log n)$	plane sweep	[HM85]
$O(n \log n)$	local sweep	[RR94]

COVERS AND PARTITIONS

The problem of decomposing polygons into different types of simpler polygons has numerous applications within and outside computational geometry (see, e.g., [Chapter 43](#)). Unlike the triangulation problem, most variants of the covering and partitioning problems turn out to be provably hard. In a covering problem, the goal is to cover the interior of the polygon with the smallest number of subpolygons of a particular type, for instance, convex or star-shaped polygons. [Table 26.2.3](#) lists results for various polygon covering problems. In this table, “cover type” refers to the family of polygons allowed in the cover, while “domain” refers to the polygonal region that needs to be covered. For the most part, we consider only four types of domains: simple polygons, with and without holes, and orthogonal polygons, with and without (orthogonal) holes. In all of these problems, the cover or partition pieces are allowed to use Steiner points for their vertices. Almost all variations of the covering problem are intractable. The last important open problem in this area, determining the complexity of covering polygons by convex pieces, was settled in [CR88]; this paper also serves as a good source of pointers to related work on polygon covering problems. It remains unclear if their NP-hardness proof could be adapted to settle the same question without Steiner points.

The polygon-partitioning problems are similar to the covering problem, except that the tessellating pieces are not allowed to overlap. [Table 26.2.4](#) collects results on polygon partitioning problems permitting Steiner points. Polynomial-time algorithms can be achieved for simple polygons using the dynamic programming technique. The same problems, however, turn out to be intractable when the polygon has holes. Disallowing Steiner points also leads to polynomial-time algorithms. For example, partitioning a polygon without holes into the fewest convex pieces, not employing Steiner points, is achievable in $O(n^3 \log n)$ time [Kei85, KS98].

Two useful references for polygon partitioning problems are [AAI86] and [Kei85]. The latter presents several polynomial-time algorithms for optimally partitioning

TABLE 26.2.3 Results on polygon covering problems.

COVER TYPE	DOMAIN	HOLES	COMPLEXITY	SOURCE
Rectangles	orthogonal	Y	NP-complete	[Mas78]
Convex-star	polygons	Y	NP-hard	[OS83]
Star	polygons	N	NP-hard	[Agg84]
Rectangles	orthogonal	N	NP-hard	[CR94]
Convex	polygons	N	NP-hard	[CR94]

TABLE 26.2.4 Results on polygon partitioning problems.

PARTITION	DOMAIN	HOLES	COMPLEXITY	SOURCE
Convex	polygons	N	$O(n^3)$	[CD79]
Convex	polygons	Y	NP-hard	[CD79]
Trapezoids	polygons	N	$O(n^2)$	[Kei85]
Trapezoids	polygons	Y	NP-complete	[AAI86]
Rectangles	orthogonal	Y	$O(n^{3/2} \log n)$	[LLL ⁺ 79, OSTT83]

a simple polygon into convex pieces *without* using Steiner points. See [Chapter 43](#) for applications of polygon decomposition problems.

The intractability of most covering and partitioning problems naturally leads to the question of approximability—how well can we approximate the size of an optimal cover or partition in polynomial time. In many cases, there are only a polynomial number of covering candidates—for instance, rectangle covers or convex polygon covers. In these cases, a greedy set-cover heuristic can be used to achieve an approximation factor of $O(\log n)$.

FAT PARTITIONS

Because many algorithms work faster on “fat” shapes, partitioning polygons into fat pieces has become a recent focus. One notion of fatness asks for a partition into convex polygons that minimizes the largest aspect ratio of any piece of the partition. The *aspect ratio* of a polygon P is the ratio of the diameters of the smallest circumscribing circle to the largest inscribed circle. Thus, the fatness corresponds to circularity. If Steiner points are disallowed, i.e., if the pieces of the partition must have their vertices chosen among P ’s vertices, then a polynomial-time algorithm is known [DI02]. Permitting Steiner points leads to considerable complexity. For example, the optimal partition of an equilateral triangle needs an infinite number of pieces, and the optimal partition for a square is not yet known [DO03]. See [Figure 26.2.1](#).

ORTHOGONAL POLYGONS

Partitions and covers of orthogonal polygons into rectangles were mentioned above. With the goal achieving the fewest number of rectangles, finding optimal covers is NP-complete, whereas finding optimal partitions is polynomial, $O(n^{3/2} \log n)$. If the goal is to minimize the total length of the “cuts” between the rectangles (minimum “ink”), then an optimum partition can be found in $O(n^4)$ time for poly-

FIGURE 26.2.1

A 92-piece partition achieving an aspect ratio of 1.29950, the smallest so far achieved. ([DO03])

gons without holes, but is NP-complete with holes [LTL89]. Approximations are available; for example, one that guarantees a solution within a factor of 3 of the minimum length [GZ90]. For the goal of maximizing the shortest rectangle side over all rectangles in the partition (a type of “fat” partition, motivated by VLSI chip masking), a polynomial-time algorithm is known for polygons without holes [OT02]. See Figure 26.2.2 for such a partition, here only employing cuts incident to vertices.

FIGURE 26.2.2

38-rectangle partition of a $n = 82$ vertex orthogonal polygon. The dark rectangle is the thinnest.

Covering orthogonal polygons without holes with the fewest squares is polynomial, $O(n^{3/2})$, but NP-complete for polygons with holes [ACKO88].

AREA BISECTION

A particularly useful partition of a polygon P is an **area bisection**: a line determining a halfplane H such that $H \cap P$ and $\bar{H} \cap P$ have the same area. In [DO90] an $O(n \log n)$ algorithm for area bisection was developed, and then used to “ham-sandwich section” a pair of polygons. Motivated by positioning parts in industrial

part-feeding systems, Böhringer et al. [BDH99] developed an output-size sensitive algorithm for computing the complete set of combinatorially distinct area bisectors, which they show can have size $\Omega(n^2)$.

DISSECTIONS

A **dissection** of one polygon P to another Q is a partition of P into a finite number of pieces that may be reassembled to form Q . P and Q are then said to be *equidecomposable*. Dissections have been studied as puzzles for centuries. A typical example is shown in Figure 26.2.3 [Fre97, p. 66]. It has been known since the early

FIGURE 26.2.3

Sam Loyd’s “A&P Baking Powder” puzzle reassembles a rectangle with a hole to a rectangle without a hole via a two-piece dissection.

19th century that any two polygons of equal area are equidecomposable [Fre97, p. 221]. The same question for the more constrained **hinged dissections** remains unresolved. See Fig. 26.2.4 for the famous Dudeney-McElroy hinged dissection between a square and an equilateral triangle [Fre02]. Partial results here are that any two polyominoes (Chapter 15) of the same area have a hinged dissection [DDE⁺03], and any asymmetric polygon has a hinged dissection to its mirror image [Epp01].

FIGURE 26.2.4

A four-piece hinged dissection between a square and an equilateral triangle.

OPEN PROBLEMS

1. *Convex cover without Steiner points:* What is the complexity of covering a polygon without holes by convex pieces, without employing Steiner points? The Culberson-Reckhow NP-hardness proof [CR94] uses Steiner points.
2. *Approximating the number of art gallery guards:* Give a polynomial-time algorithm for computing a constant-factor approximation of the minimum number of point guards needed to cover a simple polygon.
3. *Fat partition of a square:* What is the optimal partition of a square into “fat” convex polygons?
4. *Hinged dissections:* Does every pair of equal-area polygons have a hinged dissection?

26.3 POLYGON INTERSECTION

Polygon intersection problems deal with issues of detection and computation of the collision between two polygonal shapes. In the detection problem, one is only interested in deciding *whether* the two polygons have a point in common. In the intersection computation problem, the algorithm is asked to report the overlapping parts of the two polygons. Such problems arise naturally in robotics and computer games; see [Chapter 33](#) for additional material.

The maximum *number* of points at which two polygons may cross each other depends on the type of polygons. If p and q , respectively, denote the number of vertices of the two polygons, then the maximum number of intersections is $\min(2p, 2q)$ if both polygons are convex, $\max(2p, 2q)$ if one is convex, and pq otherwise.

Algorithmically, intersection-detection between convex polygons can be done significantly faster than intersection computation, if we allow reasonable preprocessing of polygons. By a reasonable preprocessing, we mean that the preprocessing algorithm takes into account the *structure* of the polygons but *not their positions*. In Table 26.3.1, n denotes the total number of vertices in the two polygons; that is, $n = p + q$.

TABLE 26.3.1 Intersecting polygons.

POLYGON TYPES	PREPROCESSING	QUERY	SOURCE
Convex-convex	$O(1)$	$O(n)$	[CD80]
Convex-convex	$O(n)$	$O(\log n)$	[CD80]
Simple-simple	$O(1)$	$O(n)$	[Cha91]
Simple-simple	$O(n \log n)$	$O(m \log^2 n)$	[Mou92]

The parameter m in the query time for intersections of two simple polygons is the complexity of a *minimum link witness* for the intersection or disjointness of the

two polygons, and we always have $m \leq n$. The preprocessing space requirement is linear when the polygons are preprocessed.

26.4 PATHS IN POLYGONS

Path planning in polygons is another well-studied area of research. An abstract robot motion planning problem ([Chapter 40](#)) is to find a shortest path for a point in the midst of a collection of disjoint polygons in the plane. This simplified scenario lets us focus exclusively on the combinatorial aspect of the robotics problem, ignoring such practical issues as kinematics and control ([Chapter 41](#)). The polygons represent obstacles in the path of the robot, which itself is modeled as a point. The free space is the set of all points accessible to the robot via a free path. By convention, for the case of a single polygon, the free space is defined to be the closed interior of the polygon (think of an art gallery).

GLOSSARY

- Free space:** The complement of the union of the interiors of obstacle polygons.
- Free path:** A path lying entirely in the free space.
- Shortest path:** A free path of minimum total length.
- Shortest path tree:** The union of shortest paths from one fixed vertex to all other vertices. (Strictly speaking, this may not be a tree in special cases.)
- Shortest path map:** The minimal partition of the plane with respect to a fixed source point s so that all points in a region have the same combinatorial structure for their shortest path to s , i.e., the list of vertices on the path is the same. See [Figure 24.0.1](#).
- Geodesic diameter:** The maximum shortest path distance between any points.
- Geodesic center:** A point minimizing the maximum shortest path distance to all other points.
- Minimum link path:** An obstacle-avoiding path between two given points with the minimum number of edges.
- Link distance:** The link distance between two points p and q is the minimum number of straight-line segments needed in any free path connecting p and q .
- Window partition:** The window partition of a polygon P with respect to a source point s (or a line segment) is the minimal partition of P into regions with the property that all points in a region have the same link distance to s .

EUCLIDEAN MEASURE

The problem of computing a shortest Euclidean path between two points in the presence of polygonal obstacles is one of the best-known problems of computational geometry (see [Chapter 24](#)). The geometry of the Euclidean plane ensures that the shortest path is a nonself-intersecting polygonal path with corners at obstacle vertices. [Figure 26.4.1](#) shows an example of a shortest path problem. A *shortest*

path tree [GHL⁺87] extends the notion of a single shortest path to shortest paths to all vertices of the polygonal domain from a specified source point.

FIGURE 26.4.1

A shortest path among polygons.

The shortest path distance function is a metric, and therefore several natural measures lend themselves to our new setting: in particular, the *shortest path diameter* (also called the *geodesic diameter*) and the *geodesic center*. The following table summarizes the main results known today for these shortest path problems. The long-standing open problem of computing a shortest path map in optimal time was settled only recently [HS93]. A related question is computing the shortest diagonal in a simple polygon. It may be found in linear time [HS97].

TABLE 26.4.1 Results for Euclidean shortest paths in the plane.

PROBLEM	DOMAIN	RESULT	SOURCE
Shortest path	simple polygon	$O(n \log n)$	[GM91]
Shortest path tree	simple polygon	$O(n \log n)$	[GHL ⁺ 86]
Shortest path tree	triang. simple poly.	$O(n)$	[HS91]
Geodesic diameter	simple polygon	$O(n)$	[AT87]
Geodesic center	simple polygon	$O(n \log n)$	[PSR89]
Shortest path tree	polygon with holes	$O(E + n \log n)$	[GM91]
Shortest path map	polygon with holes	$O(n \log n)$	[HS93]

In the Table 26.4.1, the use of a triangulated polygon in [GHL⁺87, HS91] is meant to separate the cost of triangulating the polygon from the cost of computing a shortest path tree. However, since the publication of these results, a linear-time algorithm for polygon triangulation has been achieved [Cha91], making this distinction unnecessary. Interest in the geodesic diameter and center was partly motivated by Lantuejoul and Maisonneuve [LM84], who proposed these measures for quantitative image analysis.

SHORTEST PATH QUERIES

Often it is desirable to preprocess a polygon (with or without holes) to speed up subsequent query answering. For the case where the domain is a simple polygon and all queries are with respect to a fixed source point, an optimal data structure is presented in [GHL⁺87]. Essentially, the shortest path tree implicitly partitions the polygon into regions that have the same shortest path structure. In combination with a point-location data structure, this partition achieves $O(\log n)$ query time using $O(n)$ space. When the source point is not fixed, the problem is more difficult and requires more advanced data structuring methods. Nevertheless, an optimal solution is known with $O(n)$ space and $O(\log n)$ query time [GH89, Her91].

For polygons with holes, only the case of a fixed source point is satisfactorily solved: the algorithm of Hershberger and Suri [HS93] computes an $O(n)$ -space shortest path map, which can be used to answer queries in $O(\log n)$ time apiece. When the source is not fixed, we know of no sublinear time query algorithm! The most promising direction in this case is via fast approximation algorithms; only recently has some progress been made in this direction. An algorithm by Chen [Che95] takes $O(n^{3/2} \log n)$ space and $O(\log n)$ query time to compute a $(6 + \epsilon)$ -approximation of the shortest path distance.

LINK MEASURE

Another measure of distance that has received considerable attention in computational geometry is the link distance [Sur87, Sur90]. The motivation behind the link distance comes from situations where the cost of “turning” outweighs the cost of straight-line travel. Figure 26.4.2 shows an example of a minimum link path which is not a shortest path.

FIGURE 26.4.2
A minimum link path.

For link distance problems in a simple polygon, a construction known as a window partition has proved to be very useful [Sur90]. A window partition is best explained using the idea of visibility. All points of the polygon directly visible from s are at link distance one. Call this set V_1 . The boundary between the visible and invisible region of the polygon consists of a collection of chords, called *windows* of V_1 . The points in $P \setminus V_1$ that are visible from some point of a window of V_1 form the region with link distance two. Repeating this construction yield the window partition of P . For a fixed source point in a simple polygon, the **window tree** data structure of Suri [Sur90] yields the optimal query time of $O(\log n)$ using $O(n)$ space.

When both source and destination are specified as part of the query, the best data structure known is due to Arkin, Mitchell, and Suri [AMS92], achieving $O(\log n)$ time but at the expense of $O(n^3)$ space. Further results on link and geodesic queries can be found in Chiang and Tamassia [CT94], and Section 24.3 of this Handbook.

The problems of computing a shortest path, the diameter, and the center all extend to the link measure, and Table 26.4.2 summarizes the known results for these problems.

TABLE 26.4.2 Results for minimum link path problems.

PROBLEM	DOMAIN	RESULT	SOURCE
Min link path	triang simple poly	$O(n)$	[Sur87, Sur90]
Min link tree	triang simple poly	$O(n)$	[Sur87, Sur90, GM90]
Orthogonal min link path	orthogonal obstacles	$O(n \log n)$	[OSTT83]
Link diameter	simple polygon	$O(n \log n)$	[Sur87]
Link center	simple polygon	$O(n \log n)$	[Ke89, DLS92]
Link dist query	simple poly, arbitrary s, t	$O(\log n), O(n^3)$ space	[AMS92]

The result in [DLS92], achieving $O(n \log n)$ for both link center and radius of a simple polygon, is the culmination of the window trees ideas initiated in [Sur87] and further articulated in [Ke89].

VISIBILITY AND RAY SHOOTING

Algorithms and data structures for computing visibility have come to occupy an important role in computational geometry, in large part due to their successful application in solving other problems. In a polyhedral environment modeling a real-life scene, determining what is visible from a particular location has obvious relevance to the problem of robot motion planning. The ray shooting problem represents a very specific instance of visibility computation: determine the first point of contact between a query ray and the polyhedral scene. In addition to obvious applications in collision-detection, the ray shooting problem also plays a fundamental role in designing other computational geometry algorithms, such as data structures for the equally important “point-location” problem.

The topic of computing the visibility region of a point, line segment, or other objects is treated in [Chapter 25](#). In the present section, we cover the results on ray shooting, which are presented in [Table 26.4.3](#).

The query performance in the case of polygons with holes is sensitive to the number of holes—if the number of holes is $k \leq n$, then the query time for the last two algorithms improves to $O(\sqrt{k} \log n)$, with preprocessing cost $O(n\sqrt{k} + n \log n + k^{3/2} \log k)$.

TABLE 26.4.3 Results for the ray shooting problem in polygons.

DOMAIN	PREPROCESSING	QUERY	SOURCE
Convex polygon	$O(n)$	$O(\log n)$	[GHL ⁺ 87]
Simple polygon	$O(n)$	$O(\log n)$	
Polygon with holes	$O(n)$	$O(\sqrt{n} \log n)$	[HS93]

OPEN PROBLEMS

1. *Shortest path query problem:* Build a data structure to compute shortest-path distance between pairs of query points in the presence of polygonal obstacles. The goal is to achieve $O(n \log n)$ space, $O(\log n)$ query time, and $O(1)$ approximation factor on the distance. (The constant of approximation should be small, say, at most 2.) No sublinear query algorithm for the exact problem is known.
2. *Non-Steiner minimum link path problem:* Given a simple polygon P and a pair of points $p, q \in P$, find a minimum link path in P from p to q subject to the condition that the path turns only at the vertices of P . Can this problem be solved in $O(n \log n)$ time?

26.5 POLYGON CONTAINMENT

Polygon containment refers to a class of problems that deals with the placement of one polygonal figure inside another. Polygon inscription, polygon circumscription, and polygon nesting are other variants of this type of problem.

GLOSSARY

- Inscribed polygon:** We will say that a polygon Q is inscribed in polygon P if $Q \subset P$. P is then called a *circumscribing polygon*.
- Polygon nesting:** P, Q is a nested pair if $Q \subset P$ or vice versa.

CONTAINMENT OF POLYGONS

Let P, Q be two simple polygons with p and q vertices, respectively. The polygon containment problem asks for the largest copy of Q that can be contained in P using rotations and translations. (In this section, all scalings are assumed to be *uniform*; thus “shearing” is not permitted.) Several authors have considered the polygonal containment problem under various restrictions on the shape of the polygons and the allowable motions. Table 26.5.1 collects the best results known for the most important cases. See Section 47.4 for a description of the near-linear λ_s function.

TABLE 26.5.1 Results for the polygon containment problem.

P	Q	TRANSFORMS	RESULTS	SOURCE
Ortho-convex	ortho-convex	translate, scale	$O((p+q)^2 \log pq)$	[For85]
Convex	convex	translate, scale	$O((p+q)^2 \log pq)$	[For85]
Convex	convex	translate, rotate	$O(qp^2)$	[Cha83]
Simple	simple	translate, rotate	$O(p^3 q^3 \log pq)$	[AB88]
Convex	polygon w holes	translate, rotate, scale	$O(q^4 p \lambda_4(pq) \log p)$	[CK93]
Convex	points	translate, rotate, scale	$O(q^2 p \lambda_3(pq) \log p)$	[CK93]

It has been shown recently that the decision problem—whether there exists a transformation of Q that permits it to be contained in P —is 3SUM-hard, under a variety of allowable transformations [BHP01]. Thus it is unlikely the above complexities can be pushed below quadratic.

Considerable work has focused on packing shapes for its practical applications. For example, the apparel industry is interested in packing clothing patterns on a bolt of cloth efficiently. Much of the progress on this inherently intractable problem has proceeded by studying particular containment problems. See, e.g., [Mil96, DMR97, Mil99]. Finally, a number of specialized results are available. For example, there is an $O(n \log n)$ randomized algorithm for placing two equal-radii disks in a convex polygon, a problem with application to facility location [KSY00]. Finding the largest pair of equal-radii disks in an arbitrary simple polygon has a surprising application to folding polygons [BDD⁺98], and can be found again in $O(n \log n)$ randomized time [BMV01].

INSCRIBING/CIRCUMSCRIBING POLYGONS

We now consider problems related to inscribing and circumscribing polygons. In these problems, a polygon P is given, and the task is to find a polygon Q of some specified number of vertices k that is inscribed in (resp. circumscribes) P while maximizing (resp. minimizing) certain measure of Q . The common measures include area and perimeter. See Table 26.5.2 for results concerning this class of problems; n denotes the number of vertices of P . See references [AP88] and [MS90] for these results and other relevant material on this problem. The latest addition is [BM02], an improvement of the $O(n \log n)$ minimum perimeter algorithm of [AP88] to $O(n)$.

TABLE 26.5.2 Inscribing and circumscribing polygons.

TYPE	k	P	MEASURE	RESULTS	SOURCE
Inscribe	3	convex	max area	$O(n)$	[DS79]
Inscribe	k	convex	max area/perimeter	$O(kn + n \log n)$	[AKM ⁺ 87]
Inscribe	convex	simple	max area	$O(n^7)$	[CY86]
Inscribe		simple	max area/perimeter	$O(n^4)$	[MS90]
Circumscribe	3	convex	min area	$O(n)$	[OAMB86]
Circumscribe	3	convex	min perimeter	$O(n)$	[BM02]
Circumscribe	k	convex	min area	$O(kn + n \log n)$	[AP88]

NESTING POLYGONS

The nested polygon problem asks for a polygon with the smallest number of vertices that fits between two nested polygons. More precisely, given two nested polygons P and Q , where $Q \subset P$, find a polygon K of the least number of vertices such that $Q \subset K \subset P$. Generalizing the notion of nested polygons, one can also pose the problem of determining a polygonal subdivision of the least number of *edges* that “separates” a family of polygons. Table 26.5.3 lists the results on these problems. In this table, n is the total number of vertices in the input polygons, while k is the number of vertices in the output polygon (or subdivision). Reference [MS92] is a good source of pointers to other results on polygon nesting problems.

TABLE 26.5.3 Results for polygon nesting.

TYPES OF P, Q	TYPE OF K	RESULTS	SOURCE
Convex-convex	convex	$O(n \log k)$	[ABO ⁺ 89]
Simple-simple	simple	$O(n \log k)$	[Gho91]
Polygonal family	subdivision	NP-complete	[Das90]
Polygonal family	subdivision	$O(1)$ -Opt in $O(n \log n)$	[MS92]

Several other results on polygon nesting have been obtained. In particular, if the minimum-vertex nested polygon is nonconvex, then it can be found in $O(n)$ time [GM90]. There is also a relation here to *offset polygons* (Chapter 56), e.g., [BBDG98].

26.6 MISCELLANEOUS

There is a rather large number of results pertaining to polygons, and it would be impossible to cover them all in a single chapter. Having focused on a selected list of topics so far, we now provide below an unorganized collection of some miscellaneous results.

POLYGON MORPHING

To *morph* one polygon into another is to find a continuous deformation from the source polygon to the target polygon. Guibas and Hershberger [GH94] introduce the problem of morphing a simple polygon P to another simple polygon Q whose edges, taken in counterclockwise order, are parallel to the corresponding edges of P and oriented the same way. An atomic morphing step is a uniform scaling or translation of a part of the polygon. It is shown in [GH94] that $O(n^{4/3+\epsilon})$ morphing steps are always sufficient to convert one polygon to another. This result was improved shortly afterward by Hershberger and Suri [HS95], who reduced the number of morphing steps to $O(n \log n)$.

An alternative approach to morphing is suggested by *polyhedral reconstruction*: Given two polygons lying in parallel planes, construct an interpolating polyhedron whose top and bottom faces are the two given polygons and all intermediate slices are simple polygons. See [Chapter 26](#) for more details on reconstruction problems.

FLIPPING POCKETS

Let a **pocket** of a polygon P be a region bounded by a subchain of the polygon edges and an edge of the convex hull of P , the **pocket lid**. Every nonconvex polygon has at least one pocket. Erdős defined a **flip** as a rotation of a pocket's chain of edges into 3D about the pocket lid by 180° , landing the subchain back in the plane of the polygon, and asked [Erd35] whether every polygon may be convexified by a finite number of simultaneous pocket flips. The answer is YES [dSN39], although no bound may be placed on the number of required flips as a function of the number of polygon vertices n .

FIGURE 26.6.1

A *flipturn* about pocket lid ab .

This motivates the **flipturn** operation, which rotates by 180° a subchain bounding a pocket of the polygon, not in 3D about the pocket lid, but in 2D around the midpoint of the lid; see Figure 26.6.1. It was established in [ACD⁺02] that the length of the longest convexifying flipturn sequence is at most $n^2/4 - O(1)$. Whether there might be a smaller upper bound remains open.

For related questions of moving between polygons whose vertices are defined by a fixed point set, via flips or other local transformations, see [HHH02].

CSG REPRESENTATION

In [DGHS88] Dobkin et al. consider the problem of deriving a **Peterson-style** formula given the boundary representation of a simple polygon. A Peterson-style formula is a “constructive solid geometry” representation, in which the polygon is presented as a set of Boolean operations; see [Chapter 47](#). Peterson proved that every simple polygon in two dimensions admits a representation by a Boolean formula

on the halfplanes supporting the edges of the polygon. Furthermore, the resulting formula is *monotone*; that is, there is no negation and each halfplane appears exactly once. Dobkin et al. consider the algorithmic problem of constructing such a formula, and give an $O(n \log n)$ time algorithm, where n is the number of vertices of the polygon. Interestingly, it turns out that not all 3D polyhedra admit a Peterson-style formula [DGHS88].

POLYGON SEARCHING

In these problems, the goal is to design *on-line* search strategies for locating an (identifiable) object in a polygon; the word “on-line” means that the searcher does not have a complete knowledge of the polygon, rather it “discovers” the polygon during its navigation. The motivation stems from robotics applications. Table 26.6.1 summarizes some basic results on this class of problems. (The parameter k in the last line denotes the number of distinct initial placements of the robot having the same visibility polygon.) References [IK95] and [DRW98] provide a good starting point for a search on this topic.

TABLE 26.6.1 Results for polygon searching.

ENVIRONMENT	GOAL	COMPETITIVE RATIO	SOURCE
n oriented rectangles	shortest path	$\Theta(\sqrt{n})$	[BRS91]
“Street” polygon	shortest path	$1 + \frac{3}{2}\pi$	[Kle92]
Gen. Streets	shortest path	9.06-Opt	[DI99]
Star-shaped polygon	reach kernel	≈ 5.52	[IK95]
Orthogonal polygon	exploration	randomized $5/4$	[Kle94]
Simple polygon	localization with min travel	$(k-1)$ -Opt	[DRW98]
Simple polygon	shortest watchman tour	26.5-Opt	[HIKK01]

THREE-DIMENSIONAL POLYGONS

A 3D polygon is an unknotted closed chain of segments in $\mathbb{R}^3$ such that adjacent segments share an endpoint, and nonadjacent segments do not intersect. A triangulation of a 3D polygon has the same combinatorial structure as a triangulation of a planar polygon—all triangle vertices are polygon vertices, each polygon edge is a side of one triangle, each diagonal is shared by exactly two triangles—with the surface they define a nonself-intersecting topological disk. This disk is said to *span* the polygon. Barequet et al. proved that determining whether a 3D polygon has a triangulation in this sense is NP-complete [BDE98]. Another negative result along the same lines is that there exist 3D polygons of n vertices that can only be spanned by nonself-intersecting piecewise-linear disks which, when triangulated, need $2^{\Omega(n)}$ triangles [HST03]. Note that here the triangle vertices are not necessarily polygon vertices, i.e., Steiner points are (necessarily) used. This exponential lower bound shows that *knot triviality* algorithms (which check whether a closed chain is the trivial “unknot”) that search for such spanning disks necessarily

lead to exponential-time algorithms. This unknotting problem is known to be in NP [HLP97].

OPEN PROBLEMS

1. *Natural morphing*: The transformation in [GH94] is not very natural: it morphs the source polygon to a simple intermediate shape, and then expands it to the target polygon. Explore a more natural morphing transformation.
2. *Morphing with holes*: Investigate the morphing problem for polygons with holes.
3. *3D Peterson formulas*: Characterize the 3D polyhedra that can be represented by Peterson-style formulas.
4. *Shortest flipturn sequence*: Is there a subquadratic upper bound on the length of the shortest flipturn sequence to convexify a polygon of n vertices?

26.7 SOURCES AND RELATED MATERIAL

SURVEYS

The survey article by Mitchell and Suri [MS95] addresses optimization problems in computational geometry, many involving polygons. Keil surveys polygon decomposition algorithms in [Kei00]. Link distance problems are surveyed in [MSD00].

27 SHORTEST PATHS AND NETWORKS

Joseph S.B. Mitchell

INTRODUCTION

Computing an optimal path in a geometric domain is a fundamental problem in computational geometry, with applications in robotics, geographic information systems (GIS), wire routing, etc.

A taxonomy of shortest-path problems arises from several parameters that define the problem:

1. Objective function: the length of the path may be measured according to the Euclidean metric, an L_p metric, the number of links, a combination of criteria, etc.
2. Constraints on the path: the path may have to get from s to t while visiting a specified set of points or regions along the way.
3. Input geometry: the map of the geometric domain also specifies constraints on the path, requiring it to avoid various types of obstacles.
4. Type of moving object: the object to be moved along the path may be a single point or may be a robot of some specified geometry.
5. Dimension of the problem: often the problem is in 2 or 3 dimensions, but higher dimensions arise in some applications.
6. Single shot vs. repetitive mode queries.
7. Static vs. dynamic environments: in some cases, obstacles may be inserted or deleted or may be moving in time.
8. Exact vs. approximate algorithms.
9. Known vs. unknown map: the on-line version of the problem requires that the moving robot sense and discover the shape of the environment along its way.

We survey various forms of the problem, primarily in two and three dimensions, for motion of a single point, since most results have focused on these cases. We discuss shortest paths in a simple polygon (Section 27.1), shortest paths among obstacles (Section 27.2), and other metrics for length (Section 27.3). We also survey other related network optimization problems (Section 27.4). Higher dimensions are discussed in Section 27.5. Finally, in Section 27.6, we survey results on t -spanners and their application to shortest paths and network optimization.

GLOSSARY

Polygonal s - t path: A path from point s to point t consisting of a finite number of line segments (*edges*, or *links*) joining a sequence of points (*vertices*).

Length of a path: A nonnegative number associated with a path, measuring its total cost according to some prescribed metric. Unless otherwise specified, the length will be the Euclidean length of the path.

Shortest/optimal/geodesic path: A path of minimum length among all paths that are feasible (satisfying all imposed constraints). See Figure 27.0.1.

Shortest-path distance: The metric induced by a shortest-path problem. The shortest-path distance between s and t is the length of a shortest s - t path; in many geometric contexts, it is also referred to as *geodesic distance*.

Locally shortest/optimal path: A path that cannot be improved by making a small change to it that preserves its *combinatorial structure* (e.g., the ordered sequence of triangles visited, for some triangulation of a polygonal domain P); also known as a *taut-string* path in the case of a shortest obstacle-avoiding path.

Simple polygon P of n vertices: A closed, simply-connected region whose boundary is a union of n (straight) line segments (edges), whose endpoints are the vertices of P .

Polygonal domain of n vertices and h holes: A closed, multiply-connected region whose boundary is a union of n line segments, forming $h + 1$ closed (polygonal) cycles. A simple polygon is a polygonal domain with $h = 0$.

Triangulation of a simple polygon P : A decomposition of P into triangles such that any two triangles intersect in either a common vertex, a common edge, or not at all. A triangulation of P can be computed in $O(n)$ time. See [Section 25.2](#).

FIGURE 27.0.1

The visibility graph $VG(P)$. Edges of $VG(P)$ are of two types: (1) the heavy dark boundary edges of P , and (2) the edges that intersect the interior of P , shown with thin dashed segments. A shortest s - t path is highlighted.

Obstacle: A region of space whose interior is forbidden to paths. The complement of the set of obstacles is the *free space*. If the free space is a polygonal domain P , the obstacles are the $h + 1$ connected components (h *holes*, plus the *face at infinity*) of the complement of P .

Visibility graph $VG(P)$: A graph whose nodes are the vertices of P and whose edges join pairs of nodes for which the corresponding segment lies inside P . See [Chapter 27](#). An example is shown in Figure 27.0.1.

Single-source query: A query that specifies a goal point t , and requests the length of a shortest path from a *fixed* source point s to t . The query may also require that a shortest s - t path be reported; in general, this can be done in additional time $O(k)$, where k is the number of edges in the output path.

FIGURE 27.0.2

A shortest path map with respect to source point s within a polygonal domain. The dotted path indicates the shortest s - t path, which reaches t via the root r of its cell.

Shortest path map, $\text{SPM}(s)$: A decomposition of free space into regions (*cells*) according to the “combinatorial structure” of shortest paths from a fixed source point s to points in the regions. Specifically, for shortest paths in a polygonal domain, $\text{SPM}(s)$ is a decomposition of P into cells such that for all points t interior to a cell, the sequence of obstacle vertices along an s - t path is fixed. In particular, the *last* obstacle vertex along a shortest s - t path is the **root** of the cell containing t . Each cell is **star-shaped** with respect to its root, which lies on the boundary of the cell. See Figure 27.0.2, where the root of the cell containing t is labeled r . If $\text{SPM}(s)$ is preprocessed for point location (see [Chapter 34](#)), then single-source queries can be answered efficiently by locating the query point t within the decomposition.

Two-point query: A query that specifies two points, s and t , and requests the length of a shortest path between them. It may also request that a path be reported.

Geodesic Voronoi diagram (VD): A Voronoi diagram for a set of *sites*, in which the underlying metric is the geodesic distance. See [Chapters 23](#) and [25](#).

Geodesic center of P : A point within P that minimizes the maximum of the shortest-path lengths to any other point in P .

Geodesic diameter of P : The length of a longest shortest path between a pair of points $s, t \in P$; s and t are vertices for any longest s - t shortest path.

27.1 PATHS IN A SIMPLE POLYGON

The most basic geometric shortest-path problem is to find a shortest path inside a **simple** polygon P (having no holes), connecting two points, s and t . The complement of P serves as an obstacle through which the path is not allowed to travel. In this case, there is a unique taut-string path from s to t , since there is only one way

to “thread” a string through a simply-connected region.

Algorithms for computing a shortest s - t path begin with a triangulation of P ($O(n)$ time; Section 25.2), whose dual graph is a tree. The *sleeve* is comprised of the triangles that correspond to the (unique) path in the dual that joins the triangle containing s to that containing t . By considering the effect of adding the triangles in order along the sleeve, it is not hard to obtain an $O(n)$ time algorithm for collapsing the sleeve into a shortest path. At a generic step of the algorithm, the sleeve has been collapsed to a structure called a *funnel* (with *base* ab and *root* r) consisting of the shortest path from s to a vertex r , and two (concave) shortest paths joining r to the endpoints of the segment ab that bounds the triangle abc processed next (see Figure 27.1.1). In adding triangle abc , we “split” the funnel in two according to the taut-string path from r to c , which will, in general, include a segment uc joining c to some (vertex) point of tangency u , along one of the two concave chains of the funnel. After the split, we keep that funnel (with base ac or bc) that contains the s - t taut-string path. The work needed to search for u can easily be charged off to those vertices that are discarded from further consideration. Thus, a shortest s - t path is found in time $O(n)$, which is worst-case optimal.

FIGURE 27.1.1
Splitting a funnel.

SHORTEST PATH MAPS

The shortest path map $\text{SPM}(s)$ for a simple polygon has a particularly simple structure, since the boundaries between cells in the map are (line segment) chords of P obtained by extending appropriate edges of the visibility graph $\text{VG}(P)$. It can be computed in time $O(n)$ by using somewhat more sophisticated data structures to do funnel splitting efficiently; in this case, we cannot discard one side of each split funnel. Single-source queries can be answered in $O(\log n)$ time, after storing the $\text{SPM}(s)$ in an appropriate $O(n)$ -size point location data structure (see [Chapter 34](#)). $\text{SPM}(s)$ includes a tree of shortest paths from s to every vertex of P .

TWO-POINT QUERIES

A simple polygon can be preprocessed in time $O(n)$, into a data structure of size $O(n)$, to support shortest-path queries between any two points $s, t \in P$. In time $O(\log n)$ the length of the shortest path can be reported, and in additional time $O(k)$, the shortest path can be reported, where k is the number of vertices in the output path [GH89].

TABLE 27.1.1 Shortest paths and geodesic distance in simple polygons.

PROBLEM VERSION	COMPLEXITY	NOTES	SOURCE
Shortest s - t path	$O(n)$		[LP84]
Single-source query; SPM(s)	$O(\log n)$ query $O(n)$ preproc/space	builds SPM(s)	[GHL ⁺ 87]
Two-point query	$O(\log n)$ query $O(n)$ preproc/space		[GH89]
Two-polygon query	$O(\log k + \log n)$ query $O(n)$ space	between convex k -gons in simple n -gon	[CT97]
Dynamic two-point query	$O(\log^2 n)$ update/query $O(n)$ space		[GT97]
Dynamic two-polygon query	$O(\log k + \log^2 n)$ query $O(\log^2 n)$ update $O(n)$ space	between convex k -gons in simple n -gon	[CT97]
Parallel algorithm (CREW PRAM)	$O(\log n)$ time $O(n/\log n)$ processors	in triangulated polygon also builds SPM(s)	[Her95]
Geodesic VD	$O((n+k)\log(n+k))$	k point sites	[PL98]
All nearest neighbors	$O(n)$	for set of vertices	[HS97]
Geodesic farthest-site VD	$O((n+k)\log(n+k))$ time $O(n+k)$ space	k point sites	[AFW93]
All farthest neighbors	$O(n)$	for set of vertices	[HS97]
Geodesic diameter	$O(n)$		[HS97]
Geodesic center	$O(n \log n)$		[PSR89]

DYNAMIC VERSION

In the dynamic version of the problem, one allows the polygon P to change with addition and deletion of edges and vertices. If the changes are always made in such a way that the set of all edges yields a **connected planar subdivision** of the plane into simple polygons (i.e., no “islands” are created), then one can maintain a data structure of size $O(n)$ that supports two-point query time of $O(\log^2 n)$ (plus $O(k)$ if the path is to be reported), and update time of $O(\log^2 n)$ for each addition/deletion of an edge/vertex [GT93].

OTHER RESULTS

Several other problems studied with respect to geodesic distances induced by a simple polygon are summarized in Table 27.1.1. See also Table 25.4.1.

Shortest paths within simple polygons yield a wealth of structural information about the polygon. In particular, they have been used to give an output-sensitive algorithm for constructing the visibility graph of a simple polygon ([Her89]) and can be used for constructing a **geodesic triangulation** of a simple polygon, which allows for efficient ray-shooting (see [CEG⁺94]). They also form a crucial step in solving **link distance** problems, as we will discuss later.

OPEN PROBLEMS

1. Can one devise a simple $O(n)$ time algorithm for computing the shortest path between two points in a simple polygon, *without* resorting to a (complicated) linear-time triangulation algorithm?

2. Can the geodesic Voronoi diagram for k sites within P be computed in time $O(n + k \log k)$?
3. Can the geodesic center of a simple polygon be computed in $O(n)$ time?

27.2 PATHS IN A POLYGONAL DOMAIN

While in a simple polygon there is a unique taut-string path between two points, in a general polygonal domain P , there can be an exponential number of taut-string simple paths between two points.

The homotopy type of a path can be expressed as a sequence (with repetitions) of triangles visited, for some triangulation of P . For any given homotopy type, expressed with N triangles, a shortest path of that type can be computed in $O(N)$ time [HS94]. Efficient algorithms for computing a set of homotopic shortest paths among obstacles, for many pairs of start and goal points, have been recently given [Bes03, EKL02]. One can also efficiently test, in time $O(n \log n)$, if two simple paths are of the same homotopy type in a polygonal domain; here, n is the total number of vertices of the input paths and the polygonal domain [CLMS02].

SEARCHING THE VISIBILITY GRAPH

Without loss of generality, we can assume that s and t are vertices of P (since we can make “point” holes in P at s and t). It is easy to show that any locally optimal s - t path must lie on the visibility graph $\text{VG}(P)$ (Figure 27.0.1). We can construct $\text{VG}(P)$ in output-sensitive time $O(E_{\text{VG}} + n \log n)$, where E_{VG} denotes the number of edges of $\text{VG}(P)$ [GM91], even if we allow only $O(n)$ working space [PV95]. Given the graph $\text{VG}(P)$, whose edges are weighted by their Euclidean lengths, we can use Dijkstra’s algorithm to construct a tree of shortest paths from s to all vertices of P , in time $O(E_{\text{VG}} + n \log n)$ [FT87]. Thus, Euclidean shortest paths among obstacles in the plane can be computed in time $O(E_{\text{VG}} + n \log n)$. This bound is worst-case quadratic in n , since $E_{\text{VG}} \leq \binom{n}{2}$; note too that domains exist with $E_{\text{VG}} = \Omega(n^2)$.

Given the tree of shortest paths from s , we can compute $\text{SPM}(s)$ in time $O(n \log n)$, by computing an additive weight Voronoi diagram (see Chapter 23) of the vertices, with each vertex weighted by its distance from s .

CONTINUOUS DIJKSTRA METHOD

Instead of searching the visibility graph (which may have quadratic size), an alternative paradigm for shortest-path problems is to construct the (linear-size) shortest path map directly. The *continuous Dijkstra* method was developed for this purpose.

Building on the success of the method in solving (in nearly linear time) the shortest-path problem for the L_1 metric, Mitchell [Mit96] developed a version of the continuous Dijkstra method applicable to the Euclidean shortest-path problem, obtaining the first subquadratic ($O(n^{1.5+\epsilon})$) time bound. Subsequently, this result was improved by Hershberger and Suri [HS99], who achieve a nearly optimal algo-

rithm based also on the continuous Dijkstra method. They give an $O(n \log n)$ time and $O(n \log n)$ space algorithm, coming close to the lower bounds of $\Omega(n + h \log h)$ time and $O(n)$ space.

The continuous Dijkstra paradigm involves simulating the effect of a wavefront propagating out from the source point, s . The **wavefront** at distance δ from s is the set of all points of P that are at geodesic distance δ from s . It consists of a set of curve pieces, called **wavelets**, which are arcs of circles centered at obstacle vertices that have already been reached. At certain critical “events,” the structure of the wavefront changes due to one of the following possibilities:

- (1) a wavelet disappears (due to the closure of a cell of the SPM);
- (2) a wavelet collides with an obstacle vertex;
- (3) a wavelet collides with another wavelet; or
- (4) a wavelet collides with an obstacle edge at a point interior to that edge.

It is not difficult to see from the fact that $\text{SPM}(s)$ has linear size, that the total number of such events is $O(n)$. The challenge in applying this propagation scheme is devising an efficient method to know *what* events are going to occur and in being able to *process* each event as it occurs (updating the combinatorial structure of the wavefront).

One approach, used in [Mit96], is to track a “pseudo-wavefront,” which is allowed to run over itself, and to “clip” only when a wavelet collides with a vertex that has already been labeled due to an earlier event. Detection of when a wavelet collides with a vertex is accomplished with range-searching techniques. An alternative approach, used in [HS99], simplifies the problem by first decomposing the domain P using a *conforming subdivision*, which allows one to propagate an approximate wavefront on a cell-by-cell basis. A key property of a conforming subdivision is that any edge of length L of the subdivision has only a constant number of (constant-sized) cells within geodesic distance L .

APPROXIMATION ALGORITHMS

One can compute approximate Euclidean shortest paths using standard methods of discretizing the set of directions. Clarkson [Cla87] gives an algorithm that uses $O((n \log n)/\epsilon)$ time to build a data structure of size $O(n/\epsilon)$, after which a $(1 + \epsilon)$ -approximate shortest path query can be answered in time $O(n \log n + n/\epsilon)$. (These bounds rely also on an observation in [Che95].) Using a related approach, based on approximating Euclidean distance with fixed orientation distances, Mitchell [Mit92] computes a $(1 + \epsilon)$ -approximate shortest path in time $O((n \log n)/\sqrt{\epsilon})$ using $O(n/\sqrt{\epsilon})$ space. Chen, Das, and Smid [CDS01] have shown an $\Omega(n \log n)$ lower bound, in the algebraic computation tree model, on the time required to compute a $(1 + \epsilon)$ -approximate shortest path.

TWO-POINT QUERIES

Two-point queries in a polygonal domain are much more challenging than the case of simple polygons, where optimal algorithms are known. One natural approach (observed by Chen et al. [CDK01]) is to store the shortest path map, $\text{SPM}(v)$,

rooted at each vertex v ; this requires $O(n^2)$ space. Then, for a query pair (s, t) , we compute the set of k_s vertices visible to s and k_t vertices visible to t , in time $O(\min\{k_s, k_t\} \log n)$, using the visibility complex of Pocchiola and Vegter [PV93]. Then, assuming that $k_s \leq k_t$, we simply locate t in each of the k_s SPM's rooted at the vertices visible from s . This permits two-point queries to be answered in time $O(\min\{k_s, k_t\} \log n)$, which is worst-case $\Omega(n \log n)$, making it no better than computing a shortest path from scratch, in the worst case.

Methods for exact two-point queries that are efficient in the worst case utilize an *equivalence decomposition* of the domain P , for which all points z within a cell of the decomposition have topologically equivalent shortest path maps. Given query points s and t , one locates s within the decomposition, and then uses the resulting SPM, along with a parametric point location data structure, to locate t within the SPM with respect to s . The complexity of the decomposition can be quite high; there can be $\Omega(n^4)$ topologically distinct shortest path maps with respect to points within P . Chiang and Mitchell [CM99] have utilized this approach to obtain various tradeoffs between space and query time; see Table 27.2.1. Unfortunately, the space bounds are all impractically high.

More efficient methods allow one to approximately answer two-point queries. As observed in [Che95], the method of Clarkson [Cla87] can be used to construct a data structure of size $O(n^2 + n/\epsilon)$ in $O(n^2 \log n + (n/\epsilon) \log n)$ time, so that two-point $(1 + \epsilon)$ -optimal queries can be answered in time $O((\log n)/\epsilon)$, for any fixed $\epsilon > 0$. Chen [Che95] was the first to obtain nearly *linear*-space data structures for approximate shortest path queries; these were obtained, though, at the cost of a higher approximation factor. He obtains a $(6 + \epsilon)$ -approximation, using $O(n^{3/2}/\log^{1/2} n)$ time to build a data structure of size $O(n \log n)$, after which queries can be answered in time $O(\log n)$. The best current bounds are given by Arikati et al. [ACC⁺96], who give a spectrum of results based on planar t -spanners (see Section 27.6), with tradeoffs among the approximation factor and the preprocessing time, storage space, and query time. One such result gives a $(3\sqrt{2} + \epsilon)$ -approximation in query time $O(\log n)$, after using $O(n^{3/2}/\log^{1/2} n)$ time to build a data structure of size $O(n \log n)$.

In the special case that the polygonal domain is “ t -rounded,” meaning that the shortest path distance between any two vertices is at most some constant t times the Euclidean distance between them, Gudmundsson et al. [GLNS02a, GLNS02b] show that in query time $O(\log n)$, one can give a $(1 + \epsilon)$ -approximate answer to a two-point shortest path query while using only $O(n \log n)$ space and preprocessing time. Their result utilizes approximate distance oracles in t -spanner graphs, giving $O(1)$ -time approximate distance queries between pairs of vertices; see Section 27.6.

OTHER RESULTS

The geodesic Voronoi diagram of k sites inside P can be constructed in time $O((n + k) \log(n + k))$, using the continuous Dijkstra method, simply starting with multiple source points. While the geodesic center/diameter problem has been carefully examined for the case of simple polygons, we are unaware of results, beyond brute force, for polygonal domains.

Table 27.2.1 summarizes various results.

TABLE 27.2.1 Shortest paths among planar obstacles, in a polygonal domain.

OPEN PROBLEMS

1. Can the Euclidean shortest-path problem be solved in $O(n + h \log h)$ time and $O(n)$ space?
2. How efficiently, and using what size data structure, can one preprocess a polygonal domain for exact two-point queries? Can one obtain sublinear queries using a reasonable amount of space (say, subquadratic)?
3. How efficiently can one compute a geodesic center/diameter for a polygonal domain?

27.3 OTHER METRICS FOR LENGTH

In the problems considered so far, the Euclidean metric has been used to measure the length of a path. We consider now several other possible objective functions for measuring path length. Tables 27.3.1 and 27.3.2 summarize results.

GLOSSARY

L_p metric: The L_p distance between $q = (q_x, q_y)$ and $r = (r_x, r_y)$ is given by $d_p(q, r) = [|q_x - r_x|^p + |q_y - r_y|^p]^{1/p}$. The L_p length of a polygonal path is the

sum of the L_p lengths of each edge of the path. Special cases of the L_p metric include the L_1 metric (*Manhattan metric*) and the L_∞ metric ($d_\infty(q, r) = \max\{|q_x - r_x|, |q_y - r_y|\}$).

Rectilinear path: A polygonal path with each edge parallel to a coordinate axis; also known as an *isothetic* path.

C-oriented path: A polygonal path with each edge parallel to one of a set C of $c = |C|$ *fixed orientations*.

Link distance: The minimum number of edges in a polygonal path from s to t within a polygonal domain P . If the paths are restricted to be rectilinear or C -oriented, then we obtain the *rectilinear link distance* or *C-oriented link distance*.

Min-link s-t path: A polygonal path from s to t that achieves the link distance.

Weighted region problem: Given a piecewise-constant function $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ that is defined by assigning a nonnegative *weight* to each face of a given triangulation in the plane. The *weighted length* of an s - t path π is the path integral, $\int_\pi f(x, y) d\sigma$, of the weight function along π . The *weighted region metric* associated with f defines the distance $d_f(s, t)$ to be the infimum over all s - t paths π of the weighted length of π . The *weighted region problem* (WRP) asks for an s - t path of minimum weighted length.

Sailor's problem: Compute a minimum-cost path, where the cost of motion is *direction-dependent*, and there is a cost L per turn (in a polygonal path).

Bounded curvature shortest-path problem: Compute a shortest obstacle-avoiding smooth (C^1) path joining point s , with prescribed velocity orientation, to point t , with prescribed velocity orientation, such that at each point of the path the radius of curvature is at least 1.

Maximum concealment path: A path within polygonal domain P that minimizes the length during which the robot is exposed to a given set of “enemy” observers. This problem is a special case of the weighted region problem, in which weights are 0 (for travel in concealed free space), 1 (for travel in exposed free space), or ∞ (for travel through obstacles).

Total turn for an s-t path: The sum of the absolute values of all turn angles for a polygonal s - t path.

Minimum-time path problem: Find a path to minimize the total time required to move from an initial position, at an initial velocity, to a goal position and velocity, subject to bounds on the allowed acceleration and velocity along the path. This problem is also known as the *kinodynamic motion planning problem*.

LINK DISTANCE

In the min-link path problem, our goal is to minimize the number of links (and hence the number of turns) in a path connecting s and t . In many problems, the link distance provides a more natural measure of path complexity than the Euclidean length, as well as having applications to curve simplification.

In a simple polygon P , a min-link path can be computed in time $O(n)$, as described in Section 28.4; see also [MSD00] for a survey on link distance. In fact, in

TABLE 27.3.1 Link distance shortest-path problems.

PROBLEM	COMPLEXITY	NOTES	SOURCE

time $O(n)$ a *window partition* of P with respect to a point s can be computed, after which a min-link path from s to t can be reported in time proportional to the link distance. The algorithm described in Section 28.4 computes the partition via “staged illumination,” essentially a form of the continuous Dijkstra method under the link distance metric.

In a polygonal domain with holes, min-link paths can also be computed using a staged illumination method, but the algorithm is not simple: it relies on efficient methods for computing a single face in an arrangement of line segments (see Chapter 23). A min-link s - t path can be computed in time $O(E_{VG}\alpha^2(n)\log n)$, where $\alpha(n)$ is the inverse Ackermann function (Section 47.4). If we consider C -oriented and rectilinear link distance, then some better time/space bounds are possible, and some of these apply also to combined metrics, in which there is a cost for length as well as links.

Refer to Table 27.3.1 for many related results on link distance, including rectilinear link distance, and on two-point queries. See also Table 27.4.2 for more results specifically on simple polygons.

L_1 METRIC

Instead of measuring path length according to the L_2 (Euclidean) metric, consider the problem of computing shortest paths in a polygonal domain P that are short according to the L_1 metric.

A method based on visibility graph principles allows one to construct a sparse graph (with $O(n\log n)$ nodes and edges) that is *path-preserving* in that it is guaranteed to contain a shortest path between any two vertices. Applying Dijkstra’s algorithm then gives an $O(n\log^{1.5}n)$ time ($O(n\log n)$ space) algorithm for L_1 -shortest paths.

A method based on the continuous Dijkstra paradigm allows the SPM(s) to be constructed in time $O(n\log n)$, using $O(n)$ space [Mit92]. The special property of the L_1 metric that is exploited in this algorithm is the fact that the wavefront in this case is piecewise-linear, with wavelets that are line segments of slope ± 1 , so that the first vertex hit by a wavelet can be determined by rectangular range searching techniques (see Chapter 36).

Methods for finding L_1 -shortest paths generalize to the case of C -oriented paths, in which $c = |C|$ fixed directions are given. Shortest C -oriented paths

can be computed in time $O(cn \log n)$. Since the Euclidean metric is approximated to within accuracy $O(1/c^2)$ if we use c equally spaced orientations, this results in an algorithm that computes, in time $O((n/\sqrt{\epsilon}) \log n)$, a path guaranteed to have length within a factor $(1+\epsilon)$ of the Euclidean shortest path length.

WEIGHTED REGION METRIC

The weighted region problem (WRP) seeks an optimal s - t path according to the weighted region metric d_f induced by a given piecewise-constant weight function f . This problem is a natural generalization of the shortest-path problem in a polygonal domain: consider a weight function that assigns weight 1 to P and weight ∞ (or a sufficiently large constant) to the obstacles (the complement of P).

The weighted region problem models the minimum-time path problem for a point robot moving in a terrain of varied types (e.g., grassland, brushland, blacktop, bodies of water, etc.), where each type of terrain has an assigned weight equal to the reciprocal of the maximum speed of traversal for the robot.

Assume that f is specified by a triangulation having n vertices, with each face assigned an integer weight $\alpha \in \{0, 1, \dots, W, +\infty\}$. (We can allow each edge of the triangulation to have a weight that is possibly distinct from that of the triangular facets on either side of it; in this way, linear features such as roads can be modeled.) Using an algorithm based on the continuous Dijkstra method, one can find a path

whose weighted length is guaranteed to be within a factor $(1+\epsilon)$ of optimal, where $\epsilon > 0$ is any user-specified degree of precision [MP91]. The time complexity of the algorithm is $O(E \cdot S)$, where E is the number of “events” in the continuous Dijkstra algorithm, and S is the complexity of performing a numerical search to solve the following subproblem: Find a $(1+\epsilon)$ -shortest path from s to t that goes through a given sequence of k edges of the triangulation. It is known that $E = \Theta(n^4)$ in the worst case. The numerical search can be accomplished using a form of binary search that exploits the local optimality condition: An optimal path bends according to *Snell’s Law of Refraction* when crossing a region boundary. This leads to a bound of $S = O(k^2 \log(nNW/\epsilon))$ on the time needed to perform a search on a k -edge sequence, where N is the largest coordinate of any vertex of the triangulation (and all coordinates are integers). Since one can show that $k = O(n^2)$, this yields an overall time bound of $O(n^8 L)$, where $L = \log(nNW/\epsilon)$ can be thought of as the bit complexity of the problem instance.

A simple and practical approach for computing an approximate solution is based on searching a discrete graph, such as an “edge subdivision graph” or a “pathnet” [LMS01, MM97], placing Steiner points judiciously on the edges (or, possibly interior to faces) of the input subdivision. In fact, using a logarithmic discretization (as in [Pap85]), with care in how Steiner points are placed near vertices [AMS00, SR01], provable approximation guarantees are obtained whose dependence on n is $O(n \log n)$, which compares favorably with the worst-case upper bounds for the algorithm of [MP91]. See Table 27.3.2. It should be noted, though, that the dependence on $1/\epsilon$ is polynomial (vs. logarithmic) and that the “constants” in the big- O bounds reported conceal dependence on certain geometric parameters that may be unbounded in terms of ϵ and the combinatorial input size n .

Various special cases of the weighted region problem admit faster and simpler algorithms. For example, if the weighted subdivision is rectilinear, and path length is measured according to weighted L_1 length, then efficient algorithms for single-source and two-point queries can be based on searching a path-preserving graph [CKT00]. Similarly, if the region weights are restricted to $\{0, 1, \infty\}$ (while edges may have arbitrary (nonnegative) weights), then an $O(n^2)$ algorithm can be based on constructing a path-preserving graph similar to a visibility graph. This also leads to an efficient method for performing *lexicographic* optimization, in which one prioritizes various types of regions according to which is most important for path length minimization.

MINIMUM-TIME PATHS

The *kinodynamic motion planning problem* (also known as the *minimum-time path problem*) is a nonholonomic motion planning problem in which the objective is to compute a *trajectory* (a time-parameterized path, $(x(t), y(t))$) within a domain P that minimizes the total time necessary to move from an initial configuration (position and initial velocity) to a goal configuration (position and velocity), subject to bounds on the allowed acceleration and velocity along the path. The minimum-time path problem is a difficult optimal control problem; optimal paths will be complicated curves given by solutions to differential equations.

The bounds on acceleration and velocity are most often given by upper bounds on the L_∞ norm (the “decoupled case”) or the L_2 norm (the “coupled case”).

If there is an upper bound on the L_∞ norm of the velocity and acceleration vectors, one can obtain an *exact*, exponential-time, polynomial-space algorithm, based on characterizing a set of “canonical solutions” (related to “bang-bang” controls) that are guaranteed to include an optimal solution path. This leads to an expression in the first-order theory of the reals, which can be solved exactly; see [Chapter 33](#). However, it remains an open question whether or not a polynomial-time algorithm exists.

Donald et al. [DXCR93, DX95, RW00] developed approximation methods, including a polynomial-time algorithm that produces a trajectory requiring time at most $(1 + \epsilon)$ times optimal, for the decoupled case. Their approach is to discretize (uniformly) the four-dimensional phase space that represents position and velocity, with special care to ensure that the size of the grid is bounded by a polynomial in $1/\epsilon$ and n . Approximation algorithms for the coupled case are also known [DX95, RT94].

A closely related shortest-path problem is the ***bounded curvature shortest-path problem***, in which we require that no point of the path have a radius of curvature less than 1. For this problem, $(1+\epsilon)$ -approximation algorithms are known, with polynomial $(O(\frac{n^2}{\epsilon^2} \log n))$ running time [WA96]. The problem is known to be NP-hard in a polygonal domain [RW98]. For the special case in which the obstacles are “moderate” (have differentiable boundary curves, with radius of curvature at least 1), both an approximation algorithm and an exact $O(n^4 \log n)$ algorithm have been found [BL96].

OPTIMAL ROBOT MOTION

So far, we have considered only the problem of optimally moving a *point* robot. If the robot is modeled as a circle, or as a nonrotating polygon, then many of the results carry over by simply applying the standard ***configuration space*** approach in motion planning (see [Chapters 47](#) and [48](#)): “shrink” the robot to a (reference) point, and “grow” the obstacles (using a Minkowski sum) so that the complement of the grown obstacles models the region of the plane for which there is no collision with an obstacle if the robot has its reference point placed there.

Optimal motion of *rotating* noncircular robots is a much harder problem. Even the simplest case, of moving a (unit) line segment (a ***ladder***) in the plane, is highly nontrivial. One notion of optimal motion requires that we minimize the average distance traveled by a set of k fixed points, evenly distributed along the ladder. This “ d_k -distance” in fact defines a metric (for $k \geq 2$). The special case of $k = 2$ is the well-known ***Ulam’s problem***, for which optimal motions are fully characterized in the absence of obstacles [IRWY93]. The case of $k = \infty$ is an especially interesting case, requiring that we compute a minimum *work* motion of a ladder; however, no results are known for this problem. (The work measures the integral (over $\lambda \in [0, 1]$) of the path length, $L(\lambda)$, for each infinitesimal subsegment of length $d\lambda$.) While d_1 does not define a metric, several cases of d_1 -motion, and its generalization of measuring the distance traveled by any fixed “focus” F on the ladder, have been studied. In particular, if F is restricted to move on the visibility graph of a polygonal environment, polynomial-time algorithms are known. Without restrictions, minimizing the d_1 -distance (for any F not at an endpoint of the ladder) is NP-hard, but there exists an approximation algorithm [AKY96].

MULTIPLE CRITERION OPTIMAL PATHS

The standard shortest-path problem asks for paths that minimize some *one* objective (length) function. Frequently, however, an application requires us to find paths to minimize *two or more* objectives; the resulting problem is a ***bicriterion*** (or ***multi-criterion***) shortest-path problem. A path is called ***efficient*** or ***Pareto optimal*** if no other path has a better value for one criterion without having a worse value for the other criterion.

Multi-criterion optimization problems tend to be hard. Even the bicriterion path problem in a graph is NP-hard: Does there exist a path from s to t whose length is less than L and whose weight is less than W ? Pseudo-polynomial-time algorithms are known, and many heuristics have been devised.

In geometric problems, various optimality criteria are of interest, including any pair from the following list: Euclidean (L_2) length, rectilinear (L_1) length, other L_p metrics, link distance, total turn, and so on. NP-hardness lower bounds are known for several versions [AMP91]. One problem of particular interest is to compute a Euclidean shortest path within a polygonal domain, constrained to have at most k links. No exact solution is currently known for this problem. Part of the difficulty is that a minimum-link path will not, in general, lie on the visibility graph (or on any simple discrete graph). Furthermore, the computation of the turn points of such an optimal path appears to require the solution to high-degree polynomials. A $(1 + \epsilon)$ -approximation to the shortest k -link path in a simple polygon P can be found in time $O(n^3 k^3 \log(Nk/\epsilon^{1/k}))$, where N is the largest integer coordinate of any vertex of P [MPA92]. In a *simple* polygon, one can always find an s - t path that simultaneously is within a factor 2 of optimal in link distance and within a factor $\sqrt{2}$ of optimal in Euclidean length; a corresponding result is not possible for polygons with holes. However, in $O(kE_{VG}^2)$ time, one can compute a path in a polygonal domain having at most $2k$ links and length at most that of a shortest k -link path.

In a rectilinear polygonal domain, efficient algorithms are known for the bicriterion path problem that combines *rectilinear* link distance and L_1 length [LYW96]. For example, efficient algorithms are known in two or more dimensions for computing optimal paths according to a *combined metric*, defined to be a linear combination of rectilinear link distance and L_1 path length [dBvKNO92]. (Note that this is not the same as computing the Pareto-optimal solutions.) Chen et al. [CDK97] give efficient algorithms for computing a shortest k -link rectilinear path, a minimum-link shortest rectilinear path, or any combined objective that uses a monotonic function of rectilinear link length and L_1 length in a rectilinear polygonal domain. Single-source queries can be answered in time $O(\log n)$, after $O(n \log^{3/2} n)$ preprocessing time to construct a data structure of size $O(n \log n)$; two-point queries can be answered in time $O(\log^2 n)$, using $O(n^2 \log^2 n)$ preprocessing time and space [CDK97].

OPEN PROBLEMS

1. Can a minimum-link path in a polygonal domain be computed in subquadratic time? The only lower bound known is $\Omega(n \log n)$.
2. What is the smallest size data structure for a simple polygon P that allows logarithmic-time two-point link distance queries?

3. For a polygonal domain (with holes), what is the complexity of computing a shortest k -link path between two given points?
4. What is the complexity of the ladder problem for a polygonal domain, in which the cost of motion is the total work involved in translation/rotation?
5. Is it NP-hard to minimize the d_1 -distance of a ladder endpoint?
6. What is the complexity of the bounded curvature shortest-path problem in a simple polygon?

27.4 OTHER NETWORK OPTIMIZATION PROBLEMS

All of the problems considered so far involved computing a shortest path from one point to another (or from one point to all other points). We consider now some other network optimization problems, in which the objective is to compute a shortest path, cycle, tree, or other graph, subject to various constraints. A summary of results is given in [Table 27.4.1](#).

GLOSSARY

Minimum spanning tree (MST) of S : A tree of minimum total length whose nodes are a given set S of n points, and whose edges are line segments joining pairs of points.

Minimum Steiner spanning tree (Steiner tree) of S : A tree of minimum total length whose nodes are a superset of a given set S of n points, and whose edges are line segments joining pairs of points. Those nodes that are not points of S are called *Steiner points*.

k -minimum spanning tree (k -MST): A minimum-length tree that spans some subset of $k \leq n$ points of S .

Traveling salesman problem (TSP): Find a shortest cycle that visits every point of a set S of n points.

MAX TSP: Find a *longest* cycle that visits every point of a set S of n points.

Minimum latency tour problem: Find a tour on S that minimizes the sum of the “latencies,” where the latency of $p \in S$ is the length of the tour from the given depot to p . Also known as the *deliveryman problem* or the *traveling repairman problem*.

k -Traveling repairman problem: Find k tours covering S for k repairmen at a common depot, minimizing the total latency.

Min/max-area TSP: Find a cycle on a given set S of points such that the cycle defines a simple polygon of minimum/maximum area.

TSP with neighborhoods: Find a shortest cycle that visits at least one point in each of a set of neighborhoods (e.g., polygons), $\{P_1, P_2, \dots, P_k\}$.

Touring polygons problem: Find a shortest path/cycle that visits *in order* at least one point of each polygon in a sequence $(P_1, P_2, \dots, P_k)$.

Watchman route (path) problem: Find a shortest cycle (path) within a polygonal domain P such that every point of P is visible from some point of the cycle.

Lawnmowing problem: Find a shortest cycle (path) for the center of a disk (a “lawnmower” or “cutter”) such that every point of a given (possibly disconnected) region is covered by the disk at some position along the cycle (path).

Milling problem: Similar to the lawnmowing problem, but with the constraint that the cutter must at all times remain inside the given region (the “pocket” to be milled).

Zookeeper’s problem: Find a shortest cycle in a simple polygon P (the *zoo*) through a given vertex v such that the cycle visits every one of a set of k disjoint convex polygons (*cages*), each sharing an edge with P .

Aquarium-keeper’s problem: Find a shortest cycle in a simple polygon P (the *aquarium*) such that the cycle touches every edge of P .

Safari route problem: Find a shortest tour visiting a set of convex polygonal cages attached to the inside wall of a simple polygon P .

Relative convex hull of point set S within simple polygon P : The shortest cycle within P that surrounds S . The relative convex hull is necessarily a simple polygon, with vertices among the points of S and the vertices of P .

Monotone path problem: Find a shortest monotone path (if any) from s to t in a polygonal domain P . A polygonal path is *monotone* if there exists a direction vector d such that every directed edge of the path has a nonnegative inner product with d .

MINIMUM SPANNING TREES

The (Euclidean) minimum spanning tree problem can be solved to optimality in the plane in time $O(n \log n)$ by appealing to the fact that the MST is a subgraph of the Delaunay triangulation; see [Chapters 22](#) and [24](#). Efficient approximations in $\mathbb{R}^d$ are based on spanners (Section 27.6).

The Steiner tree and k -MST problems, however, are NP-hard. Polynomial-time approximation schemes have been obtained, allowing one, for any fixed $\epsilon > 0$, to get within a factor $(1+\epsilon)$ of optimality [Aro98, Mit99], in fact in time $O(n \log n)$ in any fixed dimension [RS98].

TRAVELING SALESMAN PROBLEM

The traveling salesman problem is a classical problem in combinatorial optimization, and has been studied extensively in its geometric forms. The problem is NP-hard, but has a simple 2-approximation algorithm based on “doubling” the minimum spanning tree. The somewhat more involved Christofides heuristic yields a 1.5-approximation factor, which, until recently, was the best factor known. There is now a polynomial-time approximation scheme for geometric versions of the planar TSP, allowing one, for any fixed $\epsilon > 0$, to get within a factor $(1+\epsilon)$ of optimality [Aro98, Mit99], in fact in time $O(n \log n)$ in any fixed dimension [RS98]. This result is based on a generalization of the notion of t -spanners (Section 27.6)—the “ t -banyan”—which approximates to within factor t the interconnection cost (allowing Steiner points) for subsets of sites of *any* cardinality (not just 2 sites, as in the

TABLE 27.4.1 Other optimal path/cycle/network problems.

PROBLEM	COMPLEXITY	NOTES	SOURCE

case of t -spanners). It is shown that for any fixed $\epsilon > 0$ and $d \geq 1$, there exists a $(1 + \epsilon)$ -banyan having $O(n)$ vertices and $O(n)$ edges, computable in $O(n \log n)$ time.

The **TSP-with-neighborhoods** problem arises when we require the tour/path to visit a set of regions, rather than a set of points. Constant-factor approximation algorithms are known for some special cases [AH94, dBGK+02, DM01], and an $O(\log n)$ -approximation algorithm is known for the general case in the plane.

A closely related problem is that of computing an optimal path for a lawnmower, modeled as, say, a circular cutter that must sweep out a region that covers a given domain of “grass.” This problem is NP-hard in general, but constant-factor approximation algorithms are known.

WATCHMAN ROUTE PROBLEM

Another problem closely related to the TSP is the watchman route problem, which can be thought of as a shortest-path/tour problem in which we have the constraint

that the path/tour must visit the visibility region associated with each point of the domain.

In the case of a simple polygonal domain, the watchman route problem has an $O(n^4 \log n)$ time algorithm to compute an exact solution and $O(n^3 \log n)$ is possible if we are given a point through which the tour must pass [DELM03]. In the case of a polygonal domain with holes, the problem is easily seen to be NP-hard (from Euclidean TSP), and the best approximation algorithm is one with factor $O(\log n)$, assuming rectilinear visibility.

OPEN PROBLEMS

1. Is the MAX TSP NP-hard in the Euclidean plane? What if the tour is required to be noncrossing?
2. Is there a PTAS for the minimum latency problem for points in fixed dimension?
3. Can one obtain a PTAS for the TSP with neighborhoods problem if the regions are disjoint? (Hardness of approximation is known for general regions [DBGK⁺02].) Is there an $O(1)$ -approximation if the neighborhoods are not connected sets (e.g., if the neighborhoods are pairs of points)?
4. Is the milling problem in simple polygons NP-hard?
5. Does the watchman route problem in a polygonal domain have an $O(1)$ -approximation algorithm? Is there a PTAS?

27.5 HIGHER DIMENSIONS

GLOSSARY

Polyhedral domain: A set $P \subset \mathbb{R}^3$ whose interior is connected and whose boundary consists of a union of a finite number of triangles. (The definition is readily extended to d dimensions, where the boundary must consist of a union of $(d-1)$ -simplices.) The complement of P consists of connected (polyhedral) components, which are the *obstacles*.

Orthohedral domain: A polyhedral domain having each boundary facet orthogonal to one of the coordinate axes.

Polyhedral surface: A connected union of triangles, with any two triangles intersecting in a common edge, a common vertex, or not at all, and such that every point in the relative interior of the surface has a neighborhood homeomorphic to a disk.

Edge sequence: The ordered list of obstacle edges that are intersected by a path.

COMPLEXITY

In three or more dimensions, most shortest-path problems become very difficult. In particular, there are two sources of complexity, even in the most basic Euclidean shortest-path problem in a polyhedral domain P .

One difficulty arises from algebraic considerations. In general, the structure of a shortest path in a polyhedral domain need not lie on any kind of discrete graph. Shortest paths in a polyhedral domain will be polygonal, with bend points that generally lie *interior* to obstacle edges, obeying a simple “unfolding” property: The path must enter and leave at the same angle to the edge. It follows that any locally optimal subpath joining two consecutive obstacle vertices can be “unfolded” at each edge along its edge sequence, thereby obtaining a straight segment. Given an edge sequence, this local optimality property uniquely identifies a shortest path through that edge sequence. However, to compare the lengths of two paths, each one shortest with respect to two (different) edge sequences, requires exponentially many bits, since the algebraic numbers that describe the optimal path lengths may have exponential degree.

A second difficulty arises from combinatorial considerations. The number of combinatorially distinct (i.e., having distinct edge sequences) shortest paths between two points may be exponential. This fact leads to a proof of the NP-hardness of the shortest-path problem [CR87], even if the obstacles are simply a set of parallel triangles.

Thus, it is natural to consider approximation algorithms for the general case, or to consider special cases for which polynomial bounds are achievable.

SPECIAL CASES

If the polyhedral domain P has only a small number k of convex obstacles, a shortest path can be found in $n^{O(k)}$ time. If the obstacles are known to be vertical “buildings” (prisms) having only k different heights, then shortest paths can be found in time $O(n^{6k-1})$, but it is not known if this version of the problem is NP-hard if k is allowed to be large.

If we require paths to stay on a polyhedral surface (i.e., the domain P is essentially 2D), then the unfolding property of optimal paths can be exploited to yield polynomial-time algorithms. The continuous Dijkstra paradigm leads to an algorithm requiring $O(n^2)$ time (and $O(n)$ space) algorithm to construct a shortest path map (or a geodesic Voronoi diagram), where n is the number of vertices of the surface [CH96, MMP87]. Kapoor [Kap99, O99] has recently announced an $O(n \log^2 n)$ time algorithm based on the continuous Dijkstra paradigm.

Several facts are known about the set of edge sequences corresponding to shortest paths on the surface of a *convex* polytope P in $\mathbb{R}^3$. In particular, the worst-case number of distinct edge sequences that correspond to a shortest path between some pair of points is $\Theta(n^4)$, and the exact set of such sequences can be computed in time $O(n^6 \beta(n) \log n)$, where $\beta(n) = o(\log^* n)$ [AAOS97]. (A simpler $O(n^6)$ algorithm can compute a small superset of the sequences.) The number of *maximal* edge sequences for shortest paths is $\Theta(n^3)$. Some of these results depend on a careful study of the *star unfolding* with respect to a point p on the boundary, ∂P , of P . The star unfolding is the (nonoverlapping) cell complex obtained by subtracting from ∂P the shortest paths from p to the vertices of P , and then flattening the

resulting boundary.

Results on exact algorithms for special cases are summarized in [Table 27.5.1](#).

APPROXIMATION ALGORITHMS

Papadimitriou [Pap85] was the first to study the general problem from the point of view of approximations. He gave a fully polynomial approximation scheme that produces a path guaranteed to be no longer than $(1+\epsilon)$ times the length of a shortest path. His algorithm requires time $O(n^3(L + \log(n/\epsilon))^2/\epsilon)$, where L is the number of bits necessary to represent the value of an integer coordinate of a vertex of P . Clarkson [Cla87] also gives a fully polynomial approximation scheme, which improves upon that of Papadimitriou in the case that $n\epsilon^3$ is large.

Choi, Sellen, and Yap [CSY95, CSY97] have re-examined closely the analysis of Papadimitriou and have addressed some inconsistencies found in the original algorithm, drawing attention to the distinction between bit complexity and algebraic complexity. They have also introduced the notion of “precision-sensitivity” in algorithms, writing the complexity in terms of an implicit parameter, δ , that measures the implicit precision of the input instance [CSY95].

Har-Peled [HP98] shows how to compute an *approximate shortest path map* in polyhedral domains, computing, for fixed source s and $0 < \epsilon < 1$, a subdivision of size $O(n^2/\epsilon^{4+\delta})$ in time roughly $O(n^4/\epsilon^6)$, so that for any point $t \in \mathbb{R}^3$ a $(1+\epsilon)$ -approximation of the length of a shortest s - t path can be reported in time $O(\log(n/\epsilon))$.

Considerable effort has been devoted to approximation algorithms for shortest paths on polyhedral surfaces. Given a convex polytope obstacle, Agarwal et al. [AHP97] show how to surround the polytope with a constant-size ($O(\epsilon^{-3/2})$, now improved to $O(\epsilon^{-5/4})$ [CLM03]) convex polytope having the property that shortest paths are approximately preserved (within factor $(1+\epsilon)$) on the outer polytope. This results in an approximation algorithm of time complexity $O(n \log(1/\epsilon) + f(\epsilon^{-5/4}))$, where $f(m)$ denotes the time complexity of solving exactly a shortest-path problem on an m -vertex convex surface (e.g., $f(m) = O(m^2)$ using [CH96], $f(m) = O(m \log^2 m)$ using [Kap99]). Har-Peled [HP99] gives an $O(n)$ -time algorithm to preprocess a convex polytope so that a two-point query can be answered in time $O((\log n)/\epsilon^{3/2} + 1/\epsilon^3)$, yielding the $(1+\epsilon)$ -approximate shortest path distance, as well as a path having $O(1/\epsilon^{3/2})$ segments that avoids the interior of the input polytope.

Varadarajan and Agarwal [VA99] obtained the first subquadratic-time algorithms for approximating shortest paths on general (nonconvex) polyhedral surfaces, computing a $7(1+\epsilon)$ -approximation in $O(n^{5/3} \log^{5/3} n)$ time, or a $15(1+\epsilon)$ -approximation in $O(n^{8/5} \log^{8/5} n)$ time. Their method is based on a partitioning of the surface into $O(n/r)$ patches, each having at most r faces, using a planar separator theorem. (The parameter r is chosen to be $n^{1/3} \log^{1/3} n$ or $n^{2/5} \log^{2/5} n$.) Then, on the boundary of each patch, a carefully selected set of points (“portals”) is selected, and these are interconnected with a graph that approximates shortest paths within each patch.

Practical approximation algorithms are based on searching a discrete graph (an “edge subdivision graph,” or a “pathnet”)[LMS01, MM97] by placing Steiner points judiciously on the edges (or, possibly interior to faces) of the input surface. This approach applies also to the case of weighted surfaces and weighted convex

decompositions of $\mathbb{R}^3$; see the earlier discussion of the weighted region problem. One can obtain provable results on the approximation factor; see Table 27.5.2. It is worth noting, however, that these complexity bounds are under the assumption that certain geometric parameters are “constants”; these parameters may be unbounded in terms of ϵ and the combinatorial input size n .

OTHER METRICS

Link distance in a polyhedral domain in $\mathbb{R}^d$ can be approximated (within factor 2) in polynomial time by searching a weak visibility graph whose nodes correspond to simplices in a simplicial decomposition of the domain. The complexity of computing the exact link distance is open.

For the case of orthohedral domains and rectilinear (L_1) shortest paths, the shortest-path problem in $\mathbb{R}^d$ becomes relatively easy to solve in polynomial time, since the grid graph induced by the facets of the domain serves as a path-preserving graph that we can search for an optimal path. In $\mathbb{R}^3$, we can do better than to use the $O(n^3)$ grid graph induced by $O(n)$ facets; an $O(n^2 \log^2 n)$ size subgraph suffices, which allows a shortest path to be found using Dijkstra’s algorithm in time $O(n^2 \log^3 n)$. More generally, in $\mathbb{R}^d$ one can compute a data structure of size $O((n \log n)^{d-1})$, in $O(n^d \log n)$ preprocessing time, that supports fixed-source link distance queries in $O(\log^{d-1} n)$ time. In fact, this last result can be extended, within the same complexities, to the case of a combined metric, in which path cost is measured as a linear combination of L_1 length and rectilinear link distance.

For the special case of disjoint rectilinear box obstacles and rectilinear (L_1) shortest paths, a recent structural result may help in devising very efficient algorithms: There always exists a coordinate direction such that *every* shortest path from s to t is monotone in this direction [CY96]. In fact, this result has led to an $O(n^2 \log n)$ algorithm for the case $d = 3$.

OPEN PROBLEMS

1. Can one compute shortest paths on a polyhedral surface in $\mathbb{R}^3$ in $O(n \log n)$ time using $O(n)$ space?
2. Can one compute a shortest path map for a polyhedral domain in output-sensitive time?
3. What is the complexity of the minimum-link path problem in 3-space?
4. What is the complexity of the shortest-path problem in 3-space for special cases of obstacles—e.g., disjoint axis-parallel boxes, unit spheres, etc.?

27.6 GEOMETRIC SPANNERS

GLOSSARY

Geometric graph: A graph $G = (V, E)$ together with an embedding in $\mathbb{R}^d$ that maps vertices V to points and edges E to straight line segments. (See [Chapter 10](#).)

Euclidean graph: A geometric graph with Euclidean lengths associated with the edges.

Complete geometric graph: A geometric graph $G = (V, E)$ whose edge set E joins each pair of points of V .

θ -Graph: A geometric graph in which each $v \in V$ is joined by an edge to a “closest” point $u \in V \cap C_i$, where each C_i is a **wedge** with apex v and angle at most θ .

Planar straight-line graph (PSLG): A geometric graph $G = (V, E)$ embedded in $\mathbb{R}^2$ with noncrossing edges.

t -Spanner: A subgraph $G' = (V, E')$ of a graph $G = (V, E)$ such that for any $u, v \in V$ the distance $\delta_{G'}(u, v)$ within G' is at most t times the distance $\delta_G(u, v)$ within G . We focus on **Euclidean t -spanners** for which the underlying graph G is the complete Euclidean graph in $\mathbb{R}^d$.

Planar t -spanner: A Euclidean t -spanner that is a PSLG in $\mathbb{R}^2$.

Dilation, t^* , of a Euclidean graph $G = (V, E)$:

$$t^* = \max_{u, v \in V, u \neq v} \left\{ \frac{\delta_G(u, v)}{\delta_2(u, v)} \right\}$$

where $\delta_2(u, v)$ is the Euclidean distance between u and v . Thus, t^* is the smallest value of t for which G is a Euclidean t -spanner. The dilation is also known as the **stretch factor** or the **spanning ratio** of G .

Size of a Euclidean graph $G = (V, E)$: The number of edges, $|E|$.

Weight of a Euclidean graph $G = (V, E)$: The sum of the Euclidean lengths of all edges $e \in E$.

Degree of a graph $G = (V, E)$: The maximum number of edges incident on a common vertex $v \in V$.

k -Vertex Fault-Tolerant t -Spanner: A t -spanner with the property that the removal of any subset of at most k nodes, along with the incident edges, results in a subgraph that remains a t -spanner on the remaining set of points.

Well-separated pairs decomposition (WSPD) of a set $S \subset \mathbb{R}^d$ of points for a fixed separation constant $s > 0$: A set, $\{\{A_1, B_1\}, \{A_2, B_2\}, \dots, \{A_m, B_m\}\}$, of pairs of nonempty subsets of S such that (i) $A_i \cap B_i = \emptyset$, for each $i = 1, 2, \dots, m$; (ii) each pair of distinct elements $\{a, b\} \subset S$ has a unique pair $\{A_i, B_i\}$ with $a \in A_i$, $b \in B_i$; and (iii) A_i and B_i are **well-separated**. Sets X and Y are **well-separated** if there are two radius- r enclosing balls, $B_X \supset X$ and $B_Y \supset Y$, such that the distance between B_X and B_Y is at least sr . The **size** of the WSPD is m .

Fair-split tree T associated with a set $S \subset \mathbb{R}^d$: A binary tree, with each node ν having an associated subset $S(\nu) \subseteq S$ and the axis-parallel bounding box $R(\nu)$ of $S(\nu)$, such that (i) $|S(\nu)| = 1$ if ν is a leaf; and (ii) for each internal node ν , there exists a hyperplane orthogonal to the longest edge, ξ , of $R(\nu)$ separating the sets, $S(\nu_1)$ and $S(\nu_2)$, associated with the two children of ν , such that the hyperplane is at distance at least $|\xi|/3$ from each of the sides of $R(\nu)$ parallel to it.

t -SPANNERS

A natural greedy algorithm, similar to Kruskal's minimum spanning tree algorithm, can be used to construct t -spanners:

Given an input geometric graph $G = (V, E)$ and a real number $t > 1$. Initialize edge set $E' \leftarrow \emptyset$. For each edge $(u, v) \in E$, considered in nondecreasing order of length $\delta_2(u, v)$, if $\delta_{G'}(u, v) > t \cdot \delta_2(u, v)$, then $E' \leftarrow E' \cup \{(u, v)\}$. Output the graph $G' = (V, E')$.

The greedy algorithm results in a t -spanner of size $O(n)$, weight $O(\log n) \cdot |MST|$, and degree $O(1)$, for any fixed dimension d and dilation $t > 1$ [ADD⁺93, CDNS95]. It can be applied also to general (nongeometric) graphs with weighted edges.

The θ -graph construction explicitly takes advantage of geometry and yields a t -spanner with dilation arbitrarily close to 1; specifically, $t = 1 + O(1/\theta)$, for sufficiently small θ [ADD⁺93, Kei88, Yao82].

Callahan and Kosaraju [CK95a] defined the notion of a well-separated pair decomposition (WSPD) and showed the remarkable theorem that a WSPD of size $O(n)$ can be constructed in time $O(n)$, given a fair split tree of an input set S of n points in $\mathbb{R}^d$, for any fixed dimension d and separation constant s . (More precisely, the size of the WSPD is $O(s^d n)$.) A fair split tree can be constructed using quadtree methods in time $O(n \log n)$ for any fixed dimension.

By selecting a representative edge from each pair in a WSPD, one obtains a t -spanner of size $O(n)$ with dilation that can be made arbitrarily close to 1, depending on the separation constant s . The WSPD has numerous other applications in approximation algorithms for geometric network optimization. One important application is to give a $(1 + \epsilon)$ -approximation algorithm, running in time $O(n \log n)$, for Euclidean minimum spanning trees in any fixed dimension d for any fixed $\epsilon > 0$.

One can in fact obtain t -spanners for n points in $\mathbb{R}^d$ that are simultaneously good with respect to size, weight, and degree—size $O(n)$, weight $O(|MST|)$, and bounded degree (independent of the dimension d). Gudmundsson et al. [GLN02] show that such spanners can be computed in time $O(n \log n)$, improving the previous bound of $O(n \log^2 n)$ [DN97] and re-establishing the time bound claimed in Arya et al [ADM⁺95] (which was found to be flawed). $\Omega(n \log n)$ time is required for constructing *any* t -spanner for n points in $\mathbb{R}^d$ in the algebraic decision tree model [CDS01].

Levcopoulos et al. [LNS02] showed that k -vertex fault-tolerant spanners of size $O(k^2 n)$ can be constructed in time $O(n \log n + k^2 n)$; alternatively, spanners of size $O(kn \log n)$ can be constructed in time $O(kn \log n)$. Lukovszki [Luk99] and recently Czumaj and Shao [CZ03] have shown how to obtain even smaller, degree-bounded low-weight k -vertex fault-tolerant spanners; degree $O(k)$ and weight $O(k^2 |MST|)$ can be obtained, and these bounds are asymptotically optimal.

The dilation (stretch factor) of a graph $G = (V, E)$ can be computed exactly in worst-case time $O(n^2 \log n + n|E|)$ using an all-pairs shortest path computation. Given a Euclidean graph with n vertices and m edges, its dilation (stretch factor) can be $(1 + \epsilon)$ -approximated in time $O(m + n \log n)$ [GLNS02a]. Narasimhan and Smid [NS02] have studied the *bottleneck stretch factor problem*, in which the goal is to be able to compute quickly, for any given $b > 0$, an approximate stretch factor of the *bottleneck graph* $G_b = (V, E_b)$ whose edge set E_b consists of those edges of the complete graph whose length is at most b . We say that t is a (c_1, c_2) -approximate

stretch factor of a graph if the true stretch factor, t^* , satisfies $t/c_1 \leq t^* \leq c_2 t$. A data structure of size $O(\log n)$ can be constructed that supports $O(\log \log n)$ -time queries, for any $b > 0$, yielding a (c_1, c_2) -approximate stretch factor of G_b . The construction of the data structure, which is based on a WSPD, is done using a randomized algorithm with expected running time that is slightly subquadratic.

Spanners can be computed for geodesic distances in a polygonal domain P : a $(1+\epsilon)$ -spanner of the visibility graph $\text{VG}(P)$ can be computed in time $O(n \log n)$, for any $\epsilon > 0$ [ACC⁺96]. Geometric spanners can be used to obtain very efficient approximate two-point shortest path distance queries. For any constant $t > 1$, a t -spanner G for n points in $\mathbb{R}^d$ with m edges can be processed in time $O(m \log n)$, building a structure of size $O(n \log n)$, to support $(1+\epsilon)$ -approximate shortest path (in G) distance queries in $O(1)$ time between any two vertices of G . (A path can be reported in additional time proportional to the number of its edges.) Then, if the visibility graph $\text{VG}(P)$ is a t -spanner of the vertices of P , for some constant t , one obtains $O(1)$ -time (resp., $O(\log n)$ -time) $(1+\epsilon)$ -approximate shortest path distance queries between any two vertices (resp., points) of P . The assumption on $\text{VG}(P)$ holds if P has the “ t -rounded” property for some t : the shortest path distance between any pair of vertices is at most t times the Euclidean distance between them; such is the case if the obstacles are *fat*, as shown by Chew et al. [CDKK02].

PLANAR t -SPANNERS

For point sets in the plane it is natural to consider constructing *planar* t -spanner networks. One cannot hope, in general, to obtain planar t -spanners with t arbitrarily close to 1: four points at the corner of a square have no t -spanner with $t < \sqrt{2}$.

The first result on planar t -spanners is due to Chew [Che86], who showed that the Delaunay triangulation in the L_1 metric is a $\sqrt{10}$ -spanner for the complete Euclidean graph. (It is a $\sqrt{5}$ -spanner for the complete graph whose length are measured in the L_1 metric.) Chew [Che89] improved this result, showing that the Delaunay triangulation in the convex distance function based on an equilateral triangle is a planar graph with dilation at most 2. This is the current best dilation known for a planar t -spanner; the lower bound is $\sqrt{2}$, given by the example just mentioned.

The Euclidean Delaunay triangulation cannot, in general, yield a t -spanner with $t < \pi/2$, as shown by the example of placing points around a circle. The best known upper bound on the dilation, τ_{Del} , of the Euclidean Delaunay triangulation, is $\frac{4\sqrt{3}}{9}\pi \approx 2.42$ [KG92]. It is known that β -skeletons, for any $\beta > 0$, can have unbounded dilation [Epp00]; in particular, the Gabriel graph ($\beta = 1$) and the relative neighborhood graph ($\beta = 2$) are not t -spanners for any constant t . The minimum weight triangulation and the greedy triangulation (see Chapter 24) are t -spanners for constant t . This follows from a more general result of Das and Joseph [DJ89], who show that a PSLG is a t -spanner if it has the “**diamond property**” and the “**good polygon property**.” A **fat triangulation** triangulation of S , for which the aspect ratio (ratio of the length of the longest side to the corresponding height) of every triangle is at most α , is known to be a 2α -spanner [KG01].

One can compute planar t -spanners of low weight. In linear time, for any $r > 0$, a planar t -spanner, with $t = (1+1/r)\tau_{\text{Del}}$, of weight at most $(2r+1)|MST|$ can be computed from a Delaunay triangulation, where τ_{Del} is the dilation of the Delaunay

triangulation [LL92] One can compute in time $O(n \log n)$ a planar t -spanner that is simultaneously low weight ($O(|MST|)$) and low degree (degree at most $14 + \lceil \frac{2\pi}{\alpha} \rceil$), where $t = \max\{\frac{\pi}{2}, \pi \sin \frac{\alpha}{2} + 1\} \cdot \tau_{Del}(1+\epsilon)$ and $0 < \alpha < \frac{\pi}{2}$. One can compute in time $O(n \log n)$ a planar t -spanner that is simultaneously low weight ($O(|MST|)$) and low degree (degree at most 27), with $t = (\pi+1)(1+\epsilon)\tau_{Del} \approx 10.02$ and any $\epsilon > 0$ [BGS02].

Planar t -spanners are also known for geodesic distances. A *conforming triangulation* for a polygonal domain P having triangles of aspect ratio at most α is a 2α -spanner for geodesic distances between vertices of P [KG01]. (A triangulation is *conforming* for P if all vertices of P is a vertex of the triangulation and each edge of P is the union of some edges of the triangulation.) The *constrained Delaunay triangulation* of P is a $\phi\pi$ -spanner [KG01].

OPEN PROBLEMS

1. What is the dilation of the Euclidean Delaunay triangulation? It is known to be between $\pi/2 \approx 1.57$ and $\frac{2\pi}{3 \cos(\pi/6)} \approx 2.42$.
2. What is the minimum possible worst-case dilation for triangulations of point sets? It is known to be between $\sqrt{2}$ and 2. (For the L_1 or L_∞ metric, the tight bound on dilation is 2 [ACC⁺96].)

28 VISIBILITY

Joseph O'Rourke

INTRODUCTION

In a geometric context, two objects are “visible” to each other if there is a line segment connecting them that does not cross any obstacles. Over 500 papers have been published on aspects of visibility in computational geometry in the last 25 years. The research can be broadly classified as primarily focused on combinatorial issues, or primarily focused on algorithms. We partition the combinatorial work into “art gallery theorems” (Section 28.1) and illumination of convex sets (28.2), and research on visibility graphs (28.3) and the algorithmic work into that concerned with polygons (28.4), more general planar environments (28.5), paths (28.6), and mirror reflections (28.7). All of this work concerns visibility in two dimensions. Investigations in three dimensions, both combinatorial and algorithmic, are discussed in Section 28.8, and the final section (28.9) touches on visibility in $\mathbb{R}^d$.

28.1 ART GALLERY THEOREMS

A typical “art gallery theorem” provides combinatorial bounds on the number of guards needed to visually cover a polygonal region P (the art gallery) defined by n vertices. Equivalently, one can imagine light bulbs instead of guards and require full direct-light illumination.

GLOSSARY

Guard: A point, a source of visibility or illumination.

Vertex guard: A guard at a polygon vertex.

Point guard: A guard at an arbitrary point.

Interior visibility: A guard $x \in P$ can see a point $y \in P$ if the segment xy is nowhere exterior to P : $xy \subset P$.

Exterior visibility: A guard x can see a point y outside of P if the segment xy is nowhere interior to P ; xy may intersect ∂P , the boundary of P .

Star polygon: A polygon visible from a single interior point.

Diagonal: A segment inside a polygon whose endpoints are vertices, and which otherwise does not touch ∂P .

Floodlight: A light that illuminates from the apex of a cone with aperture α .

Vertex floodlight: One whose apex is at a vertex (at most one per vertex).

MAIN RESULTS

The most general results obtained to date are summarized in Table 28.1.1. In all cases, the number of guards listed is the number that is necessary for some polygons, and sufficient for all polygons. Thus all bounds listed are tight.

TABLE 28.1.1 Number of guards needed.

PROBLEM NAME	POLYGONS	INT/EXT	GUARD	NUMBER
Art gallery theorem	simple	interior	vertex	$\lfloor n/3 \rfloor$
Fortress problem	simple	exterior	point	$\lceil n/3 \rceil$
Prison yard problem	simple	int & ext	vertex	$\lceil n/2 \rceil$
Prison yard problem	orthogonal	int & ext	vertex	$\lceil \lceil 5n/16 \rceil, \lfloor 5n/12 \rfloor + 2 \rceil$
Orthogonal polygons	simple orthogonal	interior	vertex	$\lfloor n/4 \rfloor$
Orthogonal with holes	orthogonal with h holes	interior	vertex	$\lfloor n/4 \rfloor$
Polygons with holes	polygons with h holes	interior	point	$\lfloor (n + h)/3 \rfloor$

Of special note is the difficult *orthogonal prison yard problem*: How many vertex guards are needed to cover both the interior and the exterior of an orthogonal polygon? See Figure 28.1.1. The lower and upper bounds listed in the table were obtained by [HK96] via this new graph-coloring theorem: Every plane, bipartite, 2-connected graph has an *even triangulation* (all nodes have even degree) and therefore the resulting graph is 3-colorable.

FIGURE 28.1.1
A pyramid polygon with $n = 24$ vertices whose interior and exterior are covered by 8 guards. Repeating the pattern establishes a lower bound of $5n/16 + c$ on the orthogonal prison yard problem [HK93].

COVERS AND PARTITIONS

Each art gallery theorem above implies a cover result, a cover by star polygons. Many of the theorem proofs rely on certain partitions. For example, the orthogonal polygon result depends on the theorem that every orthogonal polygon may be partitioned via diagonals into convex quadrilaterals. See [Section 26.2](#) for more on covers and partitions.

EDGE GUARDS

A variation permits guards (*mobile guards*) to patrol segments, diagonals, or edges; equivalent is illumination by line segment/diagonal/edge light sources (fluorescent light bulbs). Here there are fewer results; see Table 28.1.2. Toussaint conjectures that the last line of this table should be $\lfloor n/4 \rfloor$ for n sufficiently large.

TABLE 28.1.2 Edge guards.

POLYGONS	GUARD	BOUNDS	SOURCE
Polygon	diagonal	$\lfloor n/4 \rfloor$	[O'R83]
Orthogonal polygons	segment	$\lfloor (3n + 4)/16 \rfloor$	[Agg84, O'R87]
Orthogonal polygons with h holes	segment	$\lfloor (3n + 4h + 4)/16 \rfloor$	[GHKS96]
Polygon ($n > 11$)	edge	$\lfloor \lfloor n/4 \rfloor, \lfloor 3n/10 \rfloor \rfloor$	[She94].

28.1.1 FLOODLIGHT ILLUMINATION

Urrutia introduced a class of questions involving guards with restricted vision, or, equivalently, illumination by floodlights: How many floodlights, each with aperture α , and with their apexes at distinct nonexterior points, are sufficient to cover any polygon of n vertices? One surprise is that $\lfloor n/3 \rfloor$ half-guards/ π -floodlights suffice, although not when restricted to vertices. A second surprise is that, for any $\alpha < \pi$, there is a polygon that cannot be illuminated by an α floodlight at every vertex. See Table 28.1.3. A third surprise is that the best result on vertex π -floodlights employs pointed pseudotriangulations (cf. [Chapter 5](#)) in an essential way.

TABLE 28.1.3 Floodlights.

APEX	ALPHA	BOUNDS	SOURCE
Any point	$[180^\circ, 360^\circ]$	$\lfloor n/3 \rfloor$	[T6t00]
Any point	$[90^\circ, 180^\circ]$	$2\lfloor n/3 \rfloor$	[T6t00]
Any point	$[45^\circ, 60^\circ]$	$\lfloor n - 2, n - 1 \rfloor$	[T6t03a]
Vertex	$< 180^\circ$	not always possible	[ECOUX95]
Vertex	180°	$\lfloor 9n/14 - c, \lfloor 2n/3 \rfloor - 1 \rfloor$	[ST03]

28.2 ILLUMINATION OF PLANAR CONVEX SETS

A natural extension of exterior visibility is illumination of the plane in the presence of obstacles. Here it is natural to use “illumination” in the same sense as “visibility.” Under this model, results depend on whether light sources are permitted to lie on obstacle boundaries: $\lfloor 2n/3 \rfloor$ lights are necessary and sufficient (for $n > 5$) if they may [O’R87], and $\lfloor 2(n+1)/3 \rfloor$ if they may not [Tót02]. More work has been done on illuminating the boundary of the obstacles, under a stronger notion of illumination, corresponding to “clear visibility.”

GLOSSARY

Illuminate: x illuminates y if xy does not include a point strictly interior to an obstacle, and does not cross a segment obstacle.

Cross: xy crosses segment s if they have exactly one point p in common, and p is in the relative interior of both xy and s .

Clearly illuminate: x clearly illuminates y if the open segment (x, y) does not include any point of an obstacle.

Compact: Bounded.

Homothetic: Similar and in parallel position.

Isothetic: Sides parallel to the coordinate axes.

MAIN RESULTS

A third, even stronger notion of illumination is considered in Section 28.9 below. The main question that has been investigated is: How many point lights strictly exterior to a collection of n pairwise disjoint compact, convex objects in the plane are needed to clearly illuminate every object boundary point? Answers for a variety of restricted sets are shown in Table 28.2.1.

TABLE 28.2.1 Illuminating convex sets in plane.

FAMILY	BOUNDS	SOURCE
Convex sets	$4n - 7$	[Fej77]
Circular disks	$2n - 2$	[Fej77]
Isothetic rectangles	$[n - 1, n + 1]$	[Urr00]
Homothetic triangles	$[n, n + 1]$	[CRCU93]
Triangles	$[n, \lfloor (5n + 1)/4 \rfloor]$	[Tót01b]
Segments (one side)	$[4n/9 - 2, \lfloor (n + 1)/2 \rfloor]$	[Tót03b]
Segments (both sides)	$\lfloor 4(n + 1)/5 \rfloor$	[Tót01a]

The most interesting open problem here is to close the gap for triangles. Urrutia conjectures [Urr00] that $n + c$ lights suffice for some constant c .

28.3 VISIBILITY GRAPHS

Whereas art gallery theorems seek to encapsulate an environment's visibility into one function of n , the study of visibility graphs endeavors to uncover the more fine-grained structure of visibility. The original impetus for their investigation came from pattern recognition, and its connection to shape continues to be one of its primary sources of motivation; see [Chapter 51](#). Another application is graphics ([Chapter 49](#)): illumination and radiosity depend on 3D visibility relations (Section 28.8.)

GLOSSARY

Visibility graph: A graph with nodes for each object, and arcs between objects that can see one another.

Vertex visibility graph: The objects are the vertices of a simple polygon.

Endpoint visibility graph: The objects are the endpoints of line segments in the plane. See [Figure 28.3.1b](#).

Segment visibility graph: The objects are whole line segments in the plane, either open or closed.

Object visibility: Two objects A and B are visible to one another if there are points $x \in A$ and $y \in B$ such that x sees y .

Point visibility: Two points x and y can see one another if the segment xy is not “obstructed,” where the meaning of “obstruction” depends on the problem.

ϵ -visibility: Lines of sight are finite-width beams of visibility.

Hamiltonian: A graph is Hamiltonian if there is a simple cycle that includes every node.

OBSTRUCTIONS TO VISIBILITY

For polygon vertices, x sees y if xy is nowhere exterior to the polygon, just as in art gallery visibility; this implies that polygon edges are part of the visibility graph. For segment endpoints, x sees y if the closed segment xy intersects the union of all the segments either in just the two endpoints, or in the entire closed segment. This disallows grazing contact with a segment, but includes the segments themselves in the graph.

GOALS

Four goals can be discerned in research on visibility graphs:

1. Characterization: asks for a precise delimiting of the class of graphs realizable by a certain class of geometric objects.

FIGURE 28.3.1

(a) A set of segments. (b) Their endpoint visibility graph G . (c) A Hamiltonian cycle in G .

2. Recognition: asks for an algorithm to recognize when a graph is a visibility graph.
3. Reconstruction: asks for an algorithm that will take a visibility graph as input, and output a geometric realization.
4. Counting: concerned with the number of visibility graphs under various restrictions [HN01].

VERTEX VISIBILITY GRAPHS

A complete characterization of polygon vertex visibility graphs has remained elusive, but progress has been made by:

1. Restricting the class of polygons: polynomial-time recognition and reconstruction algorithms for orthogonal staircase polygons have been obtained. See Figure 28.3.2.
2. Restricting the class of graphs: every 3-connected vertex visibility graph has a 3-clique ordering, i.e., an ordering of the vertices so that each vertex is part of a triangle composed of preceding vertices.
3. Adding information: assuming knowledge of the boundary Hamiltonian circuit, four necessary conditions have been established by Ghosh and others [Gho97], and conjectured to be sufficient.

FIGURE 28.3.2

A staircase polygon and its vertex visibility graph.

ENDPOINT VISIBILITY GRAPHS

For segment endpoint visibility graphs, there have been two foci:

1. Are the graphs Hamiltonian? See [Figure 28.3.1c](#). Posed by Mirzaian, this has recently been settled via a complex proof [HT01]: YES, there is always a Hamiltonian polygon (i.e., a noncrossing circuit).
2. Size questions: there must be at least $5n - 4$ edges [SE87], and at least $6n - 6$ when no segment is a “chord” splitting the convex hull [GOH⁺02]; the smallest clique cover has size $\Omega(n^2/\log^2 n)$ [AAAS94].

SEGMENT VISIBILITY GRAPHS

Whole segment visibility graphs have been investigated most thoroughly under the restriction that the segments are all (say) vertical and visibility is horizontal. Such segments are often called *bars*. The visibility is usually required to be ϵ -visibility. Endpoints on the same horizontal often play an important role here, as does the distinction between closed segments and intervals (which may or may not include their endpoints). There are several characterizations:

1. G is representable by segments, with no two endpoints on the same horizontal, iff there is a planar embedding of G such that, for every interior k -face F , the induced subgraph of F has exactly $2k - 3$ edges.
2. G is representable by segments, with endpoints on the same horizontal permitted, iff there is a planar embedding of G with all cutpoints on the exterior face.
3. Every 3-connected planar graph is representable by intervals.

OTHER VISIBILITY GRAPHS

The notion of a visibility graph can be extended to objects such as disjoint disks: each disk is a node, with an arc if there is a segment connecting them that avoids touching any other disk. Rappaport proved that the visibility graph of disjoint congruent disks is Hamiltonian [R03]. *Rectangle visibility graphs*, which restrict visibility to vertical or horizontal lines of sight between disjoint rectangles, have been studied for their role in graph drawing ([Chapter 52](#)). A typical result is that any graph with a maximum vertex degree of 4 can be realized as a rectangle visibility graph [BDHS97].

OPEN PROBLEMS

1. Given a visibility graph G and a Hamiltonian circuit C , construct in polynomial time a simple polygon such that its vertex visibility graph is G , with C corresponding to the polygon's boundary.

2. Develop an algorithm to recognize whether a polygon vertex visibility graph is planar. Necessary and sufficient conditions are known [LC94].

28.4 ALGORITHMS FOR VISIBILITY IN A POLYGON

Designing algorithms to compute aspects of visibility in a polygon P was a major focus of the computational geometry community in the 1980s. For most of the basic problems, optimal algorithms were found, several depending on Chazelle's linear-time triangulation algorithm [Cha91].

GLOSSARY

Throughout, P is a polygon.

Kernel: The set of points in P that can see all of P . See Figure 33.4.4.

Point visibility polygon: The region visible from a point in P .

Segment visibility polygon: The region visible from a segment in P .

MAIN RESULTS

The main algorithms are listed in Table 28.4.1. We discuss two of these algorithms below to illustrate their flavor.

TABLE 28.4.1 Polygon visibility algorithms.

ALGORITHM TO COMPUTE	TIME COMPLEXITY	SOURCE
Kernel	$O(n)$	[LP79]
Point visibility polygon	$O(n)$	[JS87]
Segment visibility polygon	$O(n)$	[GHL ⁺ 87]
Shortest illuminating segment	$O(n)$	[DN94]
Vertex visibility graph	$O(E)$	[Her89]

VISIBILITY POLYGON ALGORITHM

Let $x \in P$ be the visibility source. Lee's linear-time algorithm [JS87] processes the vertices of P in a single counterclockwise boundary traversal. At each step, a vertex is either pushed on or popped off a stack, or a *wait* event is processed. The latter occurs when the boundary at that point is invisible from x . At any stage, the stack represents the visible portion of the boundary processed so far.

Although this algorithm is elementary in its tools, it has proved delicate to implement correctly.

VISIBILITY GRAPH ALGORITHM

In contrast, Hershberger's vertex visibility algorithm [Her89] uses sophisticated tools to achieve output-size sensitive time complexity $O(E)$, where E is the number of edges of the graph. His algorithm exploits the intimate connection between shortest paths and visibility in polygons. It first computes the *shortest path map* (Chapter 27) in $O(n)$ time for a vertex, and then systematically transforms this into the map of an adjacent vertex in time proportional to the number of changes. Repeating this achieves $O(E)$ time overall.

Most of the above algorithms have been parallelized; see, for example, [GSG92].

28.5 ALGORITHMS FOR VISIBILITY AMONG OBSTACLES

The shortest path between two points in an environment of polygonal obstacles follows lines of sight between obstacle vertices. This has provided an impetus for developing efficient algorithms for constructing visibility regions and graphs in such settings. The obstacles most studied are noncrossing line segments, which can be joined end-to-end to form polygonal obstacles. Many of the questions mentioned in the previous section can be revisited for this environment.

The major results are shown in Table 28.5.1; the first three are described in [O'R87]; the fourth is discussed below.

TABLE 28.5.1 Algorithms for visibility among obstacles.

ALGORITHM TO COMPUTE	TIME COMPLEXITY
Point visibility region	$O(n \log n)$
Segment visibility region	$\Theta(n^4)$
Endpoint visibility graph	$O(n^2)$
Endpoint visibility graph	$O(n \log n + E)$

ENDPOINT VISIBILITY GRAPH

The largest effort has concentrated on constructing the endpoint visibility graph. Worst-case optimal algorithms were first discovered by constructing the line arrangement dual to the endpoints in $O(n^2)$ time. Since many visibility graphs have less than a quadratic number of edges, an output-size sensitive algorithm was a significant improvement: $O(n \log n + E)$ where E is the number of edges of the graph [GM91].

FIGURE 28.6.1
The link center is shown darkly shaded: every point in the polygon can be reached with no more than three links from a point in the center. Several key visibility chords are drawn.

28.6 VISIBILITY PATHS

A fruitful idea was introduced to visibility research in the mid-1980s: the notion of “link distance” between two points, which represents the smallest number of mutually visible relay stations needed to communicate from one point to another (Sections 26.4 and 27.3). A related notion called “watchman tours” was introduced a bit later, mixing shortest paths and visibility problems, and employing many of the concepts developed for link-path problems (Section 26.4).

GLOSSARY

- Link:** A segment.
- Link distance:** The smallest number of links in a polygonal path connecting the points.
- Link diameter of P :** The largest link distance between any two points in P .
- Link center of P :** The collection of points whose maximal link distance to any point of P is as small as possible. See Figure 28.6.1.
- Shortest watchman tour in P :** A shortest closed path π in a polygon P such that every point of P is visible from some point of π .

MAIN RESULTS

The main results for link centers are shown in Table 28.6.1. See [Tables 27.4.2](#) and [27.3.1](#) and the related sections for further results.

TABLE 28.6.1 Algorithms for link centers.

LINK CENTER WITHIN	TIME COMPLEXITY	SOURCE
Polygon	$O(n \log n)$	[DLS92]
Orthogonal polygon	$O(n)$	[NS91]
Polygon with holes	NP-hard	[AL93]

FIGURE 28.7.1
 100 mirror disks fail to trap 10 rays
 from a point source (near the center) [OP01].

28.7 MIRROR REFLECTIONS

GLOSSARY

Light ray reflection: A light ray reflects from an interior point of a mirror with reflected angle equal to incident angle; a ray that hits a mirror endpoint is absorbed.

Mirror polygon: A polygon all of whose edges are mirrors reflecting light rays.

Periodic light ray: A ray that reflects from a collection of mirrors and, after a finite number of reflections, rejoins its path (and thenceforth repeats that path).

Trapped light ray: One that reflects forever, and so never “reaches” infinity.

Klee asked whether every polygonal room whose walls are mirrors (a mirror polygon) is illuminable from every interior point [Kle69, KW91]. Tokarsky answered NO by constructing rooms that leave one point dark when the light source is located at a particular spot [Tok95]. However, a second question of Klee remains open: Is every mirror polygon illuminable from some interior point?

The behavior of light reflecting in a polygon is complex. Aronov et al. [ADD⁺98] proved that after k reflections, the boundary of the illuminated region has combinatorial complexity $O(n^{2k})$, with a matching lower bound for any fixed k . Even determining whether every triangle supports a periodic ray is unresolved; see [HH00].

Pach asked whether a finite set of disjoint circular mirrors can trap all the rays from a point light source [Ste96]. See Fig. 28.7.1. This and many other related questions [OP01] remain open.

28.8 VISIBILITY IN THREE DIMENSIONS

Research on visibility in three dimensions (3D) has concentrated on three topics: hidden surface removal, polyhedral terrains, and various 3D visibility graphs.

28.8.1 HIDDEN SURFACE REMOVAL

“Hidden surface removal” is one of the key problems in computer graphics (Chapter 49), and has been the focus of intense research for two decades. The typical problem instance is a collection of (planar) polygons in space, from which the view from $z = \infty$ must be constructed. Traditionally, hidden-surface algorithms have been classified as either *image-space* algorithms, exploiting the ultimate need to compute visible colors for image pixels, and *object-space* algorithms, which perform exact computations on object polygons. We only discuss the latter.

The complexity of the output scene can be quadratic in the number of input vertices n . A worst-case optimal $\Theta(n^2)$ algorithm can be achieved by projecting the lines containing each polygon edge to a plane and constructing the resulting arrangement of lines [Dév86, McK87]. Most recent work has focused on obtaining output-size sensitive algorithms, whose time complexity depends on the number of vertices k in the output scene (the complexity of the *visibility map*), which is often less than quadratic in n . See Table 28.8.1 for selected results. In the table, k is the complexity of the *visibility map*, the “wire-frame” projection of the scene. A notable example is based on careful construction of “visibility maps,” which leads, e.g., to a complexity of $O((n + k) \log^2 n)$ for performing hidden surface removal on nonintersecting spheres, where k is the complexity of the output map.

TABLE 28.8.1 Hidden-surface algorithm complexities.

ENVIRONMENT	COMPLEXITY	SOURCE
Isothetic rectangles	$O((n + k) \log n)$	[dBO92]
Polyhedral terrain	$O((n + k) \log n \log \log n)$	[RS88]
Nonintersecting polyhedra	$O(n\sqrt{k} \log n)$	[SO92]
	$O(n^{1+\epsilon}\sqrt{k})$	[dBHO ⁺ 94]
	$O(n^{2/3+\epsilon}k^{2/3} + n^{1+\epsilon})$	[AM93]
Arbitrary intersecting spheres	$O(n^{2+\epsilon})$	[AS00]
Nonintersecting spheres	$O(k + n^{3/2} \log n)$	[SO92]
Restricted-intersecting spheres	$O((n + k) \log^2 n)$	[KOS92]

28.8.2 BINARY SPACE PARTITION TREES

Binary Space Partition (BSP) trees have become a popular method of implementing the basic *painter’s algorithm*, which displays objects back-to-front to obtain proper occlusion of front-most surfaces. A *BSP* partitions $\mathbb{R}^d$ into empty, open

FIGURE 28.8.1

A binary space partition tree for 3 segments.

convex sets by hyperplanes in a recursive fashion. A BSP for a set S of n line segments in $\mathbb{R}^2$ is a partition such that all the open regions corresponding to leaf nodes of the tree are empty of points from S : all the segments in S lie along the boundaries of the regions. An example is shown in Fig. 28.8.1. In general, a BSP for S will “cut up” the segments in S , in the sense that a particular $s \in S$ will not lie in the boundary of a single leaf region. In the figure, partitions 1 and 2 both cut segments, but partition 3 does not.

An attractive feature of BSPs is that an implementation to construct them is easy: In $\mathbb{R}^3$, select a polygon, partition all objects by the plane containing it, and recurse. Bounding the size (number of leaves) of BSP trees has been a challenge. The long-standing conjecture that $O(n)$ size in $\mathbb{R}^2$ is achievable has recently been shown to be false. See Table 28.8.2 for selected results.

TABLE 28.8.2 BSP complexities.

DIM	CLASS	BOUND	SOURCE
2	segments	$O(n \log n)$	[PY90]
2	isothetic	$\Theta(n)$	[PY92]
2	fat	$\Theta(n)$	[dBdGO97]
2	segments	$\Omega(n[\log n / \log \log n])$	[Tót01c]
3	polyhedra	$O(n^2)$	[PY90]
3	polyhedra	$\Omega(n^2)$	Eppstein
3	isothetic	$\Theta(n^{3/2})$	[PY92]
3	fat orthog. rects.	$n^{O(\sqrt{\log n})}$	[AGMV00]

28.8.3 POLYHEDRAL TERRAINS

Polyhedral terrains are an important special class of 3D surfaces, arising in a variety of applications, most notably geographic information systems ([Chapter 58](#)).

GLOSSARY

- Polyhedral terrain:*** A polyhedral surface that intersects every vertical line in at most a single point.
- Perspective view:*** A view from a point.
- Orthographic view:*** A view from infinity (parallel lines of sight).
- Ray-shooting query:*** A query asking which terrain face is first hit by a ray shooting in a given direction from a given point. (See [Chapter 37](#).)
- $\alpha(n)$:*** The inverse Ackermann function (nearly a constant). See [Section 47.4](#).

COMBINATORIAL BOUNDS

Several almost-tight bounds on the maximum number of combinatorially different views of a terrain have been obtained, as listed in Table 28.8.3.

TABLE 28.8.3 Bounds for polyhedral terrains.

VIEW TYPE	BOUND	SOURCE
Along vertical	$O(n^2 2^{\alpha(n)})$	[CS89]
Orthographic	$O(n^{5+\epsilon})$	[AS94]
Perspective	$O(n^{8+\epsilon})$	[AS94]

Bose et al. established that $\lfloor n/2 \rfloor$ vertex guards are sometimes necessary and always sufficient to guard a polyhedral terrain of n vertices [BSTZ97, BKL96].

ALGORITHMS

Algorithms seek to exploit the terrain constraints to improve on the same computations for general polyhedra:

1. To compute the orthographic view from above the terrain:
time $O((k + n) \log n \log \log n)$, where k is the output size [RS88].
2. To preprocess for $O(\log n)$ ray-shooting queries for rays with origin on a vertical line [BDEG94].

28.8.4 3D VISIBILITY GRAPHS

GLOSSARY

Aspect graph: A graph with a node for each combinatorially distinct view of a collection of polyhedra, with two nodes connected by an arc if the views can be reached directly from one another by a continuous movement of the viewpoint.

Isothetic: Edges parallel to Cartesian coordinate axes.

Box visibility graph: A graph realizable by disjoint isothetic boxes in 3D with orthogonal visibility.

K_n : The complete graph on n nodes.

There have been three primary motivations for studying visibility graphs of objects in three dimensions.

1. Computer graphics: Useful for accelerating interactive “walkthroughs” of complex polyhedral scenes [TS91], and for radiosity computations [TH93]. See [Chapter 49](#).
2. Computer vision: “Aspect graphs” are used to aid image recognition. The maximum number of nodes in an aspect graph for a polyhedron of n vertices depends on both convexity and the type of view. See Table 28.8.4. Note that the nonconvex bounds are significantly larger than those for terrains.

TABLE 28.8.4 Combinatorial complexity of visibility graphs.

CONVEXITY	ORTHOGRAPHIC	PERSPECTIVE	SOURCE
Convex polyhedron	$\Theta(n^2)$	$\Theta(n^3)$	[PD90]
Nonconvex polyhedron	$\Theta(n^6)$	$\Theta(n^9)$	[GCS91]

3. Combinatorics: It has been shown that K_{22} is realizable by disjoint isothetic rectangles in “ $2\frac{1}{2}$ D” with vertical visibility (all rectangles are parallel to the xy -plane), but that K_{56} (and therefore all larger complete graphs) cannot be so represented [BEF⁺93]. It is known that K_{42} is a box visibility graph [BJMO94] but that K_{184} is not [FM99].

28.9 PENETRATING ILLUMINATION OF CONVEX BODIES

A rich vein of problems was initiated by Hadwiger, Levi, Gohberg and Markus; see [MS99] for the complex history. The problems employ a different notion of

exterior illumination, which could be called *penetrating illumination* (or perhaps “stabbing”), and focuses on a single convex body in $\mathbb{R}^d$.

GLOSSARY

Penetrating illumination: An exterior point x penetratingly illuminates a point y on the boundary ∂K of an object K if the ray from x through y has a non-empty intersection with the interior $\text{int } K$ of K .

Direction illumination: A point $y \in \partial K$ is illuminated from direction $\mathbf{v}$ if the ray from the exterior through y with direction $\mathbf{v}$ has a non-empty intersection with $\text{int } K$.

Affine symmetry: An object has affine symmetry if it is unchanged after reflection through a point, reflection in a plane, or rotation about a line by angle $2\pi/n$, $n = 2, 3, \dots$

The central problem may be stated: What is the fewest number of exterior points sufficient to penetratingly illuminate any compact, convex body K in $\mathbb{R}^d$? The problem is only completely solved in 2D: 4 lights are needed for a parallelogram, and 3 for all other convex bodies. In 3D it is known that 8 lights are needed for a parallelepiped (Fig. 28.9.1), and conjectured that 7 suffice for all other convex bodies. Bezdek proved that 8 lights suffice for any 3-polytope with an affine symmetry [Bez93]. Lassak proved that no more than 20 lights are needed for any compact, convex body in 3D [Bol81].

FIGURE 28.9.1

A parallelepiped requires $2^3 = 8$ lights for penetrating illumination of its boundary.

One reason for the interest in this problem is its connection to other problems, particularly covering problems. Define:

$I_0(K)$: the fewest number of points sufficient to penetratingly illuminate K .

$I_\infty(K)$: the fewest number of directions sufficient to direction-illuminate K .

$H(K)$: the fewest number of smaller homothetic copies of K that cover K .

$i(K)$: the fewest number of copies of $\text{int } K$ that cover K .

Remarkably,

$$I_0(K) = I_\infty(K) = H(K) = i(K) .$$

as established by Boltjanski, Hadwiger, and Soltan; see again [MS99]. Several have conjectured that these quantities are $\leq 2^d$ for compact, convex bodies in $\mathbb{R}^d$, with equality only for the d -parallelotope.. The conjecture has been established only for special classes of bodies, e.g., [Bol01].

29 GEOMETRIC RECONSTRUCTION PROBLEMS

Steven S. Skiena

INTRODUCTION

Many problems from mathematics and engineering can be described in terms of reconstruction from geometric information. *Reconstruction* is the algorithmic problem of combining the results of one or more measurements of some aspect of a physical or mathematical object to obtain certain desired information about the object. Geometric reconstruction problems arise in a number of applications, such as robotics and computer-aided tomography, and also are of theoretical interest.

In this chapter, we consider three different classes of geometric reconstruction problems. In Section 29.1, we examine static reconstruction problems, where we are given a geometric structure G' derived from an original structure G , and seek to invert this transformation. In Section 29.2, we consider interactive reconstruction problems, where we are permitted to “probe” the object at arbitrary places and seek to reconstruct the desired structure using the fewest such probes. Finally, in Section 29.3, we provide pointers to the literature for work on (typically ill-defined) geometric reconstruction problems that often arise in practice.

29.1 STATIC RECONSTRUCTION PROBLEMS

Here we consider inverse problems of the following type. Let A be a geometric structure, and T a transformation such that $T(A) \rightarrow B$, where B is some different geometric structure. Now, given T and B , construct a structure A' such that $T(A') \rightarrow B$. If T is 1–1, then $A = A'$. If not, we may be interested in finding or counting all solutions.

An example of an important class of reconstruction problems is recognizing visibility graphs, i.e., given a graph G , construct a polygon P whose visibility graph is G . See [Section 28.2](#).

Results on static reconstruction problems are summarized in [Table 29.1.1](#). We characterize each problem by its input instance and desired inverted structure. Static reconstruction problems include reconstructing sets of points from inter-point distances, extended Gaussian images [GH95][GM03], points from Voronoi diagrams [AB85], and orthogonal polygons from points [O’R88].

A special class of problems concerns proximity drawability. Given a graph G , we seek a set of points corresponding to vertices of G such that two points are “sufficiently” close iff there is an edge in G for the corresponding vertices. Examples of proximity drawability problems include finding points to realize graphs as minimum spanning trees (MST), Delaunay triangulations ([Chapter 25](#)), Gabriel graphs, and relative neighborhood graphs (RNGs) ([Chapter 51](#)). Although many of the results are quite technical, Di Battista et al. [DLL95] provide an excellent survey

of results on these and other classes of proximity drawings; see also [Chapter 52](#).

To provide some intuition about the minimum spanning tree results, observe that very low degree graphs are easily embedded as point sets. If the maximum degree is 2, i.e., the graph is a simple path, then any straight line embedding will work. To realize a vertex v of degree 6 as a minimum spanning tree, a geometric argument shows that all adjacent points must be spaced at equal angles of 60 degrees around v , a very restrictive condition leading to the hardness result. Such equal spacing is not possible for degree larger than six.

GLOSSARY

Extended Gaussian image: A transform that maps each face of a convex polyhedron to a vector normal to the face whose length is proportional to the area of the face. These vectors uniquely represent convex polyhedra and have been applied to problems in robot vision.

Hammer's X-ray problem: Given a fixed set of X-ray projections of a convex body, can you reconstruct the body?

Determination: A class of sets is determined by n directions if there are n fixed directions such that all sets can be reconstructed from projections along these directions.

Verification: A class of sets is verified by n directions if, for each particular set, there are n projections that distinguish this set from any other.

Gabriel graph: A graph whose vertices are points in $\mathbb{E}^2$, with edge (x, y) iff points x and y define the diameter of an empty circle.

Relative neighborhood graph: A graph whose vertices are points in $\mathbb{E}^2$, with an edge (x, y) iff there exists no point z such that z is closer to x than y is and z is closer to y than x is. See [Section 51.2](#).

Interpoint distances: The complete set of $\binom{n}{2}$ distances defined between pairs of points in an n point set. The distance set is **labeled** if the identities of the two points defining the distance are associated with the distance, and **unlabeled** otherwise.

A final set of problems concern reconstructing objects from a fixed set of X-ray projections, conventionally called Hammer's X-ray problem. Different problems arise depending upon whether the X-rays originate from a point or line source, and whether we seek to verify or determine the object. A selection of results on parallel X-rays (line sources) are listed in [Table 29.1.2](#). For example, parallel X-rays in certain sets of four directions suffice to determine any convex body; the directions must not be a subset of the edges of an affinely regular polygon. If the directions do form such a subset, then there exist noncongruent polygons that are not distinguished by any number n of parallel X-rays in these directions. Nevertheless, any pair of nonparallel directions suffice to determine "most" (in the sense of Baire category) convex sets.

There is also a collection of results on *point source X-rays*. For example, convex sets in $\mathbb{E}^2$ are determined by directed X-rays from three noncollinear point sources. The substantial literature on such X-ray problems is most ably covered by Gardner's monograph [Gar95], from which several of the open problems listed below are drawn.

TABLE 29.1.1 Static reconstruction problems.

INPUT	INVERTED STRUCTURE	RESULT
Tree with max degree ≤ 5	points embedding it as MST	every tree realizable
Tree with max degree 6	points embedding it as MST	NP-hard
Tree with max degree ≥ 7	points embedding it as MST	no tree realizable
Planar graph	points embedding it as a Gabriel graph	partial characterization
Planar graph	points embedding it as a RNG	partial characterization
Triangulated graph	points embedding it as a Delaunay tri	partial characterization
Points in $\mathbb{E}^2$	orthogonal polygon through them	algorithm: $O(n \log n)$
Planar graph	points embedding it as a Voronoi diag	partial characterization
Extended Gaussian image	convex polyhedra in $\mathbb{E}^3$	algorithm: $O(n \log n)$ per iter
Labeled interpoint dists	points realizing these in $\mathbb{E}^d$	algorithm: $O(2^d n^2)$
Unlabeled interpoint dists	points realizing these on $\mathbb{E}^1$	algorithm: $O(2^n n \log n)$
Unlabeled interpoint dists	points realizing these in $\mathbb{E}^d$	NP-hard

Discrete tomography is a new area of study inspired by the use of electron microscopy to reconstruct the positions of atoms in crystal structures. A typical problem is placing integers in a matrix so as to realize a given set of row and column sums. The problem becomes more complex when the reconstructed body must satisfy connectivity constraints or simultaneously satisfy row/column sums of multiple colors. A collection of survey articles on discrete tomography is presented by Herman and Kuba [HK99].

TABLE 29.1.2 Selected results on parallel X-rays (Hammer's problem).

DIM	PROBLEM	SETS	RESULT
2	verify	convex polygons	2 parallel X-rays do not suffice
	verify	convex set	3 parallel X-rays suffice
	determine	convex set	4 parallel X-rays suffice ($\not\subseteq$ affinely reg polygon)
	determine	convex set	n parallel X-rays do not suffice ($\subseteq$ affinely reg polygon)
3	determine	convex set	2 parallel X-rays “usually” suffice
	determine	star-shaped polygons	no finite set of directions suffice
	determine	convex body	4 parallel X-rays suffice (coplanar directions)
d	determine	convex body	4 parallel X-rays do not suffice (noncoplanar directions)
	determine	compact sets	2 parallel X-rays “usually” suffice no finite set of directions suffice

OPEN PROBLEMS

1. Give an algorithm (polynomial in n) to reconstruct a set of n points on a line from the set of $\binom{n}{2}$ unlabeled interpoint distances it defines. See [SSL90].
2. Do there exist two distinct n -point sets, $n \geq 7$, realizing identical unlabeled interpoint distance sets, where each distance is unique in the set? See [Blo77].
3. Characterize the convex sets in $\mathbb{E}^2$ that can be determined by two parallel X-rays [Gar95, Problem 1.1].
4. Are convex bodies in $\mathbb{E}^3$ determined by parallel X-rays in some set of five directions [Gar95, Problem 2.2]?
5. Find an algorithm to reconstruct a convex set from its directed X-rays from three noncollinear points [Gar95, Problem 5.5]. The uniqueness proof is non-constructive.
6. Given both the red and blue column sums of a matrix, color the matrix elements red, blue, and white so as to realize these sums. The problem is known to be polynomial for one color and NP-complete for three or more colors [CD01, Dur01].
7. Given the (single color) column sums of a matrix, find a convex polyomino which realizes these sums, if one exists. It is open as to whether there exists a polynomial-time algorithm for this problem [CD01, Dur01].

29.2 INTERACTIVE RECONSTRUCTION PROBLEMS

Geometric probing considers problems of determining a geometric structure or some aspect of that structure from the results of a mathematical or physical measuring device, a **probe**. A variety of problems from robotics, medical instrumentation, mathematical optimization, integral and computational geometry, graph theory, and other areas fit into this paradigm. The key issue is interaction, where the n th probe depends upon the outcome of the previous probes.

The problem of geometric probing was introduced by Cole and Yap [CY87] and inspired by work in robotics and tactile sensing (Section 48.7). A substantial body of work has followed it, which is extensively surveyed in [Ski92]. A collection of open problems in probing appears in [Ski89].

GLOSSARY

Determination: The algorithmic problem of computing how many probes of a particular model are necessary to completely determine or reconstruct an object drawn from a particular class of objects.

Verification: The algorithmic problem, given a supposed description of an object, of computing how many probes of a particular model are necessary to test if the description is valid.

Model-based: A problem where any object is constrained to be one of a known, finite set of m possible objects.

Point probe: An oracle that tests whether a given point is within an object or not.

Finger probe: An oracle that returns the first point of intersection between a directed line and an object.

Hyperplane probe: An oracle that measures the first time at which a hyperplane moving parallel to itself intersects an object.

X-ray probe: An oracle that measures the length of the intersection between a line and an object.

Silhouette probe: An oracle that returns a $(d-1)$ -dimensional projection (in a given direction) of a d -dimensional object.

Halfspace probe: An oracle that measures the area or volume of the intersection between a halfspace and an object.

Cut-set probe: An oracle that for a specified graph and partition of the vertices returns the size of the cut-set determined by the partition.

FIGURE 29.2.1

Determining the next edge of P using finger probes.

MAIN RESULTS

For a particular probing model, the determination problem asks how many probes are sufficient to completely reconstruct an object from a given class. For example, Cole and Yap's strategy for reconstructing a convex polygon P from finger probes is based on the observation that three collinear contact points must define an edge. The strategy, illustrated in Figure 29.2.1, aims probes at the intersection point between a confirmed edge (defined by three collinear points) and a conjectured edge (defined by two contact points). If this intersection point is indeed a contact point, another vertex is determined due to convexity; if not, the existence of another edge is known. Since we avoid probing the interior of any edge that has been determined, $\approx 3n$ probes suffice in total since no more than one edge can be hit four times.

Table 29.2.1 summarizes probing results for a wide variety of models. In the table, $f_i(P)$ denotes the number of i -dimensional faces of P .

TABLE 29.2.1 Upper and lower bounds for determination for various probing models.

PROBE	OBJECT	LOWER BOUND	UPPER BOUND
Finger	convex n -gon	$3n$	$3n$
Finger	convex n -gon w known n	$2n + 1$	$3n - 1$
Finger	convex polyhedra in $\mathbb{E}^d$	$df_0(P) + f_{d-1}(P)$	$f_0(P) + (d + 2)f_{d-1}(P)$
Finger	n -gon from m conv models	$n - 1$	$n + 3$
2 fingers	convex n -gon	$2n - 2$	$2n$
3 fingers	convex n -gon	$2n - 3$	$2n$
4 or 5 fingers	convex n -gon	$(4n - 5)/3$	$\lfloor (4n + 2)/3 \rfloor$
$k \geq 6$ fingers	convex n -gon	n	$n + 1$
Enhanced fingers	n -gon w noncollinear edges	$3n - 3$	$3n - 3$
Line	convex n -gon	$3n + 1$	$3n + 1$
Line	n -gon from m conv models	$2n - 3$	$2n + 4$
Silhouette	convex n -gon	$3n - 2$	$3n - 2$
Silhouette	convex polyhedra in $\mathbb{E}^3$	$f_2(P)/2$	$5f_0(P) + f_2(P)$
X-ray	convex n -gon	$3n - 3$	$5n - 19$
Parallel X-ray	convex n -gon	3	3
Parallel X-ray	nondegenerate n -gon	$\lfloor \log n \rfloor - 2$	$2n + 2$
Halfplane	convex n -gon	$2n$	$7n + 7$
Cut-set	embedded graph	$\binom{n}{2}$	$\binom{n}{2}$
Cut-set	unembedded graph	$\Omega(n^2/\log n)$	$O(n^2/\log n)$

Cole and Yap's finger probing model is not powerful enough to determine non-convex objects. There are three major reasons for this. A tiny crack in an edge can go forever undetected, since no finite strategy can explore the entire surface of the polygon. Second, it is easy to construct nonconvex polygons whose features cannot be entirely contacted with straight-line probes originating from infinity. Finally, for nonconvex polygons there exists no constant k such that k collinear probes determine an edge. To generalize the class of objects, enhanced finger probes have been considered. One such probe [ABY90] returns surface normals as well as contact points, eliminating the second problem. When restricted to polygons with no two edges defined by the same supporting line, the first and third problems are eliminated.

In the verification problem, we are given a description of a putative object, and charged with using a small number of probes to prove that the description is correct. Verification is clearly no harder than determination, since we are free to ignore the description in planning the probes, and could simply compare the determined object to its description. Sometimes significantly fewer probes suffice for verification. For example, we can verify a putative convex polygon in $2n$ probes by sending one finger probe to contact each vertex and the interior of each edge. This gives three contact points on each edge, which by convexity suffices to verify the polygon. Table 29.2.2 summarizes results in verification.

Of course, there are other classes of problems that do not fit so easily into the confines of these tables. Verification is closely related to approximate geometric testing; see [ABP⁺97, Rom95]. An interesting application of probing to nonconvex

polygons is presented in [HP99]. See [Ric97, Ski92] for discussions of probing with uncertainty and tactile sensing in robotics.

TABLE 29.2.2 Upper and lower bounds for verification for various probing models.

PROBE	OBJECT	LOWER BOUND	UPPER BOUND
Finger	convex n -gon	$2n$	$2n$
Finger	convex n -gon with known n	$3\lceil n/2 \rceil$	$3\lceil n/2 \rceil$
Line	convex n -gon	$2n$	$2n$
X-ray	convex n -gon	$3n/2$	$3n/2 + 6$
Halfplane	convex n -gon	$2n/3$	$n + 1$

OPEN PROBLEMS

1. Tighten the gap between the lower and upper bounds for determination for finger probes in higher dimensions [DEY86].
2. Tighten the bounds for determination of convex n -gons with X-ray probes. Does a finite number (i.e., $f(n)$) of parallel X-ray probes suffice to verify or determine simple n -gons? Since each parallel X-ray probe provides a representation of the complete polygon, there is hope to detect arbitrarily small cracks in a finite number of probes; but see [MS96].
3. Consider generalizations of halfplane probes to higher dimensions. How many probes are necessary to determine convex (or nonconvex) polyhedra?
4. Silhouette probes return the shadow cast by a polytope in a specified direction. These dualize to ***cross-section probes*** that return a slice of the polytope. Tighten the current bounds [DEY86] on determination with silhouettes in $\mathbb{E}^3$.

29.3 ILL-POSED RECONSTRUCTION PROBLEMS

Many geometric reconstruction problems that arise in practice are inherently ill-defined. In this section, we mention a class of approximate reconstruction problems, typically inspired by practical problems, and describe a few approaches toward dealing with them. Specific results are not discussed, but pointers to the literature are provided.

COMPUTER VISION

Computer vision is an enormous research area, with the goal of enabling computers to understand and interpret features in digital images. There are a variety of com-

puter vision problems that can be framed as reconstruction problems, particularly those that try to use several fixed images or active sensing, where the robot is free to decide where to look next to obtain more information about its environment [Fau93, Hor86].

A particularly interesting class of active sensing problems involves navigating in an unfamiliar terrain, where we seek a short path to a goal but learn about obstacles only as we encounter them. See [BRS91] for approximation results on this problem, and Sections 27.3 and 47.7 of this Handbook.

Decision trees are a commonly used classification procedure for recognizing an object drawn from a known class of models. The classification procedure takes the form of a rooted tree, where the models are leaves and each internal node corresponds to a test or probe. All of the probing strategies discussed in previous sections can be reformulated in terms of decision trees, with the goal of minimizing the heights of the trees. The general problem of minimizing the height of a decision tree is NP-complete, but approximation algorithms for minimizing the height of geometric decision trees are known [AMM⁺98, AGM⁺93].

SURFACES FROM DATA POINTS

As described in the introduction to this section, interpolating a surface from a finite set of points in three dimensions can be considered a geometric reconstruction problem. These problems often arise in cartographic data, where we seek to construct a model of a mountain given a set of points on the surface. The issue also arises in surface simplification, where given a surface we seek to approximate it with another surface with fewer points such that the maximum difference between elevations is minimized; see [Chapter 54](#). Curve and surface reconstruction has recently been cast into a new, no longer ill-posed form, with theoretical guarantees. See [Chapter 30](#) for a thorough survey.

One common approach consists of projecting the points to the plane, triangulating them, and converting this into a triangulated surface by projecting each vertex back into three dimensions. Triangulation-based approaches to surface reconstruction are surveyed in [MSS92].

TOMOGRAPHY AND SURFACES FROM CROSS-SECTIONS AND PROJECTIONS

CAT scanners and other tomographic imaging systems represent a tremendous step forward in our ability to diagnose tumors and other medical problems. Herman [Her80] defines tomography as “the process of producing an image of a two-dimensional distribution (usually of some physical property) from estimates of its line integrals along a finite number of lines of known locations.” Tomographic scanners estimate line integrals by sending an energy pulse of some type through an object and measuring how much energy is absorbed. Surveys of tomography include [SK78, SSW77].

The most important reconstruction algorithms are transform methods, which are direct implementations of the Radon inversion formula, derived using Fourier transform methods.

Electrical impedance tomography (EIT) is a recently developed medical imaging technology that constructs a map of the electrical conductivity of a region of

the body using probes that measure the resistance between pairs of surface points. See <http://www.eit.org.uk/> for a comprehensive list of references on electrical impedance tomography.

An important related geometric problem concerns splicing a series of these parallel slices into polyhedra. The most natural way to proceed is to triangulate between the slices, but this is not always possible without adding extra vertices [GOS96]. Practical algorithms include [Boi88, BS94]; see also [Section 26.6](#).

SHAPE FROM DISTRIBUTION OF CROSS-SECTIONS

In such fields as biology and geology, it is often necessary to reconstruct the shape and size distributions of particles from the cross-sections of samples. For example, cross-sections of cubes can be polygons with 3, 4, 5, or 6 sides, and the probability of each such event is well defined if the cross-sections are taken uniformly at random, as would be the case with small crystals inside a large mineral sample. This has given rise to a field known as ***stereology*** [Eli67, Hau63, Wei83], where such distributions are studied. A subfield known as ***local stereology***, where the set of cross-sections is taken through a common point, has a particularly close connection to geometric tomography. See [Jen98] for details and <http://www.stereologysociety.org/> for a comprehensive survey of the stereology literature.

3D MODELS FROM 2D IMAGES

In the field of computer vision, it is often desirable to reconstruct a 3D model of an object consistent with one or more two-dimensional images of the object. The model is not necessarily unique, as there may be features that do not appear in any of the images. These problems are surveyed in [Section 51.2](#).

After edge detection has been applied to the image, the primary algorithmic problem concerns identifying whether edges correspond to protrusions or indentations of the main object. Huffman-Clowes labeling is a constraint-based approach resulting from a case analysis of the possible types of junctions and shadows in the scene. Recent articles of such methods include [ABC⁺90, WG93, Whi89, Sug86].

30 CURVE AND SURFACE RECONSTRUCTION

Tamal K. Dey

INTRODUCTION

The problem of reconstructing a shape from its sample appears in many scientific and engineering applications. Because of the variety in shapes and applications, many algorithms have been proposed over the last two decades, some of which exploit application-specific information and some of which are more general. We will concentrate on techniques that apply to the general setting and have proved to provide some guarantees on the quality of reconstruction.

GLOSSARY

Simplex: A k -simplex in $\mathbb{R}^d$, $0 \leq k \leq d$, is the convex hull of $k + 1$ affinely independent points in $\mathbb{R}^d$ where $0 \leq k \leq d$. The 0-, 1-, 2-, and 3-simplices are also called *vertices*, *edges*, *triangles*, and *tetrahedra* respectively.

Simplicial complex: A simplicial complex $\mathcal{K}$ is a collection of simplices with the conditions that, (i) if $\sigma_1, \sigma_2 \in \mathcal{K}$ intersect, then $\sigma_1 \cap \sigma_2 \in \mathcal{K}$, and (ii) all simplices spanned by the vertices of a simplex in $\mathcal{K}$ are also in $\mathcal{K}$. The underlying space of $\mathcal{K}$ is the set of all points in its simplices. (Cf. [Chapter 31](#).)

k -manifold: A k -manifold is a topological space where each point has a neighborhood homeomorphic to $\mathbb{R}^k$ or the halfspace $\mathbb{H}^k$. The points with $\mathbb{H}^k$ neighborhood constitute the boundary of the manifold.

Voronoi diagram: Given a point set $P \in \mathbb{R}^d$, the Voronoi diagram V_P of P is a collection of Voronoi cells V_p for each point $p \in P$, where

$$V_p = \{x \in \mathbb{R}^d \mid \|x - p\| \leq \|x - q\| \forall q \in P\}.$$

Delaunay triangulation: The Delaunay triangulation of a point set $P \in \mathbb{R}^d$ is a simplicial complex D_P so that a simplex with vertices $\{p_0, \dots, p_k\}$ is in D_P if and only if $\bigcap_{i=0,k} V_{p_i} \neq \emptyset$. (Cf. [Chapter 22](#).)

Shape: A shape Σ is a subset of an Euclidean space.

Sample: A sample P of a shape Σ is a finite set of points from Σ .

Medial axis: The medial axis of a shape $\Sigma \in \mathbb{R}^d$ is the closure of the set of points in $\mathbb{R}^d$ that have more than one closest point in Σ . See [Figure 30.1.1\(a\)](#) for an illustration.

Local feature size: The local feature size for a shape $\Sigma \subseteq \mathbb{R}^d$ is a continuous function $f : \Sigma \rightarrow \mathbb{R}$ where $f(x)$ is the distance of $x \in \Sigma$ to the medial axis of Σ . See [Figure 30.1.1\(a\)](#).

Uniform sample: A sample P of a shape Σ is δ -uniform if for each $x \in \Sigma$ there is a sample point $p \in P$ so that $\|p - x\| \leq \delta f_{\min}$ where $f_{\min} = \min\{f(x), x \in \Sigma\}$ and $\delta > 0$ is a constant.

ϵ -sample: A sample P of a shape Σ is an ϵ -sample if for each $x \in \Sigma$ there is a sample point $p \in P$ so that $\|p - x\| \leq \epsilon f(x)$.

30.1 CURVE RECONSTRUCTION

In its simplest form the reconstruction problem appeared in applications such as pattern recognition (Chapter 51), computer vision, and cluster analysis, where a curve in two dimensions is to be approximated from a set of sample points. In the 1980s several geometric graphs connecting a set of points in plane were discovered which reveal a pattern among the points. The influence graph of Toussaint [AH85], the β -skeleton of Kirkpatrick and Radke [KR85], the α -shapes of Edelsbrunner, Kirkpatrick, Seidel [EKS83] are such graphs. Recently, several algorithms have been proposed that reconstruct a curve from its sample with guarantees under some sampling assumption.

FIGURE 30.1.1

A smooth curve (solid), its medial axis (dashed) (a), sample (b), reconstruction (c).

GLOSSARY

Curve: A curve C in plane is a trace of a function $p : \mathbb{R} \rightarrow \mathbb{R}^2$ where $p(t) = (x(t), y(t))$ for $t \in [0, 1]$ and $p[t] \neq p[t']$ for any $t \neq t'$ except possibly $t, t' \in \{0, 1\}$. It is *smooth* if p is differentiable and the derivative $\frac{d}{dt}p(t) = (\frac{dx(t)}{dt}, \frac{dy(t)}{dt})$ does not vanish.

Boundary: A curve C is said to have no boundary if $p[0] = p[1]$; otherwise, it is a curve with boundary.

Reconstruction: The reconstruction of C from its sample P is a geometric graph $G = (P, E)$ where an edge pq belongs to E if and only if p and q are adjacent sample points on C . See Figure 30.1.1.

Semiregular curve: One for which the left tangent and right tangent exist at each point of the curve, though they may be different.

UNIFORM SAMPLE

α -shapes: Edelsbrunner, Kirkpatrick, and Seidel [EKS83] defined the α -shape of a point set $P \subseteq \mathbb{R}^2$ as the underlying space of a simplicial complex called the α -complex. The α -complex of P is defined by all simplices with vertices in P that have an empty circumscribing disk of radius α . Bernardini and Bajaj [BB97] show that the α -shapes reconstruct curves from δ -uniform samples if δ is sufficiently small and α is chosen appropriately.

r -regular shapes Attali considered r -regular shapes that are constructed using certain morphological operations with r as a parameter [Att97]. It turns out that these shapes are characterized by requiring that any circle passing through the points on the boundary has radius greater than r . A sample P from the boundary curve C of such a shape is called γ -sample if each point $x \in C$ has a sample point within γr distance. Let η_{pq} be the sum of the angles opposite to pq in the two incident Delaunay triangles at a Delaunay edge $pq \in D_P$. The main result in [Att97] is that if $\gamma < \sin \frac{\pi}{8}$, Delaunay edges with $\eta_{pq} < \pi$ reconstruct C .

EMST: Figueiredo and Gomes [FG95] show that the Euclidean minimum spanning tree (EMST) reconstructs curves with boundaries when the sample is sufficiently dense. The sampling density condition that is used to prove this result is equivalent to that of δ -uniform sampling for an appropriate $\delta > 0$. Of course, EMST cannot reconstruct curves without boundaries and/or multiple components.

NONUNIFORM SAMPLE

Crust: Amenta, Bern, and Eppstein [ABE98] proposed the first algorithm to reconstruct a curve from a non-uniform sample with guarantee. The algorithm computes the *crust* of P in two phases. The first phase computes the Voronoi diagram of the sample points in P . Let V be the set of Voronoi vertices in this diagram. The second phase computes the Delaunay triangulation of the larger set $P \cup V$. The Delaunay edges that connect only sample points in this triangulation constitute the crust; see Figure 30.1.2.

The theoretical guarantee of the crust algorithm is based on the notion of dense sampling that respects features of the sampled curve. The important concepts of local feature size and ϵ -sampling were introduced by Amenta, Bern, and Eppstein [ABE98]. They prove that if P is an ϵ -sample of a curve C without boundary for $\epsilon \leq 0.252$, the crust reconstructs C . The two Voronoi diagram computations of the crust are reduced to one by Gold and Snoeyink [GS01].

Nearest neighbor: After the introduction of the crust, Dey and Kumar [DK99] proposed a curve reconstruction algorithm based on nearest neighbors. They showed that all nearest neighbor edges that connect a point to its Euclidean nearest neighbor must be in the reconstruction if the input is $\frac{1}{3}$ -sample. However, not all edges of the reconstruction are necessarily nearest neighbor edges. The remaining edges are characterized as follows. Let p be a sample point with only one nearest neighbor edge pq incident to it. Consider the halfplane with pq being an outward normal to its bounding line through p , and let r be the nearest to p among all sample points

FIGURE 30.1.2

Crust edges (solid) among the Delaunay triangulation of a sample and their Voronoi vertices.

lying in this halfplane. Call pr the half-neighbor edge of p . Dey and Kumar show that all half-neighbor edges must also be in the reconstruction for a $\frac{1}{3}$ -sample.

The algorithm first computes all nearest neighbor edges and then computes the half-neighbor edges to complete the reconstruction. Since all edges in the reconstruction must be a subset of Delaunay edges if the sample is sufficiently dense, all nearest neighbor and half-neighbor edges can be computed from the Delaunay triangulation. Thus, as crust this algorithm runs in $O(n \log n)$ time for a sample of n points.

NONSMOOTHNESS, BOUNDARIES

The crust and nearest neighbor algorithms assume that the sampled curve is smooth and has no boundary. Nonsmoothness and boundaries make reconstruction harder.

Traveling Salesman Path: Giesen [Gie00] considered a fairly large class of non-smooth curves and showed that Traveling Salesman Path (or Tour) reconstructs them from sufficiently dense samples. A semiregular curve C is **benign** if the angle between the two tangents at each point is less than π . Giesen proved that, for a benign curve C , there exists a $\delta > 0$ so that if each $x \in C$ has a sample point p with $\|p - x\| \leq \delta$, then C is reconstructed by the Traveling Salesman Path (or Tour) in case C has boundary (or no boundary).

The uniform sampling condition for the Traveling Salesman approach was later removed by Althaus and Mehlhorn [AM02], who also gave a polynomial-time algorithm to compute the Traveling Salesman Path (or Tour) in this special case of curve reconstruction. Obviously, the Traveling Salesman approach cannot handle curves with multiple components. Also, the sample points representing the boundary need to be known a priori to choose between path or tour.

Conservative Crust: In order to allow boundaries in curve reconstruction, it is essential that the sample points representing boundaries are detected. Dey, Mehlhorn, and Ramos presented such an algorithm, called the *conservative crust* [DMR00].

Any algorithm for handling curves with boundaries faces a dilemma when an input point set samples a curve without boundary densely and simultaneously samples another curve with boundary densely. This dilemma is resolved in conservative

crust by a justification on the output. For any input point set P , the graph output by the algorithm is guaranteed to be the reconstruction of a smooth curve C possibly with boundary for which the input point set is a dense sample. The main idea of the algorithm is that an edge pq is chosen in the output only if there is a large enough ball centering the midpoint of pq which is empty of all Voronoi vertices in the Voronoi diagram of P . The rationale behind this choice is that these edges are small enough with respect to local feature size of C since the Voronoi vertices approximate its medial axis.

With a certain sampling condition tailored to handle nonsmooth curves, Funke, and Ramos used conservative crust to reconstruct nonsmooth curves that may have boundaries [FR01].

SUMMARIZED RESULTS

The strengths and deficiencies of the discussed algorithms are summarized in Table 30.1.1.

TABLE 30.1.1 Curve reconstruction algorithms.

ALGORITHM	SAMPLE	SMOOTHNESS	BOUNDARY	COMPONENTS
α -shape	uniform	required	none	multiple
r -regular shape	uniform	required	none	multiple
EMST	uniform	required	exactly two	single
Crust	non-uniform	required	none	multiple
Nearest neighbor	non-uniform	required	none	multiple
Traveling Salesman	non-uniform	not required	must be known	single
Conservative crust	non-uniform	required	any number	multiple

OPEN PROBLEM

All algorithms described above assume that the sampled curve does not cross itself. It is open to devise an algorithm that can reconstruct such curves under some reasonable sampling condition.

30.2 SURFACE RECONSTRUCTION

A number of surface reconstruction algorithms have been designed in different application fields in recent years. The problem appeared in medical imaging where a set of cross sections obtained via CAT scan or MRI needs to be joined with a surface. The points on the boundary of the cross sections are already joined by a polygonal curve and the output surface needs to join these curves in consecutive

cross sections. A dynamic programming based solution for two such consecutive curves was first proposed by Fuchs, Kedem, and Useton [FKU77]. A negative result by Gitlin, O'Rourke, and Subramanian [GOS96] shows that, in general, two polygonal curves cannot be joined by a nonself-intersecting surface with only those vertices; even deciding its possibility is NP-hard. Several solutions with the addition of Steiner points have been proposed to overcome the problem, see [MSS92, BG93]. The most general version of the surface reconstruction problem does not assume any information about the input points other than their 3D coordinates, and requires a piecewise linear approximation of the surface from which the input point sample is derived; see Figure 30.2.1. In the context of computer graphics and vision, this problem has been investigated intensely in the past decade with emphasis on the practical effectiveness of the algorithms [BMR⁺99, Boi84, CL96, GKS00, HDD⁺92]. Lately, several algorithms have been designed mainly based on Voronoi/Delaunay diagrams that have theoretical guarantees. We focus mainly on them.

FIGURE 30.2.1
A point sample and the reconstructed surface.

GLOSSARY

Surface: A surface $S \subset \mathbb{R}^3$ is a 2-manifold embedded in $\mathbb{R}^3$. Thus each point $p \in S$ has a neighborhood homeomorphic to $\mathbb{R}^2$ or halfplane $\mathbb{H}^2$. The points with neighborhoods homeomorphic to $\mathbb{H}^2$ constitute the boundary of S .

Smooth Surface: A surface $S \subset \mathbb{R}^3$ is smooth if for each point $p \in S$ there is a neighborhood $W \subseteq \mathbb{R}^3$ and a map $\pi : U \rightarrow W \cap S$ of an open set $U \subset \mathbb{R}^2$ onto $W \cap S$ so that

- (i) π is differentiable,
- (ii) π is a homeomorphism,
- (iii) for each $q \in U$ the differential $d\pi_q$ is one-to-one.

Restricted Voronoi: Given a subspace $\mathbb{N} \subseteq \mathbb{R}^3$ and a point set $P \subseteq \mathbb{R}^3$, the restricted Voronoi diagram of V_P with respect to $\mathbb{N}$ is $V_{P,\mathbb{N}} = V_P \cap \mathbb{N}$.

Restricted Delaunay: The dual of $V_{P,\mathbb{N}}$ is called the restricted Delaunay triangulation $D_{P,\mathbb{N}}$ defined as

$$D_{P,\mathbb{N}} = \{\sigma \mid \sigma = (p_0, \dots, p_k) \in D_P \text{ where } (\cap_{i=0,k} V_{p_i}) \cap \mathbb{N} \neq \emptyset\}.$$

Watertight surface: A 2-complex $\mathcal{K}$ embedded in $\mathbb{R}^3$ is called watertight if the underlying space of $\mathcal{K}$ is same as the boundary of the closure of a 3-manifold in $\mathbb{R}^3$.

Steiner points: The points used by an algorithm that are not part of the finite input point set are called Steiner points.

α -SHAPES

Generalization of α -shapes to 3D by Edelsbrunner and Mücke [EM94] can be used for surface reconstruction in case the sample is more or less uniform. An alternate definition of α -shapes in terms of the restricted Delaunay triangulation is more appropriate for surface reconstruction. Let $\mathbb{N}$ denote the space of all points covered by open balls of radius α around each sample point $p \in P$. The α -shape for P is the underlying space of the restricted Delaunay triangulation $D_{P,\mathbb{N}}$; see Figure 30.3.1 below for an illustration in 2D. It is shown that the α -shape is always homotopic to $\mathbb{N}$, which in turn is homotopic to S if α is chosen appropriately for a sufficiently dense P [EM94]. Therefore, by transitivity of homotopy maps, the α -shape is homotopic to S if α is appropriate and the sample P is sufficiently dense.

The major drawback of α -shapes is that it requires a nearly uniform sample for reconstruction, and the value of α must be chosen appropriately. In a work under proprietary rights Edelsbrunner designed the WRAP algorithm based on Morse theory that overcomes the shortcoming of α -shapes [Ede03].

CRUST

The crust algorithm for curve reconstruction was generalized for surface reconstruction by Amenta and Bern [AB99]. In case of curves in 2D, Voronoi vertices for a dense sample lie close to the medial axis. That is why a second Voronoi diagram with the input sample points together with the Voronoi vertices is used to separate the Delaunay edges that reconstruct the curve. Unfortunately, Voronoi vertices in 3D can lie arbitrarily close to the sampled surface. One can place four arbitrarily close points on a smooth surface which lie near the diametric plane of the sphere defined by them. This sphere can be made empty of any other input point and thus its center as a Voronoi vertex lies close to the surface. With this important observation Amenta and Bern forsake the idea of putting all Voronoi vertices in the second phase of crust and instead identify a subset of Voronoi vertices called **poles** that lie far away from the surface, and in fact close to the medial axis.

Let P be an ϵ -sample of a compact smooth surface S without boundary. Let V_p be a Voronoi cell in the Voronoi diagram V_P . The farthest Voronoi vertex of V_p from p is called the positive pole of p . Call the vector from p to the positive pole the **pole vector** for p ; this vector approximates the surface normal $\mathbf{n}_p$ at p . The Voronoi vertex of V_p that lies farthest from p in the opposite direction of the pole vector is called its negative pole. The opposite direction is specified by the

condition that the vector from p to the negative pole must make an angle more than $\frac{\pi}{2}$ with the pole vector. Figure 30.2.2(a) illustrates these definitions. If V_p is unbounded, the positive pole is taken at infinity and the direction of the pole vector is taken as the average of all directions of the unbounded Voronoi edges in V_p .

The crust algorithm in 3D proceeds as follows. First, it computes the Voronoi diagram V_P and then identifies the set of poles, say L . The Delaunay triangulation of the point set $P \cup L$ is computed and the set of Delaunay triangles, T , is filtered that have all three vertices only from P . This set of triangles almost approximates S but may not form a surface. Nevertheless, the set T includes all restricted Delaunay triangles in $D_{P,S}$. According to a result by Edelsbrunner and Shah [ES97], $D_{P,S}$ is homeomorphic to S if each Voronoi cell satisfies a topological condition called the “closed ball property.” Amenta and Bern show that if P is an ϵ -sample for $\epsilon \leq 0.06$, each Voronoi cell in V_P satisfies this property. This means that, if the triangles in $D_{P,S}$ can be extracted from T , we will have a surface homeomorphic to S . Unfortunately, it is impossible to detect the restricted Delaunay triangles of $D_{P,S}$ since S is unknown. However, the fact that T contains them is used in extracting a manifold out of T after a normal filtering step. This piecewise linear manifold surface is output as crust.

The crust guarantees that the output surface lies very close to S . In particular, each point p in the output has a point x in S so that $\|p - x\| \leq O(\epsilon)f(x)$. Also, each point x in S has a point p in the output so that the same bound holds.

COCONE

The cocone algorithm was developed from the crust algorithm by Amenta, Choi, Dey, and Leekha [ACDL02]. It simplified the reconstruction algorithm and its proof of correctness.

A *cocone* C_p for a sample point p is defined as the complement of the double cone with p as apex and the pole vector as axis and an opening angle of $\frac{3\pi}{4}$; see Figure 30.2.2(b). Because the pole vector at p approximates the surface normal $\mathbf{n}_p$, the cocone C_p (clipped within V_p) approximates a thin neighborhood around the tangent plane at p . For each point p , the algorithm then determines all Voronoi edges in V_p that are intersected by the cocone C_p . The dual Delaunay triangles of these Voronoi edges constitute the set of candidate triangles T .

It is shown that the circumscribing circles of all candidate triangles are small [ACDL02]. Specifically, if $pqr \in T$ has circumradius r , then

$$(i) \ r = O(\epsilon)f(x) \text{ where } f(x) = \min\{f(p), f(q), f(r)\}.$$

It turns out that any triangle with such small circumradius must lie flat to the surface, i.e., if $\mathbf{n}_{pqr}$ is the normal to a candidate triangle pqr , then

$$(ii) \ \angle(\mathbf{n}_{pqr}, \mathbf{n}_x) = O(\epsilon) \text{ up to orientation where } x \in \{p, q, r\}.$$

Also, it is proved that

$$(iii) \ T \text{ includes all restricted Delaunay triangles in } D_{P,S}.$$

These three properties of the candidate triangles ensure that a manifold extraction step, as in crust algorithm, extracts a piecewise-linear surface N which is homeomorphic to the original surface S .

FIGURE 30.2.2

A long thin Voronoi cell V_p , the positive pole p^+ , the pole vector $\mathbf{v}_p$ and the negative pole p^- (a), the cocone (b).

Cocone uses a single Voronoi diagram as opposed to two in the crust algorithm and also eliminates the normal filtering step. It guarantees that the output surface N is topologically equivalent to the sampled surface S for $\epsilon \leq 0.06$ and each point on N has a point x in S within $O(\epsilon)f(x)$ distance. Because of the Voronoi diagram computation, the cocone runs in $O(n^2)$ time and space. Funke and Ramos [FR02] improved its complexity to $O(n \log n)$ though the resulting algorithm seems impractical.

NATURAL NEIGHBOR

Boissonnat and Cazals [BC00] revisited the approach of Hoppe et al. [HDD⁺92] by approximating the sampled surface as the zero set of a signed distance function. They used natural neighbors and ϵ -sampling to provide output guarantees.

Given an input point set $P \subset \mathbb{R}^3$, the **natural neighbors** $N_{x,P}$ of a point $x \in \mathbb{R}^3$ are the Delaunay neighbors of x in $D_{P \cup x}$. Letting $V(x)$ denote the Voronoi cell of x in $V_{P \cup x}$, this means

$$N_{x,P} = \{p \in P \mid V(x) \cap V_p \neq \emptyset\}.$$

Let $A(x,p)$ denote the volume stolen by x from V_p , i.e.,

$$A(x,p) = V(x) \cap V_p.$$

The natural coordinate associated with a point p is a continuous function $\lambda_p : \mathbb{R}^3 \rightarrow \mathbb{R}$ where

$$\lambda_p(x) = \frac{A(x,p)}{\sum_{q \in P} A(x,q)}.$$

Some of the interesting properties of λ_p are that it is continuously differentiable except at p , and any point $x \in \mathbb{R}^3$ is a convex combination of its natural neighbors:

$\Sigma_{p \in N_{x,P}} \lambda_p(x)p = x$. Boissonnat and Cazals assume that each point p is equipped with a unit normal $\mathbf{n}_p$ which can either be computed via pole vectors, or is part of the input. A distance function $h_p : \mathbb{R}^3 \rightarrow \mathbb{R}$ for each point p is defined as $h_p(x) = (p - x) \cdot \mathbf{n}_p$. A global distance function $h : \mathbb{R}^3 \rightarrow \mathbb{R}$ is defined by interpolating these local distance functions with natural coordinates. Specifically,

$$h(x) = \Sigma_{p \in P} \lambda_p^{1+\delta}(x) h_p(x).$$

The δ term in the exponent is added to make h continuously differentiable. By definition, $h(x)$ locally approximates the signed distance from the tangent plane at each point $p \in P$ and, in particular, $h(p) = 0$.

Since h is continuously differentiable, $\hat{S} = h^{-1}(0)$ is a smooth surface unless 0 is a critical value. A discrete approximation of $\hat{S}$ can be computed from the Delaunay triangulation of P as follows. All Voronoi edges that intersect $\hat{S}$ are computed via the sign of h at their two endpoints. The dual Delaunay triangles of these Voronoi edges constitute a piecewise linear approximation of $\hat{S}$. If the input sample P is an ϵ -sample for sufficiently small ϵ , then it can be shown that the output surface is geometrically close and is also topologically equivalent to the sampled surface.

UNDERSAMPLING

The assumption of ϵ -sampling for sufficiently small $\epsilon > 0$ often does not hold in practice. This undersampling may be caused by inadequate attention during the sampling process, or machine error, or nonsmoothness. Even boundaries in a surface may be viewed as the demarcation where appropriate sampling stops and the undersampling begins. Dey and Giesen [DG01] took this unified view to detect boundaries that identify the regions of undersampling.

Given a sample P of a surface S , the subset $S' \subseteq S$ is called *well-sampled* if each point x in S' has a sample point within $\epsilon f(x)$ distance. If P undersamples S , the well-sampled surface S' has boundaries. A point $p \in P$ is a *boundary sample* if V_p intersects the boundary of S' , otherwise p is *interior*. The algorithm of Dey and Giesen [DG01] works in two phases to detect all boundary samples. In the first phase, it selects a set $R \subseteq P$ based on two conditions. The first condition requires the Voronoi cell of a point in R be long and thin and the second requires its pole vector agree with those of all its neighbors on the surface (determined by cocones). These two conditions ensure that R consists of interior points only. In a second phase, the set R is expanded to include more points by relaxing the second condition. It is proved that under some mild assumptions on sampling, this algorithm determines all interior points and the remaining points are correctly detected as boundary.

Once the boundary samples are detected, the cocone algorithm is employed to filter the candidate triangles. Boundary samples are not allowed to choose any triangle. This produces the boundaries at the undersampled regions.

WATERTIGHT SURFACES

Most of the surface reconstruction algorithms face a difficulty while dealing with undersampled surfaces and noise. While the algorithm of [DG01] can detect undersampling, it leaves holes in the surface near the vicinity of undersampling. Although

this may be desirable for reconstructing surfaces with boundaries, many applications such as CAD designs require that the output surface be *watertight*, i.e., a surface that bounds a solid.

The natural neighbor algorithm of [BC00] can be adapted to guarantee a watertight surface. Recall that this algorithm approximates a surface $\hat{S}$ implicitly defined by the zero set of a smooth map $h : \mathbb{R}^3 \rightarrow \mathbb{R}$. This surface is a smooth 2-manifold without boundary in $\mathbb{R}^3$. However, if the input sample P is not dense for this surface, the reconstructed output may not be watertight. Boissonnat and Cazals suggest to sample more points on $\hat{S}$ to obtain a dense sample for $\hat{S}$ and then reconstruct it from the new sample.

Amenta, Choi, and Kolluri [ACK01] use the crust approach to design the *power crust* algorithm to produce watertight surfaces. This algorithm first distinguishes the inner poles that lie inside the solid bounded by the sampled surface S from the outer poles that lie outside. A consistent orientation of the pole vectors is used to decide between inner and outer poles. To prevent outer poles at infinity, eight corners of a large box containing the sample are added. The union of Delaunay balls with centers at the inner poles approximate the solid bounded by S . The union of Delaunay balls centered at the outer poles do not approximate the entire exterior of S although one of its boundary component approximates S . The implication is that the cells in the power diagram of the poles with the radius of the Delaunay ball as weights can be partitioned into two sets, with the boundary between approximating S . The facets in the power diagram that separate cells generated by inner poles from the ones generated by outer poles form this boundary which is output by power crust.

Recently Dey and Goswami [DG02] announced a water-tight surface reconstructor called *tight cocone*. This algorithm first computes the surface with cocone. Recall that cocone may leave some holes in the surface due to undersampling. A subsequent sculpting [Boi84] in the Delaunay triangulation of the input points recover triangles that fill the holes. Unlike power crust, tight cocone does not add Steiner points.

SUMMARIZED RESULTS

The properties of the above discussed surface reconstruction algorithms are summarized in [Table 30.2.1](#).

OPEN PROBLEMS

All guarantees given by various surface reconstruction algorithms depend on the notion of dense sampling. Watertight surface algorithms can guarantee a surface without holes, but no theoretical guarantees exists under any type of undersampling.

1. Design an algorithm that reconstructs nonsmooth surfaces under reasonable sampling conditions.
2. Design a surface reconstruction algorithm that handles noise gracefully, and with some guarantees.

TABLE 30.2.1 Surface reconstruction algorithms.

ALGORITHM	SAMPLE	PROPERTIES	SOURCE
α -shape	uniform	α to be determined.	[EM94]
Crust	non-uniform	Theoretical guarantees from Voronoi structures, two Voronoi computations.	[AB99]
Cocone	non-uniform	Simplifies crust, single Voronoi computation with topological guarantee, detects undersampling.	[ACDL02] [DG01]
Natural Neighbor	non-uniform	Theoretical guarantees using Voronoi diagram and implicit functions.	[BC00]
Power Crust	non-uniform	Watertight surface using power diagrams, introduces Steiner points.	[ACK01]
Tight Cocone	non-uniform	Watertight surface using Delaunay triangulation.	[DG02]

30.3 SHAPE RECONSTRUCTION

All algorithms discussed above are designed for reconstructing a shape of specific dimension from the samples. Thus, the curve reconstruction algorithms cannot handle samples from surfaces and the surface reconstruction algorithms cannot handle samples from curves. Therefore, if a sample is derived from shapes of mixed dimensions, i.e., both curves and surfaces in $\mathbb{R}^3$, none of the curve and surface reconstruction algorithms is adequate. General shape reconstruction algorithms should be able to handle any shape embedded in Euclidean spaces. However, this goal may be too ambitious, as it is not clear what would be a reasonable definition of dense samples for general shapes that are nonsmooth or nonmanifold. The ϵ -sampling condition would require infinite sampling in these cases. We therefore distinguish two cases: (i) smooth manifold reconstruction for which a computable sampling criterion can be defined, (ii) shape reconstruction for which it is currently unclear how a computable sampling condition could be defined to guarantee reconstruction. This leads to a different definition for the general shape reconstruction problem in the glossary below.

GLOSSARY

Shape reconstruction: Given a set of points $P \subseteq \mathbb{R}^d$, compute a shape that best approximates P .

Manifold shape: A manifold shape is a collection of smooth manifolds $\{M_1, M_2, \dots, M_\ell\}$ embedded in an Euclidean space $\mathbb{R}^d$.

Manifold reconstruction: Compute a piecewise-linear approximation to each M_i , given a sample P from a manifold shape $\{M_1, M_2, \dots, M_\ell\}$.

MAIN RESULTS

Shape reconstruction: Not many algorithms are known to reconstruct shapes. The definition of α -shapes is general enough to be applicable to shape reconstruction. In Figure 30.3.1, the α -shape reconstructs a shape in $\mathbb{R}^2$ which is not a manifold. Similarly, it can reconstruct curves, surfaces and solids and their combinations in three dimensions. Melkemi [Mel97] proposed $\mathcal{A}$ -shapes that can reconstruct shapes in $\mathbb{R}^2$. Its class of shapes includes α -shapes. Given a set of points P in $\mathbb{R}^2$, a member in this class of shapes is identified with another finite set $\mathcal{A} \subseteq \mathbb{R}^2$. The $\mathcal{A}$ -shape of S is generated by edges that connect points $p, q \in P$ if there is a circle passing through p, q and a point in $\mathcal{A}$, and all other points in $P \cup \mathcal{A}$ lie outside the circle. The α -shape is a special case of $\mathcal{A}$ -shapes where $\mathcal{A}$ is the set of all points on Voronoi edges that span empty circles with points in P . The crust is also a special case of $\mathcal{A}$ -shape where $\mathcal{A}$ is the set of Voronoi vertices.

FIGURE 30.3.1
Alpha shape of a set of points in $\mathbb{R}^2$.

Manifold reconstruction: When the sample P derives from smooth manifolds embedded in some Euclidean space $\mathbb{R}^d$, Dey et al. [DGGZ02] propose an algorithm *CoconeShape* for reconstruction. This algorithm first determines the dimension k of a sample point $p \in P$ if p is derived from a k -manifold. This dimension detection is accomplished by analyzing the structure of the Voronoi cell V_p . Subsequent to the dimension detection, a subset of k -dimensional Delaunay simplices incident to p are chosen in an output set T . This computation is performed with a generalized concept of cocones.

It is shown that the underlying space of T lies very close to the sampled manifold(s) although it may not be a triangulation of a manifold. A manifold extraction step as in the case of surfaces in $\mathbb{R}^3$ is necessary to clean T , but it is not clear how to do this effectively. In $\mathbb{R}^2$ and $\mathbb{R}^3$, the manifold extraction step can be performed and hence the manifold reconstruction problem is solved in $\mathbb{R}^2$ and $\mathbb{R}^3$.

OPEN PROBLEMS

1. Design an algorithm that outputs manifolds approximating sampled manifold shapes in $\mathbb{R}^d$, $d \geq 4$.
2. Reconstruct shapes with guarantees.

31 COMPUTATIONAL CONVEXITY

Peter Gritzmann and Victor Klee

INTRODUCTION

The subject of Computational Convexity draws its methods from discrete mathematics and convex geometry, and many of its problems from operations research, computer science, and other applied areas. In essence, it is the study of the computational and algorithmic aspects of high-dimensional convex sets (especially polytopes), with a view to applying the knowledge gained to convex bodies that arise in other mathematical disciplines or in the mathematical modeling of problems from outside mathematics.

The name *Computational Convexity* is of recent origin, having first appeared in print in 1989. However, results that retrospectively belong to this area go back a long way. In particular, many of the basic ideas of *Linear Programming* have an essentially geometric character and fit very well into the conception of Computational Convexity. The same is true of the subject of *Polyhedral Combinatorics* and of the *Algorithmic Theory of Polytopes and Convex Bodies*.

The emphasis in Computational Convexity is on problems whose underlying structure is the convex geometry of normed vector spaces of finite but generally *not* restricted dimension, rather than of fixed dimension. This leads to closer connections with the optimization problems that arise in a wide variety of disciplines. Further, in the study of Computational Convexity, the underlying model of computation is mainly the binary (Turing machine) model that is common in studies of computational complexity. This requirement is imposed by prospective applications, particularly in mathematical programming. For the study of algorithmic aspects of convex bodies that are not polytopes, the binary model is often augmented by additional devices called “oracles.” Some cases of interest involve other models of computation, but the present discussion focuses on aspects of computational convexity for which binary models seem most natural. Many of the results stated in this chapter are qualitative, in the sense that they classify certain problems as being solvable in polynomial time, or show that certain problems are NP-hard or harder. The tasks remain to find optimal exact algorithms for the problems that are polynomially solvable, and to find useful approximation algorithms or heuristics for those that are NP-hard. In most cases, the known algorithms, even when they run in polynomial time, appear to be far from optimal from the viewpoint of practical application. Hence, the qualitative complexity results should in many cases be regarded as a guide to future efforts but not as final words on the problems with which they deal.

Some of the important areas of computational convexity, such as linear and convex programming, polyhedral combinatorics, packing and covering, and pattern recognition, are covered in other chapters of this Handbook. Hence, after some remarks on presentations of polytopes in Section 31.1, the present discussion concentrates on areas that are not covered elsewhere in the Handbook. The

following sections are closely related to classical convex geometry: 31.2, Algorithmic Theory of Convex Bodies; 31.3, Volume Computations; 31.4, Mixed Volumes; 31.5, Containment Problems; 31.6, Radii. (Other such areas are geometric tomography [Gar95, GG94], discrete tomography [GG97], and the computational aspects of the following topics: projections of polytopes [Fil90, BGK96], sections of polytopes [Fil92], Minkowski addition of polytopes [GS93], and the Minkowski reconstruction of polytopes [GH99].) The final section, 31.7, Interval Matrices and Qualitative Matrices, is included as an illustration of material that, though not related to classical convex geometry, nevertheless falls under the general conception of computational convexity.

Because of the diversity of topics covered in this chapter, each section has a separate bibliography.

31.1 PRESENTATIONS OF POLYTOPES

A convex polytope $P \subset \mathbb{R}^n$ can be represented in terms of its vertices or in terms of its facet inequalities. From a theoretical viewpoint, the two possibilities are equivalent. However, as the dimension increases, the number of vertices can grow exponentially in terms of the number of facets, and vice versa, so that different presentations may lead to different classifications concerning polynomial-time computability or NP-hardness. (See [Sections 16.1, 17.3, and 22.3](#) of this Handbook.)

For algorithmic purposes it is usually not the polytope P as a *geometric* object that is relevant, but rather its *algebraic presentation*. The discussion here is based mainly on the *binary* or *Turing machine* model of computation, in which the *size of the input* is defined as the length of the binary encoding needed to present the input data to a Turing machine and the *time-complexity* of an algorithm is also defined in terms of the operations of a Turing machine. Hence the algebraic presentation of the objects at hand must be finite.

Among important special classes of polytopes, the zonotopes are particularly interesting because they can be so compactly presented.

GLOSSARY

Convex body in $\mathbb{R}^n$: A compact convex subset of $\mathbb{R}^n$.

$\mathcal{K}^n$: The family of all convex bodies in $\mathbb{R}^n$.

Proper convex body in $\mathbb{R}^n$: A convex body in $\mathbb{R}^n$ with nonempty interior.

Polytope: A convex body that has only finitely many extreme points.

$\mathcal{P}^n$: The family of all convex polytopes in $\mathbb{R}^n$.

n -polytope: Polytope of dimension n .

Face of a polytope P : P itself, the empty set, or the intersection of P with some supporting hyperplane; $f_i(P)$ is the number of i -dimensional faces of P .

Facet of an n -polytope P : Face of dimension $n - 1$.

Simple n -polytope: Each vertex is incident to precisely n edges or, equivalently, to precisely n facets.

Simplicial polytope: A polytope in which each facet is a simplex.

$\mathcal{V}$ -presentation of a polytope P : A string $(n, m; v_1, \dots, v_m)$, where $n, m \in \mathbb{N}$ and $v_1, \dots, v_m \in \mathbb{R}^n$ such that $P = \text{conv}\{v_1, \dots, v_m\}$.

$\mathcal{H}$ -presentation of a polytope P : A string $(n, m; A, b)$, where $n, m \in \mathbb{N}$, A is a real $m \times n$ matrix, and $b \in \mathbb{R}^m$ such that $P = \{x \in \mathbb{R}^n \mid Ax \leq b\}$.

$\mathcal{V}$ -polytope P : A string $(n, m; v_1, \dots, v_m)$, where $n, m \in \mathbb{N}$ and $v_1, \dots, v_m \in \mathbb{Q}^n$.
 P is usually identified with the geometric object $\text{conv}\{v_1, \dots, v_m\}$.

$\mathcal{H}$ -polytope P : A string $(n, m; A, b)$, where $n, m \in \mathbb{N}$, A is a rational $m \times n$ matrix, $b \in \mathbb{Q}^m$, and the set $\{x \in \mathbb{R}^n \mid Ax \leq b\}$ is bounded. P is usually identified with this set.

Size of a $\mathcal{V}$ - or an $\mathcal{H}$ -polytope P : Number of binary digits needed to encode the string $(n, m; v_1, \dots, v_m)$ or $(n, m; A, b)$, respectively.

Zonotope: The vector sum (Minkowski sum) of a finite number of line segments; equivalently, a polytope of which each face has a center of symmetry.

$\mathcal{S}$ -presentation of a zonotope Z in $\mathbb{R}^n$: A string $(n, m; c; z_1, \dots, z_m)$, where $n, m \in \mathbb{N}$ and $c, z_1, \dots, z_m \in \mathbb{R}^n$, such that $Z = c + \sum_{i=1}^m [-1, 1]z_i$.

Parallelotope in $\mathbb{R}^n$: A zonotope $Z = c + \sum_{i=1}^m [-1, 1]z_i$, with $z_1, \dots, z_m$ linearly independent.

$\mathcal{S}$ -zonotope Z in $\mathbb{R}^n$: A string $(n, m; c; z_1, \dots, z_m)$, where $n, m \in \mathbb{N}$ and $c, z_1, \dots, z_m \in \mathbb{Q}^n$. Z is usually identified with the geometric object $c + \sum_{i=1}^m [-1, 1]z_i$.

31.1.1 CONVERSION OF ONE PRESENTATION INTO THE OTHER

The following results indicate the difficulties that may be expected in converting the $\mathcal{H}$ -presentation of a polytope into a $\mathcal{V}$ -presentation or vice versa.

For $\mathcal{H}$ -presented n -polytopes with m facets, the *maximum* possible number of vertices is

$$\mu(m, n) = \binom{m - \lfloor (n+1)/2 \rfloor}{m-n} + \binom{m - \lfloor (n+2)/2 \rfloor}{m-n},$$

and this is also the maximum possible number of facets for a $\mathcal{V}$ -presented n -polytope with m vertices. The first maximum is attained within the family of simple n -polytopes, the second within the family of simplicial n -polytopes.

When n is fixed, the number of vertices is bounded by a polynomial in the number of facets, and vice versa, and it is possible to pass from either sort of presentation to the other in polynomial time. However, the degree of the polynomial goes to infinity with n . A consequence of this is that when the dimension n is permitted to vary in a problem concerning polytopes, the manner of presentation is often influential in determining whether the problem can be solved in polynomial time or is NP-hard. For the case of variable dimension, it is #P-hard even to determine the number of facets of a given $\mathcal{V}$ -polytope, or to determine the number of vertices of a given $\mathcal{H}$ -polytope.

For *simple* $\mathcal{H}$ -presented n -polytopes with m facets, the *minimum* possible number of vertices is $(m-n)(n-1) + 2$. The large gap between this number and the above sum of binomial coefficients makes it clear that, from a practical standpoint, the worst-case behavior of any conversion algorithm should be measured in terms of *both* input size and output size.

The maximum number of j -dimensional faces of an n -dimensional zonotope formed as the sum of m segments is

$$2 \binom{m}{j} \sum_{k=0}^{n-1-j} \binom{m-1-j}{k},$$

and hence, the number of vertices or of facets (or of faces of any dimension) of an $\mathcal{S}$ -zonotope is not bounded by any polynomial in the size of the $\mathcal{S}$ -presentation.

We end this section by mentioning two other ways of presenting polytopes.

A result of Bröcker and Scheiderer (see [BCR98]) implies that for each n -polytope P in $\mathbb{R}^n$ (no matter how complicated its facial structure may be), there exists a system of $n(n+1)/2$ polynomial inequalities that has P as its solution-set, and that n polynomial inequalities suffice to describe the interior of P . However, it is in general unknown whether one can *efficiently* produce such small polynomial presentations from the linear inequalities defining the facets of P .

For a polytope P in $\mathbb{R}^n$ whose interior is known to contain the origin, [GKW95] shows that the entire face-lattice of P can be reconstructed with the aid of at most

$$f_0(P) + (n-1)f_{n-1}^2(P) + (5n-4)f_{n-1}(P)$$

queries to the *ray-oracle* of P . In each such query, one specifies a ray issuing from the origin and the oracle is required to tell where the ray hits the boundary of P . Related results were obtained in [DEY90]

For more on oracles, see [Section 31.2](#) of this Handbook.

31.2 ALGORITHMIC THEORY OF CONVEX BODIES

Polytopes may be $\mathcal{V}$ -presented or $\mathcal{H}$ -presented. However, a different approach is required to deal with convex bodies K that are not polytopes, since an enumeration of all the extreme points of K or of its polar is not possible. A convenient way to deal with the general situation is to assume that the convex body in question is given by an algorithm (called an *oracle*) that answers certain sorts of questions about the body. A small amount of a priori information about the body may be known, but aside from this, all information about the specific convex body must be obtained from the oracle, which functions as a “black box.” In other words, while it is assumed that the oracle’s answers are always correct, nothing is assumed about the manner in which it produces those answers. The algorithmic theory of convex bodies was developed in [GLS88] with a view to proper (i.e., n -dimensional) convex bodies in $\mathbb{R}^n$. For many purposes, provisions can be made to deal meaningfully with improper bodies as well, but that aspect is largely ignored in what follows.

GLOSSARY

Outer parallel body of a convex body K : $K(\epsilon) = K + \epsilon B^n$, where B^n is the Euclidean unit ball in $\mathbb{R}^n$.

Inner parallel body of a convex body K : $K(-\epsilon) = K \setminus ((\mathbb{R}^n \setminus K) + \epsilon B^n)$.

Weak membership problem for a convex body K in $\mathbb{R}^n$: Given $y \in \mathbb{Q}^n$, and a rational number $\epsilon > 0$, conclude with one of the following: *assert that* $y \in K(\epsilon)$; or *assert that* $y \notin K(-\epsilon)$.

Weak separation problem for a convex body K in $\mathbb{R}^n$: Given a vector $y \in \mathbb{Q}^n$, and a rational number $\epsilon > 0$, conclude with one of the following: *assert that* $y \in K(\epsilon)$; or *find a vector* $z \in \mathbb{Q}^n$ *such that* $\|z\|_\infty = 1$ *and* $z^T x < z^T y + \epsilon$ *for every* $x \in K(-\epsilon)$.

Weak (linear) optimization problem for a convex body K in $\mathbb{R}^n$: Given a vector $c \in \mathbb{Q}^n$ and a rational number $\epsilon > 0$, conclude with one of the following: *find a vector* $y \in \mathbb{Q}^n \cap K(\epsilon)$ *such that* $c^T x \leq c^T y + \epsilon$ *for every* $x \in K(-\epsilon)$; or *assert that* $K(-\epsilon) = \emptyset$.

Circumscribed convex body K : A positive rational number R is given explicitly such that $K \subset RB^n$.

Well-bounded convex body K : Positive rational numbers r, R are given explicitly such that $K \subset RB^n$ and K contains a ball of radius r .

Centered well-bounded convex body K : Positive rational numbers r, R and a vector $b \in \mathbb{Q}^n$ are given explicitly such that $b + rB^n \subset K$ and $K \subset RB^n$.

Weak membership oracle for a convex body K : Algorithm that solves the weak membership problem for K .

Weak separation oracle for K : Algorithm that solves the weak separation problem for K .

Weak (linear) optimization oracle for K : Algorithm that solves the weak (linear) optimization problem for K .

The three problems above are very closely related in the sense that when the classes of proper convex bodies are appropriately restricted to those that are circumscribed, well-bounded, or centered, and when input sizes are properly defined, an algorithm that solves any one of the problems in polynomial time can be used as a subroutine to solve the others in polynomial time also. The definition of input size involves the size of ϵ , the dimension of K , the given a priori information ($size(r)$, $size(R)$, and/or $size(b)$), and the input required by the oracle. The following theorem of [GLS88] contains a list of the precise relationships among the three basic oracles for proper convex bodies. The notation “ $(\mathcal{A}; prop) \rightarrow_{\pi} \mathcal{B}$ ” indicates the existence of an (oracle-) polynomial-time algorithm that solves problem $\mathcal{B}$ for every proper convex body that is given by the oracle $\mathcal{A}$ and has all the properties specified in $prop$. ($prop = \emptyset$ means that the statement holds for general proper convex bodies.)

(WEAK MEMBERSHIP; centered, well-bounded) $\rightarrow_{\pi}$ WEAK SEPARATION;
 (WEAK MEMBERSHIP; centered, well-bounded) $\rightarrow_{\pi}$ WEAK OPTIMIZATION;
 (WEAK SEPARATION; $\emptyset$) $\rightarrow_{\pi}$ WEAK MEMBERSHIP;
 (WEAK SEPARATION; circumscribed) $\rightarrow_{\pi}$ WEAK OPTIMIZATION;
 (WEAK OPTIMIZATION; $\emptyset$) $\rightarrow_{\pi}$ WEAK MEMBERSHIP;
 (WEAK OPTIMIZATION; $\emptyset$) $\rightarrow_{\pi}$ WEAK SEPARATION.

It should be emphasized that there are polynomial-time algorithms that, accepting as input a set P that is a proper $\mathcal{V}$ -polytope, a proper $\mathcal{H}$ -polytope, or a proper $\mathcal{S}$ -zonotope, produce membership, separation, and optimization oracles for P , and also compute a lower bound on the inradius of P , an upper bound on its circumradius, and a “center” b_P for P . This implies that if an algorithm performs certain tasks for convex bodies given by some of the above (appropriately specified) oracles, then the same algorithm can also serve as a basis for procedures that perform these tasks for $\mathcal{V}$ - or $\mathcal{H}$ -polytopes and for $\mathcal{S}$ -zonotopes. Hence the oracular framework, in addition to being applicable to convex bodies that are not polytopes, serves also to modularize the approach to algorithmic aspects of polytopes. On the other hand, there are lower bounds on the performance of approximate algorithms for the oracle model that do not carry over to the case of $\mathcal{V}$ - or $\mathcal{H}$ -polytopes or $\mathcal{S}$ -zonotopes [BF87, BGK⁺03].

31.3 VOLUME COMPUTATIONS

It may be fair to say that the modern study of volume computations began with Kepler [Kep15] who derived the first *cupature formula* for measuring the capacities of wine barrels, and that it was the task of volume computation that motivated the general field of integration. The problem of computing or approximating volumes of convex bodies is certainly one of the basic problems in mathematics.

GLOSSARY

In the following, G is a subgroup of the group of all affine automorphisms of $\mathbb{R}^n$.

Dissection of an n -polytope P into n -polytopes $P_1, \dots, P_k$: $P = P_1 \cup \dots \cup P_k$, where the polytopes P_i have pairwise disjoint interiors.

Polytopes $P, Q \subset \mathbb{R}^n$ are **G -equidissectable**: For some k there exist dissections $P_1, \dots, P_k$ of P and $Q_1, \dots, Q_k$ of Q , and elements $g_1, \dots, g_k$ of G , such that $P_i = g_i(Q_i)$ for all i .

Polytopes $P, Q \subset \mathbb{R}^n$ are **G -equicomplementable**: There are polytopes P_1, P_2 and Q_1, Q_2 such that P_2 is dissected into P and P_1 , Q_2 is dissected into Q and Q_1 , P_1 and Q_1 are G -equidissectable, and P_2 and Q_2 are G -equidissectable.

Decomposition of a set S : $S = S_1 \cup \dots \cup S_k$, where the sets S_i are pairwise disjoint.

Sets S, T are **G -equidecomposable**: For some k there are decompositions $S_1, \dots, S_k$ of S and $T_1, \dots, T_k$ of T , and elements $g_1, \dots, g_k$ of G , such that $S_i = g_i(T_i)$ for all i .

Valuation on a family $\mathcal{S}$ of subsets of $\mathbb{R}^n$: A functional $\varphi : \mathcal{S} \rightarrow \mathbb{R}$ with the property that $\varphi(S_1) + \varphi(S_2) = \varphi(S_1 \cup S_2) + \varphi(S_1 \cap S_2)$ whenever the sets $S_1, S_2, S_1 \cup S_2, S_1 \cap S_2 \in \mathcal{S}$.

G -invariant valuation φ : $\varphi(S) = \varphi(g(S))$ for all $S \in \mathcal{S}$ and $g \in G$.

Simple valuation φ : $\varphi(S) = 0$ whenever $S \in \mathcal{S}$ and S is contained in a hyperplane.

Monotone valuation φ : $\varphi(S_1) \leq \varphi(S_2)$ whenever $S_1, S_2 \in \mathcal{S}$ with $S_1 \subset S_2$.

Class $\mathcal{P}$ of $\mathcal{H}$ -polytopes is **near-simplicial**: There is a nonnegative integer σ such that $\mathcal{P} = \bigcup_{n \in \mathbb{N}} \mathcal{P}_{\mathcal{H}}(n, \sigma)$, where $\mathcal{P}_{\mathcal{H}}(n, \sigma)$ is the family of all n -dimensional $\mathcal{H}$ -polytopes P in $\mathbb{R}^n$ such that each facet of P has at most $n + 1 + \sigma$ vertices.

Class $\mathcal{P}$ of $\mathcal{V}$ -polytopes is **near-simple**: There is a nonnegative integer τ such that $\mathcal{P} = \bigcup_{n \in \mathbb{N}} \mathcal{P}_{\mathcal{V}}(n, \tau)$, where $\mathcal{P}_{\mathcal{V}}(n, \tau)$ is the family of all n -dimensional $\mathcal{V}$ -polytopes P in $\mathbb{R}^n$ such that each vertex of P is incident to at most $n + \tau$ edges.

Class $\mathcal{P}$ of $\mathcal{S}$ -zonotopes is **near-parallelotopal**: There is a nonnegative integer ζ such that $\mathcal{Z} = \bigcup_{n \in \mathbb{N}} \mathcal{Z}_{\mathcal{S}}(n, \zeta)$, where $\mathcal{Z}_{\mathcal{S}}(n, \zeta)$ is the family of all $\mathcal{S}$ -zonotopes in $\mathbb{R}^n$ that are represented as the sum of at most $n + \zeta$ segments.

V: The functional that associates with a convex body K its volume.

$\mathcal{H}$ -VOLUME: For a given $\mathcal{H}$ -polytope P and a nonnegative rational ν , decide whether $V(P) \leq \nu$.

$\mathcal{V}$ -VOLUME, $\mathcal{S}$ -VOLUME: Similarly for $\mathcal{V}$ -polytopes and $\mathcal{S}$ -zonotopes.

λ -APPROXIMATION for some functional ρ : Given a positive integer n and a well-bounded convex body K given by a weak separation oracle, determine a positive rational μ such that

$$\frac{\rho(K)}{\mu} \leq 1 + \lambda \quad \text{and} \quad \frac{\mu}{\rho(K)} \leq 1 + \lambda.$$

EXPECTED VOLUME COMPUTATION: Given a positive integer n , a centered well-bounded convex body K in $\mathbb{R}^n$ given by a weak membership oracle, and positive rationals β and ϵ . Determine a positive rational random variable μ such that

$$\text{prob} \left\{ \left| \frac{\mu}{V(K)} - 1 \right| \leq \epsilon \right\} \geq 1 - \beta.$$

31.3.1 CLASSICAL BACKGROUND, CHARACTERIZATIONS

The results in this subsection connect the subject matter of volume computation with related “classical” problems. In the following, G is a group of affine automorphisms of $\mathbb{R}^n$, as above, and D is the group of isometries.

- (i) Two polytopes are G -equidissectable if and only if they are G -equicomplementable.
- (ii) Two polytopes P and Q are G -equidissectable if and only if $\varphi(P) = \varphi(Q)$ for all G -invariant simple valuations on $\mathcal{P}^n$.
- (iii) Two plane polygons are of equal area if and only if they are D -equidissectable.
- (iv) If one agrees that an a -by- b rectangle should have area ab , and also agrees that the area function should be a D -invariant simple valuation, it then follows from the preceding result that the area of any plane polygon P can be determined (at least in theory) by finding a rectangle R to which P is equidissectable. This provides a satisfyingly geometric theory of area that does not require any limiting considerations. The third problem of Hilbert [Hil00] asked, in effect, whether such a result extends to 3-polytopes. A negative answer was supplied by [Deh00], who showed that a regular tetrahedron and a cube of the same volume are not D -equidissectable.

- (v) If P and Q are n -polytopes in $\mathbb{R}^n$, then for P and Q to be equidissectable under the group of all isometries of $\mathbb{R}^n$, it is necessary that $f^*(P) = f^*(Q)$ for each additive real function f such that $f(\pi) = 0$, where $f^*(P)$ is the so-called *Dehn invariant* of P associated with f . The condition is also sufficient for equidissectability when $n \leq 4$, but the matter of sufficiency is unsettled for $n \geq 5$.
- (vi) Two plane polygons are of equal area if and only if they are D -equidecomposable.
- (vii) In [Lac90], it was proved that any two plane polygons of equal area are equidecomposable under the group of translations. That paper also settled Tarski's old problem of "squaring the circle" by showing that a square and a circular disk of equal area are equidecomposable; there too, translations suffice. On the other hand, a disk and a square cannot be *scissors congruent*, i.e., there is no equidissection (with respect to rigid motions) into pieces that, roughly speaking, could be cut out with a pair of scissors.
- (viii) If X and Y are bounded subsets of $\mathbb{R}^n$ (with $n \geq 3$), and each set has nonempty interior, then X and Y are D -equidecomposable. This is the famous ***Banach-Tarski paradox***.
- (ix) Under the group of all volume-preserving affinities of $\mathbb{R}^n$, two n -polytopes are equidissectable if and only if they are of equal volume.
- (x) If φ is a translation-invariant, nonnegative, simple valuation on $\mathcal{P}^n$ (resp. $\mathcal{K}^n$), then there exists a nonnegative real α such that $\varphi = \alpha V$.
- (xi) A translation-invariant valuation on $\mathcal{P}^n$ that is homogeneous of degree n is a constant multiple of the volume.
- (xii) A continuous, rigid-motion-invariant, simple valuation on $\mathcal{K}^n$ is a constant multiple of the volume.
- (xiii) A nonnegative simple valuation on $\mathcal{P}^n$ (resp. $\mathcal{K}^n$) that is invariant under all volume-preserving linear maps of $\mathbb{R}^n$ is a constant multiple of the volume.

31.3.2 SOME VOLUME FORMULAS

Since simplex volumes can be computed so easily, the most natural approach to the problem of computing the volume of a polytope P is to produce a *triangulation* of P (see [Chapter 17](#)). Then compute the volumes of the individual simplices and add them up to find the volume of P . (This uses the fact that the volume is a simple valuation.) As a simple consequence, one sees that when the dimension n is fixed, the volume of $\mathcal{V}$ -polytopes and of $\mathcal{H}$ -polytopes can be computed in polynomial time.

Another equally natural method is to dissect P into pyramids with common apex over its facets. Since the volume of such a pyramid is just $1/n$ times the product of its height and the $(n-1)$ -volume of its base, the volume can be computed recursively.

Another approach that has become a standard tool for many algorithmic questions in geometry is the *sweep-plane* technique. The general idea is to "sweep" a hyperplane through a polytope P , keeping track of the changes that occur when the

hyperplane sweeps through a vertex. As applied to volume computation, this leads to the volume formula given below that does not explicitly involve triangulations, [BN83, Law91].

Suppose that $(n, m; A, b)$ is an irredundant $\mathcal{H}$ -presentation of a simple polytope P (see Section 19.2). Let $b = (\beta_1, \dots, \beta_m)^T$ and denote the row-vectors of A by $a_1^T, \dots, a_m^T$. Let $M = \{1, \dots, m\}$ and for each nonempty subset I of M , let A_I denote the submatrix of A formed by rows with indices in I and let b_I denote the corresponding right-hand side. Let $\mathcal{F}_0(P)$ denote the set of all vertices of the polytope $P = \{x \in \mathbb{R}^n \mid Ax \leq b\}$. For each $v \in \mathcal{F}_0(P)$, there is a set $I = I_v \subset M$ of cardinality n such that $A_I v = b_I$ and $A_{M \setminus I} v \leq b_{M \setminus I}$. Since P is assumed to be simple and its $\mathcal{H}$ -presentation to be irredundant, the set I_v is unique.

Let $c \in \mathbb{R}^n$ be such that $\langle c, v_1 \rangle \neq \langle c, v_2 \rangle$ for any pair of vertices v_1, v_2 that form an edge of P . Then it turns out that

$$V(P) = \frac{1}{n!} \sum_{v \in \mathcal{F}_0(P)} \frac{\langle c, v \rangle^n}{\prod_{i=1}^n e_i^T A_{I_v}^{-1} c |\det(A_{I_v})|}.$$

The ingredients of this volume formula are those that are computed in the (dual) simplex algorithm. More precisely, $\langle c, v \rangle$ is just the value of the objective function at the current basic feasible solution v , $\det(A_{I_v})$ is the determinant of the current basis, and $A_{I_v}^{-1} c$ is the vector of reduced costs, i.e., the (generally infeasible) dual point that belongs to v .

For practical computations, this volume formula has to be combined with some vertex enumeration technique. Its closeness to the simplex algorithm suggests the use of a *reverse search* method [AF92], which is based on the simplex method with Bland's pivoting rule.

As it stands, the volume formula does not involve triangulation. However, when interpreted in a polar setting, it is seen to involve the faces of the simplicial polytope P° that is the polar of P . Accordingly, generalization to nonsimple polytopes involves polar triangulation. In fact, for general polytopes P , one may apply a “lexicographic rule” for moving from one basis to another, but this amounts to a particular triangulation of P° .

Another possibility for computing the volume of a polytope P is to study the *exponential integral* $\int_P e^{\langle c, x \rangle} dx$, where c is an arbitrary vector of $\mathbb{R}^n$; see [Bar93]. (Note that for $c = 0$, this integral just gives the volume of P .) Exponential integrals satisfy certain relations that make it possible to compute the integrals efficiently in some important cases. In particular, exponential sums can be used to obtain the tractability result for near-simple $\mathcal{V}$ -polytopes stated in the next subsection.

31.3.3 TRACTABILITY RESULTS

The volume of a polytope P can be computed in polynomial time in the following cases:

- (i) when the dimension is fixed and P is a $\mathcal{V}$ -polytope, an $\mathcal{H}$ -polytope, or an $\mathcal{S}$ -zonotope;
- (ii) when the dimension is part of the input and P is a near-simple $\mathcal{V}$ -polytope, a near-simplicial $\mathcal{H}$ -polytope, or a near-parallelotopal $\mathcal{S}$ -zonotope.

31.3.4 INTRACTABILITY RESULTS

- (i) There is no polynomial-space algorithm for exact computation of the volume of $\mathcal{H}$ -polytopes.
 - (ii) $\mathcal{H}$ -VOLUME is $\#P$ -hard even for the intersections of the unit cube with one rational halfspace.
 - (iii) $\mathcal{H}$ -VOLUME is $\#P$ -hard in the strong sense. (This follows from the result of [BW92] that the problem of computing the number of linear extensions of a given partially ordered set $\mathcal{O} = (\{1, \dots, n\}, \prec)$ is $\#P$ -complete, in conjunction with the fact that this number is equal to $n!V(P_{\mathcal{O}})$, where the set $P_{\mathcal{O}} = \{x = (\xi_1, \dots, \xi_n)^T \in [0, 1]^n \mid \xi_i \leq \xi_j \iff i \prec j\}$ is the *order polytope* of $\mathcal{O}$ [Sta86].)
 - (iv) The problem of computing the volume of the convex hull of the regular $\mathcal{V}$ -cross-polytope and an additional integer vector is $\#P$ -hard.
 - (v) $\mathcal{S}$ -VOLUME is $\#P$ -hard.
-

31.3.5 DETERMINISTIC APPROXIMATION

- (i) There exists an oracle-polynomial-time algorithm that, for any convex body K of $\mathbb{R}^n$ given by a weak optimization oracle, and for each $\epsilon > 0$, finds rationals μ_1 and μ_2 such that

$$\mu_1 \leq V(K) \leq \mu_2 \quad \text{and} \quad \mu_2 \leq n!(1 + \epsilon)^n \mu_1.$$

- (ii) Suppose that

$$\lambda(n) < \left(\frac{n}{\log n} \right)^{n/2} - 1 \quad \text{for all } n \in \mathbb{N}.$$

Then there exists no deterministic oracle-polynomial-time algorithm for λ -APPROXIMATION of the volume [BF87].

31.3.6 RANDOMIZED ALGORITHMS

[DFK89] proved that there is a randomized algorithm for EXPECTED VOLUME COMPUTATION that runs in time that is oracle-polynomial in n , $1/\epsilon$, and $\log(1/\beta)$.

The first step is a rounding procedure, using an algorithmic version of John's theorem; see [Section 31.5.4](#). For the second step, one may therefore assume that $B^n \subset K \subset (n+1)\sqrt{n}B^n$. Now, let

$$k = \left\lceil \frac{3}{2}(n+1)\log(n+1) \right\rceil, \quad \text{and} \quad K_i = K \cap \left(1 + \frac{1}{n}\right)^i B^n \quad \text{for } i = 0, \dots, k.$$

Then it suffices to estimate each ratio $V(K_i)/V(K_{i-1})$ up to a relative error of order $\epsilon/(n \log n)$ with error probability of order $\beta/(n \log n)$.

The main step of the algorithm of [DFK89] is based on a method for sampling nearly uniformly from within certain convex bodies K_i . It superimposes a chess-board grid of small cubes (say of edge length δ) on K_i , and performs a random

walk over the set $\mathcal{C}_i$ of cubes in this grid that intersect a suitable parallel body $K_i + \alpha B^n$, where α is small. This walk is performed by moving through a facet with probability $1/f_{n-1}(C_n) = (2n)^{-1}$ if this move ends up in a cube of $\mathcal{C}_i$, and staying at the current cube if the move would lead outside of $\mathcal{C}_i$. The random walk gives a *Markov chain* that is irreducible (since the moves are connected), aperiodic, and hence ergodic. But this implies that there is a unique stationary distribution, the limit distribution of the chain, which is easily seen to be a *uniform distribution*. Thus after a sufficiently large (but polynomially bounded) number of steps, the current cube in the random walk can be used to sample nearly uniformly from $\mathcal{C}_i$. Having obtained such a uniformly sampled cube, one determines whether it belongs to $\mathcal{C}_{i-1}$ or to $\mathcal{C}_i \setminus \mathcal{C}_{i-1}$.

Now note that if ν_i is the number of cubes in $\mathcal{C}_i$, then the number $\mu_i = \nu_i / \nu_{i-1}$ is an estimate for the volume ratio $V(K_i)/V(K_{i-1})$. It is this number μ_i that can now be “randomly approximated” using the approximation constructed above of a uniform sampling over $\mathcal{C}_i$. In fact, a cube C that is reached after sufficiently many steps in the random walk will lie in $\mathcal{C}_{i-1}$ with probability approximately $1/\mu_i$; hence this probability can be approximated closely by repeated sampling.

This algorithm has been improved by various authors; [KLS98] achieved a bound where n enters only to the fifth power.

31.4 MIXED VOLUMES

The study of mixed volumes, the *Brunn-Minkowski theory*, forms the backbone of classical convexity theory. It is also useful for applications in other areas, including combinatorics and algebraic geometry. A relationship to solving systems of polynomial equations is described at the end of this section.

GLOSSARY

Mixed volume: Let $K_1, \dots, K_s$ be convex bodies in $\mathbb{R}^n$, and let $\xi_1, \dots, \xi_s$ be non-negative reals. Then the function $V(\sum_{i=1}^s \xi_i K_i)$ is a homogeneous polynomial of degree n in the variables $\xi_1, \dots, \xi_s$, and can be written in the form

$$V\left(\sum_{i=1}^s \xi_i K_i\right) = \sum_{i_1=1}^s \sum_{i_2=1}^s \cdots \sum_{i_n=1}^s \xi_{i_1} \xi_{i_2} \cdots \xi_{i_n} V(K_{i_1}, K_{i_2}, \dots, K_{i_n}),$$

where the coefficients $V(K_{i_1}, K_{i_2}, \dots, K_{i_n})$ are invariant under permutations of their argument. The coefficient $V(K_{i_1}, K_{i_2}, \dots, K_{i_n})$ is called the mixed volume of the convex bodies $K_{i_1}, K_{i_2}, \dots, K_{i_n}$.

31.4.1 MAIN RESULTS

Mixed volumes are nonnegative, monotone, multilinear, and continuous valuations.

They generalize the ordinary volume in that $V(K) = V(\overbrace{K, \dots, K}^n)$. If A is an affine transformation, then $V(A(K_1), \dots, A(K_n)) = |\det(A)|V(K_1, \dots, K_n)$.

Among the most famous inequalities in convexity theory is the **Aleksandrov-Fenchel inequality**,

$$V(K_1, K_2, K_3, \dots, K_n)^2 \geq V(K_1, K_1, K_3, \dots, K_n) V(K_2, K_2, K_3, \dots, K_n),$$

and its consequence, the **Brunn-Minkowski theorem**, which asserts that for each $\lambda \in [0, 1]$,

$$V^{\frac{1}{n}}((1 - \lambda)K_0 + \lambda K_1) \geq (1 - \lambda)V^{\frac{1}{n}}(K_0) + \lambda V^{\frac{1}{n}}(K_1).$$

OPEN PROBLEM 31.4.1

Provide a useful geometric characterization of the sequences $(K_1, \dots, K_n)$ for which equality holds in the Aleksandrov-Fenchel inequality.

31.4.2 TRACTABILITY RESULTS

When n is fixed, there is a polynomial-time algorithm whereby, given s ($\mathcal{V}$ - or $\mathcal{H}$ -) polytopes $P_1, \dots, P_s$ in $\mathbb{R}^n$, all the mixed volumes $V(P_{i_1}, \dots, P_{i_n})$ can be computed.

When the dimension is part of the input, it follows at least that mixed volume computation is not harder than volume computation. In fact, computation (for $\mathcal{V}$ -polytopes or $\mathcal{S}$ -zonotopes) or approximation (for $\mathcal{H}$ -polytopes) of any single mixed volume is $\#P$ -easy.

31.4.3 INTRACTABILITY RESULTS

Since mixed volumes generalize the ordinary volume, it is clear that mixed volume computation cannot be easier, in general, than volume computation. In addition, there are hardness results for mixed volumes that do not trivially depend on the hardness of volume computations. One such result is described next.

As the term is used here, a *box* is a rectangular parallelotope with axis-aligned edges. Since the vector sum of boxes $V(Z_1, \dots, Z_n)$ is again a box, the volume of the sum is easy to compute. Nevertheless, computation of the mixed volume $V(Z_1, \dots, Z_n)$ is hard. This is in interesting contrast to the fact that the volume of a sum of segments (a zonotope) is hard to compute even though each of the mixed volumes can be computed in polynomial time.

31.4.4 RANDOMIZED ALGORITHMS

Since the mixed volumes of convex bodies $K_1, \dots, K_s$ are coefficients of the polynomial $\varphi(\xi_1, \dots, \xi_s) = V(\sum_{i=1}^s \xi_i K_i)$, it seems natural to estimate these coefficients by combining an interpolation method with a randomized volume algorithm. However, there are significant obstacles to this approach, even for the case of two bodies. First, for a general polynomial φ there is *no* way of obtaining *relative* estimates of its coefficients from *relative* estimates of the values of φ . This can be overcome in the case of two bodies by using the special structure of the polynomial $p(x) = V(K_1 + xK_2)$. However, even then the absolute values of the entries of the “inversion” that is used to express the coefficients of the polynomial in terms of its approximate values are not bounded by a polynomial, while the randomized volume approximation algorithm is polynomial only in $\frac{1}{\tau}$ but not in $size(\tau)$.

Suppose that $\psi : \mathbb{N} \rightarrow \mathbb{N}$ is nondecreasing with

$$\psi(n) \leq n \quad \text{and} \quad \psi(n) \log \psi(n) = o(\log n).$$

Then there is a polynomial-time algorithm for the problem whose instance consists of $n, s \in \mathbb{N}$, $m_1, \dots, m_s \in \mathbb{N}$ with $m_1 + m_2 + \dots + m_s = n$ and $m_1 \geq n - \psi(n)$, of well-presented convex bodies $K_1, \dots, K_s$ of $\mathbb{R}^n$, and of positive rational numbers ϵ and β , and whose output is a random variable $\hat{V}_{m_1, \dots, m_s} \in \mathbb{Q}$ such that

$$\text{prob} \left\{ \frac{|\hat{V}_{m_1, \dots, m_s} - V_{m_1, \dots, m_s}|}{V_{m_1, \dots, m_s}} \geq \epsilon \right\} \leq \beta,$$

where

$$V_{m_1, \dots, m_s} = V(\overbrace{K_1, \dots, K_1}^{m_1}, \dots, \overbrace{K_s, \dots, K_s}^{m_s}).$$

Note that the hypotheses above require that m_1 is close to n , and hence that the remaining m_i 's are relatively small. A special feature of an interpolation method as used for the proof of this result is that in order to compute *a specific* coefficient of the polynomial under consideration, it computes essentially *all previous* coefficients. Since there can be a polynomial-time algorithm for computing *all such* mixed volumes only if $\psi(n) \leq \log n$, the above result is essentially best possible for any interpolation method.

In terms of approximation, [Bar97] shows that a mixed volume of n proper convex bodies can be approximated by a randomized polynomial-time algorithm within a factor of $n^{O(n)}$, while [GS02] gives a deterministic algorithm for approximating mixed volumes up to such an error.

OPEN PROBLEM 31.4.2 [DGH98]

Is there a polynomial-time randomized algorithm that, for arbitrary given $n, s \in \mathbb{N}$, $m_1, \dots, m_s \in \mathbb{N}$ with $m_1 + m_2 + \dots + m_s = n$, well-presented convex bodies $K_1, \dots, K_s$ in $\mathbb{R}^n$, and positive rationals ϵ and β , computes a random variable $\hat{V}_{m_1, \dots, m_s} \in \mathbb{Q}$ such that $\text{prob}\{|\hat{V}_{m_1, \dots, m_s} - V_{m_1, \dots, m_s}|/V_{m_1, \dots, m_s} \geq \epsilon\} \leq \beta$?

Even the case $s = n$, $m_1 = \dots = m_s = 1$ is open in general. See, however, [Bar97] for some partial results.

AN APPLICATION

Let $S_1, S_2, \dots, S_n$ be subsets of $\mathbb{Z}^n$, and consider a system $F = (f_1, \dots, f_n)$ of Laurent polynomials in n variables, such that the exponents of the monomials in f_i are in S_i for all $i = 1, \dots, n$. For $i = 1, \dots, n$, let

$$f_i(x) = \sum_{q \in S_i} c_q^{(i)} x^q,$$

where $f_i \in \mathbb{C}[x_1, x_1^{-1}, \dots, x_n, x_n^{-1}]$, and x^q is an abbreviation for the monomial $x_1^{q_1} \cdots x_n^{q_n}$; $x = (x_1, \dots, x_n)$ is the vector of indeterminates and $q = (q_1, \dots, q_n)$ the vector of exponents. Further, let $\mathbb{C}^* = \mathbb{C} \setminus \{0\}$.

Now, if the coefficients $c_q^{(i)}$ ($q \in S_i$) are chosen “generically,” then the number $L(F)$ of distinct common roots of the system F in $(\mathbb{C}^*)^n$ depends only on the **Newton polytopes** $P_i = \text{conv}(S_i)$ of the polynomials. More precisely,

$$L(F) = n! \cdot V(P_1, P_2, \dots, P_n).$$

In general, $L(F) \leq n! \cdot V(P_1, P_2, \dots, P_n)$. These connections can be utilized to develop a numerical continuation method for computing the isolated solutions of sparse polynomial systems. For this, see [Emi94, HS95, Roj94, Ver96].

31.5 CONTAINMENT PROBLEMS

Typically, containment problems involve two fixed sequences, Γ and Ω , that are given as follows: for each $n \in \mathbb{N}$, let $\mathcal{C}_n$ denote a family of closed convex subsets of $\mathbb{R}^n$, and let $\omega_n : \mathcal{C}_n \rightarrow \mathbb{R}$ be a functional that is nonnegative and is monotone with respect to inclusion. Then $\Gamma = (\mathcal{C}_n)_{n \in \mathbb{N}}$ and $\Omega = (\omega_n)_{n \in \mathbb{N}}$.

GLOSSARY

(Γ, Ω) -INBODY: Accepts as input a positive integer n , a body K in $\mathbb{R}^n$ that is given by an oracle or is an $\mathcal{H}$ -polytope, a $\mathcal{V}$ -polytope, or an $\mathcal{S}$ -zonotope, and a positive rational λ . It answers the question of whether there is a $C \in \mathcal{C}_n$ such that $C \subset K$ and $\omega_n(C) \geq \lambda$.

(Γ, Ω) -CIRCUMBODY is defined similarly for $C \supset K$.

j -simplex S **bound to a polytope** P : Each vertex of S is a vertex of P .

Largest j -simplex in a given polytope: One of maximum j -measure.

31.5.1 THE GENERAL CONTAINMENT PROBLEM

The general containment problem deals with the question of computing, approximating, or measuring extremal bodies of a given class that are contained in or contain a given convex body. Since [GK94a] contains a broad survey of containment problems, the present account is confined to some selected examples.

31.5.2 OPTIMAL CONTAINMENT UNDER HOMOTHETY

The results on (Γ, Ω) -INBODY and (Γ, Ω) -CIRCUMBODY are summarized below for the case in which each $\mathcal{C}_n$ is a fixed polytope,

$$\mathcal{C}_n = \{g(C_n) \mid g \text{ is a homothety}\},$$

and

$$\omega_n(g(C_n)) = \rho, \quad \text{when } g(C_n) = a + \rho C_n \text{ for some } a \in \mathbb{R}^n \text{ and } \rho \geq 0.$$

As an abbreviation, these specific problems are denoted by $\mathcal{E}^{\text{Hom}}\text{-INBODY}$ and $\mathcal{E}^{\text{Hom}}\text{-CIRCUMBODY}$, respectively, where $\mathcal{E} = (C_n)_{n \in \mathbb{N}}$ and a subscript ($\mathcal{V}$ or $\mathcal{H}$) is used to indicate the manner in which each C_n is presented.

There are polynomial-time algorithms for the following problems:

$$\begin{array}{ll} \mathcal{E}_{\mathcal{V}}^{\text{Hom}}\text{-INBODY for } \mathcal{V}\text{-polytopes } P; & \mathcal{E}_{\mathcal{V}}^{\text{Hom}}\text{-CIRCUMBODY for } \mathcal{V}\text{-polytopes } P; \\ \mathcal{E}_{\mathcal{V}}^{\text{Hom}}\text{-INBODY for } \mathcal{H}\text{-polytopes } P; & \mathcal{E}_{\mathcal{H}}^{\text{Hom}}\text{-CIRCUMBODY for } \mathcal{V}\text{-polytopes } P; \\ \mathcal{E}_{\mathcal{H}}^{\text{Hom}}\text{-INBODY for } \mathcal{H}\text{-polytopes } P; & \mathcal{E}_{\mathcal{H}}^{\text{Hom}}\text{-CIRCUMBODY for } \mathcal{H}\text{-polytopes } P. \end{array}$$

These positive results are best possible in the sense that the cases not listed above contain instances of NP-hard problems. In fact, the problem $\mathcal{E}_{\mathcal{H}}^{\text{Hom}}\text{-INBODY}$ is coNP-complete even when C_n is the standard unit $\mathcal{H}$ -cube while P is restricted to the class of all affinely regular $\mathcal{V}$ -cross-polytopes centered at the origin. The problem $\mathcal{E}_{\mathcal{V}}^{\text{Hom}}\text{-CIRCUMBODY}$ is coNP-complete even when C_n is the standard $\mathcal{V}$ -cross-polytope while P is restricted to the class of all $\mathcal{H}$ -parallelotopes centered at the origin.

There are some results for bodies that are more general than polytopes. Suppose that for each $n \in \mathbb{N}$, C_n is a centrally symmetric body in $\mathbb{R}^n$, and that there exists a number μ_n whose size is bounded by a polynomial in n and an n -dimensional $\mathcal{S}$ -parallelotope Z that is strictly inscribed in $\mu_n C_n$ (i.e., the intersection of Z with the boundary of $\mu_n C_n$ consists of the vertex set of Z), the size of the presentation being bounded by a polynomial in n . Then with $\mathcal{E} = (C_n)_{n \in \mathbb{N}}$, (an appropriate variant of) the problem $\mathcal{E}^{\text{Hom}}\text{-CIRCUMBODY}$ is NP-hard for the classes of all centrally symmetric $(n-1)$ -dimensional $\mathcal{H}$ -polytopes in $\mathbb{R}^n$. With the aid of polarity, similar results for $\mathcal{E}^{\text{Hom}}\text{-INBODY}$ can be obtained.

31.5.3 OPTIMAL CONTAINMENT UNDER AFFINITY: SIMPLICES

This section focuses on the problem of finding a largest j -dimensional simplex in a given n -dimensional polytope, where *largest* means of maximum j -measure.

When an n -polytope P has m vertices, it contains at most $\binom{m}{j+1}$ bound j -simplices. There is always a largest j -simplex that is bound, and hence there is a finite algorithm for finding a largest j -simplex contained in P .

Each largest j -simplex in P contains at least two vertices of P . However, there are polytopes P of arbitrarily large dimension, with an arbitrarily large number of vertices, such that some of the largest n -simplices in P have only two vertices in the vertex-set of P . Hence for $j \geq 2$ it is not clear whether there is a finite algorithm for producing a useful presentation of *all* the largest j -simplices in a given n -polytope.

The problem of finding a largest j -simplex in a $\mathcal{V}$ - or $\mathcal{H}$ -polytope can be solved in polynomial time when the dimension n of the polytope is fixed. Further, for fixed j , the volumes of all j -simplices in a given $\mathcal{V}$ -polytope can be computed in polynomial time (even for varying n).

Suppose that the functions $\psi : \mathbb{N} \rightarrow \mathbb{N}$ and $\gamma : \mathbb{N} \rightarrow \mathbb{N}$ are both of order $\Omega(n^{1/k})$ for some $k \in \mathbb{N}$, and that $1 \leq \gamma(n) \leq n$ for each $n \in \mathbb{N}$. Then the following problem is NP-complete: Given $n, \lambda \in \mathbb{N}$, and the vertex set V of an n -dimensional $\mathcal{V}$ -polytope $P \subset \mathbb{R}^n$ with $|V| \leq n + \psi(n)$, and given $j = \gamma(n)$, decide whether P contains a j -simplex S such that $(j!)^2 \text{vol}(S)^2 \geq \lambda$. Note that the conditions for γ

are satisfied when $\gamma(n) = \max\{1, n - \mu\}$ for a nonnegative integer constant μ , and also when $\gamma(n) = \max\{1, \lfloor \mu n \rfloor\}$ for a fixed rational μ with $0 < \mu \leq 1$.

A similar hardness result holds for $\mathcal{H}$ -polytopes. There the question is the same, but the growth condition on the function γ is that $1 \leq \gamma(n) \leq n$ and that there exists a function $f : \mathbb{N} \rightarrow \mathbb{N}$, bounded by a polynomial in n , such that for each $n \in \mathbb{N}$, $f(n) - \gamma(f(n)) = n$. Note that such an f exists when the function γ is constant, and also when $\gamma(n) = \lfloor \mu n \rfloor$ for fixed rational μ with $0 < \mu < 1$.

The “dual” problem of finding smallest simplices containing a given polytope P seems even harder, since the relationship between a smallest such simplex and the faces of P is much weaker.

CONJECTURE 31.5.1 [GKL95]

For each function $\gamma : \mathbb{N} \rightarrow \mathbb{N}$ with $1 \leq \gamma(n) \leq n$, the problem of finding a largest j -simplex in a given n -dimensional $\mathcal{H}$ -polytope P is NP-hard, even for the case in which P is a parallelotope.

With the restriction to parallelotopes, this conjecture is still open. However, under the assumption that the function $f : \mathbb{N} \rightarrow \mathbb{N}$ is such that $f(n) = \Omega(n^{1/k})$ for some fixed $k > 0$, [Pac02] establishes the NP-hardness of four problems, for each of which an instance consists of $n \in \mathbb{N}$, a rational $\mathcal{H}$ -polytope or $\mathcal{V}$ -polytope P in $\mathbb{R}^n$, and $\lambda > 0$, and the question is one of the following: Does there exist an $f(n)$ -simplex $S \subset P$ with $V^2(S) \geq \lambda$? Does there exist an $f(n)$ -dimensional simplicial cylinder $C \subset P$ with $V^2(C) \leq \lambda$?

Some approximation results can be found in [BGK00a].

APPLICATIONS

The paper [HKL96] is in part a survey of the problem of finding largest j -simplices in an n -dimensional cube. As outlined in [GK94a], applications of this problem and its relatives include the Hadamard determinant problem, finding optimal weighing designs, and bounding the growth of pivots in Gaussian elimination with complete pivoting.

31.5.4 OPTIMAL CONTAINMENT UNDER AFFINITY: ELLIPSOIDS

For an arbitrary proper body K in $\mathbb{R}^n$, there is a unique ellipsoid E_0 of maximum volume contained in K , and it is concentric with the unique ellipsoid E of minimum volume containing K . If a is the common center, then $K \subset a + n(E_0 - a)$, where the factor n can be replaced by $\sqrt{n}$ when K is centrally symmetric. E is called the **Löwner-John ellipsoid** of K , and it plays an important role in the algorithmic theory of convex bodies.

Algorithmic approximations of the Löwner-John ellipsoid can be obtained by use of the ellipsoid method [GLS88]: There exists an oracle-polynomial-time algorithm that, for any well-bounded body K of $\mathbb{R}^n$ given by a weak separation oracle, finds a point a and a linear transformation A such that

$$a + A(B^n) \subset K \subset a + (n+1)\sqrt{n}A(B^n).$$

Further, the dilatation factor $(n+1)\sqrt{n}$ can be replaced by $\sqrt{n(n+1)}$ when K is symmetric, by $(n+1)$ when K is an $\mathcal{H}$ -polytope, and by $\sqrt{n+1}$ when K is a

symmetric $\mathcal{H}$ -polytope.

[TKE88] and [KT93] give polynomial-time algorithms for approximating the ellipsoid of maximum volume E_0 that is contained in a given $\mathcal{H}$ -polytope. For each rational $\gamma < 1$, there exists a polynomial-time algorithm that, given $n, m \in \mathbb{N}$ and $a_1, \dots, a_m \in \mathbb{Q}^n$, computes an ellipsoid $E = a + A(B^n)$ such that

$$E \subset P = \{x \in \mathbb{R}^n \mid \langle a_i, x \rangle \leq 1, \text{ for } i = 1, \dots, m\} \quad \text{and} \quad \frac{V(E)}{V(E_0)} \geq \gamma.$$

The running time of the algorithm is

$$O\left(m^{3.5} \log(mR/(r \log(1/\gamma))) \log(nR/(r \log(1/\gamma)))\right),$$

where the numbers r and R are, respectively, a lower bound on the inradius of P and an upper bound on its circumradius.

It is not known whether a similar result holds for $\mathcal{V}$ -polytopes.

As shown in [TKE88], an approximation of E_0 of the kind given above leads to the following inclusion:

$$a + A(B^n) \subset K \subset a + \frac{n(1 + 3\sqrt{1-\gamma})}{\gamma} A(B^n).$$

31.6 RADII

The diameter, width, circumradius, and inradius of a convex body are classical functionals that play an important role in convexity theory and in many applications. For other applications, generalizations have been introduced. The underlying space is a **Minkowski space** (finite-dimensional normed space) $\mathbb{M} = (\mathbb{R}^n, \|\cdot\|)$. Let B denote its unit ball, j a positive integer, and K a convex body.

GLOSSARY

Outer j -radius $R_j(K)$ of K : Infimum of the positive numbers ρ such that the space contains an $(n-j)$ -flat F for which $K \subset F + \rho B$.

j -ball of radius ρ : Set of the form $(q + \rho B) \cap F = \{x \in F \mid \|x - q\| \leq \rho\}$ for some j -flat F in $\mathbb{R}^n$ and point $q \in F$.

Inner j -radius $r_j(K)$ of K : Maximum of the radii of the j -balls contained in K .

Diameter of K : $2r_1(K)$.

Width of K : $2R_1(K)$.

Inradius of K : $r_n(K)$.

Circumradius of K : $R_n(K)$.

For the case of variable dimension (i.e., the dimension is part of the input), Tables 31.6.1, 31.6.2, and 31.6.3 provide a rapid indication of the main complexity results for the most important radii: r_1 , R_1 , r_n , and R_n ; and for the three most important ℓ_p spaces: $\mathbb{R}_2^n$, $\mathbb{R}_1^n$, and $\mathbb{R}_\infty^n$. The designations P, NPC, and NPH indicate respectively polynomial-time computability, NP-completeness, and NP-hardness. The tables provide only a rough indication of results. They are imprecise in the following respects: (i) the diameter and width are actually equal to $2r_1$ and $2R_1$ respectively; (ii) the results for $\mathbb{R}_2^n$ involve the square of the radius rather than the radius itself; (iii) some of the P entries are based on polynomial-time approximability rather than polynomial-time computability; (iv) the designations NPC and NPH do not refer to computability per se, but to the appropriately related decision problems involving the establishment of lower or upper bounds for the radii in question.

For inapproximability results in the Turing machine model see [BGK00b] and [Bri02]; for sharp bounds on the approximation error of polynomial-time algorithms in the oracle model see [BGK⁺03].

APPLICATIONS

Applications of radii include conditioning in global optimization, sensitivity analysis of linear programs, orthogonal minimax regression, computer graphics and com-

31.7 INTERVAL MATRICES, QUALITATIVE MATRICES

The mathematical modeling of practical problems often involves real matrices whose entries are not known precisely, but are known only to lie in specified bounded closed intervals or to be of specified sign. The interval case arises in many applications, while the study of the sign case was motivated by questions concerning the modeling of problems in economics. The associated complexity results and problems can be formulated in terms of systems of parallelotopes or systems of sign cones, and there have been some extensions to more general systems of convex sets. Attention is confined here to the two most-studied topics, solvability of linear algebraic systems and stability of linear dynamical systems.

GLOSSARY

- $m \times n$ system:** A sequence $\mathcal{A} = (A_1, \dots, A_n)$ of n nonempty subsets of $\mathbb{R}^m$.
- Matrices associated with an $m \times n$ system:** The set $\mathcal{M}(\mathcal{A})$ of all $m \times n$ matrices $A = [a_1, \dots, a_n]$ such that $a_j \in A_j$ for each j , where a_j denotes the j th column of A .
- L-system:** A system $\mathcal{A}$ such that for each $A \in \mathcal{M}(\mathcal{A})$, the columns of A are linearly independent.
- S-system:** A system $\mathcal{A}$ such that for each $A \in \mathcal{M}(\mathcal{A})$, the n columns of A are the vertices of an $(n-1)$ -simplex in $\mathbb{R}^m$ whose relative interior includes the origin. (Equivalently, the nullspace of A is a line in $\mathbb{R}^n$ that passes through the origin and penetrates the positive orthant of $\mathbb{R}^n$.)
- Sign cone:** A subset of $\mathbb{R}^m$ that, for some sequence of m signs $(-, 0, +)$, consists of all points of $\mathbb{R}^m$ that exhibit the specified sign pattern.
- Qualitative matrix:** An $m \times n$ matrix A in which each entry is one of the intervals $(-\infty, 0)$, $\{0\}$, and $(0, \infty)$. This may be viewed instead as an $m \times n$ system $\mathcal{A} = (A_1, \dots, A_n)$ in which each A_j is a sign cone.
- L-matrix, S-matrix:** A qualitative matrix that gives rise to an L-system or an S-system, respectively.
- Interval matrix:** An $m \times n$ matrix $A = ([\alpha_{ij}, \beta_{ij}])$ in which each entry is a bounded closed interval in $\mathbb{R}$. This may be viewed instead as an $m \times n$ system $\mathcal{A} = (A_1, \dots, A_n)$ in which each A_j is the parallelotope $[\alpha_{1j}, \beta_{1j}] \times \dots \times [\alpha_{mj}, \beta_{mj}]$.
- Nonsingularity of a system:** An $n \times n$ system $\mathcal{A}$ is nonsingular if every member of $\mathcal{M}(\mathcal{A})$ has this property.

Sign-nonsingular: When $\mathcal{A}$ is a system of sign cones, the preceding notion is called *sign-nonsingularity*. In other words, a sign-nonsingular matrix is a square matrix whose sign pattern guarantees nonsingularity.

Matrix stability: A square real matrix A is **semistable** (resp. **stable**) if each of its eigenvalues has nonnegative (resp. positive) real part. It is **quasistable** if it is semistable and, in addition, each eigenvalue with zero real part is a simple root of the minimum polynomial of A . These terms are used for an $n \times n$ system $\mathcal{A}$ when they apply to *every* $A \in \mathcal{M}(\mathcal{A})$.

Matrix sign-stability: When $\mathcal{A}$ is a system of sign cones, the preceding notion is called *sign-stability*. In other words, a **sign-stable** matrix is a square matrix whose sign pattern guarantees stability. **Sign-semistability** and **sign-quasistability** are defined similarly.

Sign-solvability: A system of linear equations, $Ax = b$, is sign-solvable if both the solvability of the system and the sign pattern of the solution x are implied by the sign patterns of A and b .

BASIC FACTS

The problem of testing a square matrix for sign-nonsingularity is polynomially equivalent to the problem of testing a digraph for the presence of a (simple) cycle that has an even number of edges. If either recognition problem admits a polynomial-time algorithm, then so does the other.

The study of sign-solvability can in a sense be decomposed into the study of L-matrices and the study of S-matrices—equivalently, into the study of L-systems and S-systems of sign cones. This result can be extended to more general $m \times n$ systems $\mathcal{A} = (A_1, \dots, A_n)$ under the assumption that each A_j has nonempty interior relative to the smallest canonical subspace of $\mathbb{R}^m$ that contains it.

For an $n \times n$ real matrix A , consider the system $x' = Ax$ of linear differential equations with constant coefficients. For each point $p_0 \in \mathbb{R}^n$, there is a unique *positive trajectory* $x : [0, \infty) \rightarrow \mathbb{R}^n$ of this system that has $x(0) = p_0$. The matrix A is stable if and only if each positive trajectory converges to the origin, is quasistable if and only if each positive trajectory is bounded, and is semistable if and only if no positive trajectory runs off to infinity at an exponential rate.

TRACTABILITY RESULTS

There is an $O(n^2)$ algorithm for deciding whether a given $n \times (n+1)$ matrix is an S-matrix. In the general case of systems of polyhedral cones presented in terms of their generators, an algorithm based on linear programming can recognize S-systems in polynomial time [KVL93].

There is a polynomial-time algorithm for deciding whether a square matrix is sign-nonsingular. This follows from independent deep studies of [McC97] and [RST99] that contain many other interesting results.

For a properly presented square matrix A , sign-stability, sign-quasistability, and sign-semistability can all be detected in time that is proportional to the number of nonzero entries of A [JKV87].

INTRACTABILITY RESULTS

Deciding whether a given rectangular sign matrix is an L-matrix is NP-hard, and this is true even when the matrix is “almost square” in a certain sense [KLM84].

Testing the nonsingularity of a symmetric square interval matrix is NP-hard, as is testing the stability of such a matrix [Roh94].

32 COMPUTATIONAL TOPOLOGY

Gert Vegter

INTRODUCTION

Topology studies point sets and their invariants under continuous deformations, invariants such as the number of connected components, holes, tunnels, or cavities. Metric properties such as the position of a point, the distance between points, or the curvature of a surface, are irrelevant to topology. A high level description of the main concepts and problems in topology is given in Section 32.1. Computational topology deals with the complexity of such problems, and with the design of efficient algorithms for their solution, in case these problems are tractable. These algorithms can deal only with spaces and maps that have a finite representation. To this end we consider simplicial complexes and maps (Section 32.2) and CW-complexes (Section 32.3). Section 32.4 deals with algebraic invariants of topological spaces, which are in general easier to compute than topological invariants. Mapping (embedding) a topological space 1–1 into another space may reveal some of its topological properties. Several types of embeddings are considered in Section 32.5. Section 32.6 deals with the classification of immersions of a space into another space. These maps are only *locally* 1–1, and hence more general than embeddings. Section 32.7 constitutes a brief introduction to Morse theory.

Many computational problems in topology are undecidable (in the sense of complexity theory). The mathematical literature of this century contains many (beautiful) topological algorithms, usually reducing to decision procedures, in many cases with exponential-time complexity. The quest for efficient algorithms for topological problems has started rather recently. Most of the problems in computational topology still await an efficient solution.

32.1 TOPOLOGICAL SPACES AND MAPS

Topology deals with the classification of spaces that are the same up to some equivalence relation. We introduce these notions, and describe some classes of topological problems.

GLOSSARY

Space: In this chapter a *topological space* (or *space*, for short) is a subset of some Euclidean space $\mathbb{R}^d$, endowed with the topology of $\mathbb{R}^d$.

Map: A function $f : X \rightarrow Y$ from a space X to a space Y is a map if f is continuous.

Homeomorphism: A 1–1 map $h : X \rightarrow Y$, with a continuous inverse, is called

a homeomorphism from X to Y (or: between X and Y).

Topological equivalence: Two spaces are topologically equivalent (or *homeomorphic*) if there is a homeomorphism between them.

Embedding: A map $f : X \rightarrow Y$ is an embedding if f is a homeomorphism onto its image. We say that X can be (topologically) embedded in Y .

Homotopy of maps: Two maps $f_0, f_1 : X \rightarrow Y$ are homotopic if there is a map $F : X \times [0, 1] \rightarrow Y$ such that $F(x, 0) = f_0(x)$ and $F(x, 1) = f_1(x)$, for all $x \in X$.

Homotopy equivalence: Two spaces X and Y are homotopy-equivalent if there are maps $f : X \rightarrow Y$ and $g : Y \rightarrow X$ such that gf and fg are homotopic to the identity mappings on X and Y , respectively. Obviously topological equivalence implies homotopy equivalence.

Topological/homotopy invariant: A map ζ associating a number, or a group, $\zeta(X)$ to a space X , is a topological invariant (resp. homotopy invariant) if $\zeta(X_1)$ and $\zeta(X_2)$ are equal, or isomorphic, for topologically equivalent (resp. homotopy-equivalent) spaces X_1 and X_2 .

Contractibility: A space is contractible if it is homotopy-equivalent to a point.

Unit interval $\mathbb{I}$: The interval $[0, 1]$ in $\mathbb{R}$.

Ball: Open d -ball: $\mathbb{B}^d = \{(x_1, \dots, x_d) \in \mathbb{R}^d \mid x_1^2 + \dots + x_d^2 < 1\}$. Closed d -ball: $\overline{\mathbb{B}}^d$ is the closure of $\mathbb{B}^d$.

Half ball: $\mathbb{B}_+^d = \{(x_1, \dots, x_d) \in \mathbb{R}^d \mid x_1^2 + \dots + x_d^2 < 1 \text{ and } x_d \geq 0\}$.

Sphere: $\mathbb{S}^d = \{(x_1, \dots, x_{d+1}) \in \mathbb{R}^{d+1} \mid x_1^2 + \dots + x_{d+1}^2 = 1\}$ is the d -sphere. It is the boundary of the $(d+1)$ -ball.

Manifold: A space X is a d -dimensional (topological) manifold (also: d -manifold) if every point of X has a neighborhood homeomorphic to $\mathbb{B}^d$. X is a d -manifold *with boundary* if every point has a neighborhood homeomorphic to $\mathbb{B}^d$ or $\mathbb{B}_+^d$.

Surface: A 2-dimensional manifold, with or without boundary. A *closed surface* is a surface without boundary.

Curve: A curve in X is a continuous map $\mathbb{I} \rightarrow X$. For $x_0 \in X$, a x_0 -based *closed curve* c is a curve for which $c(0) = c(1) = x_0$.

BASIC TOPOLOGICAL PROBLEMS AND APPLICATIONS

Topological equivalence and classification: Decide whether a space belongs to (is topologically equivalent to an element of) a class of known objects.

Application: Object recognition in computer vision.

Homotopy equivalence: Decide whether two spaces are homotopy-equivalent, or whether a curve in X is contractible (the *contractibility problem*).

Applications: α -hull, skeletons; see [Ede94]. Concurrent computing; see [HS94a].

Embedding: Decide whether X can be embedded in Y . If so, construct an embedding.

Application: Graph drawing (Chapter 52), VLSI-layout, and wire routing.

Extension of maps: Let A be a subspace of X . Decide whether a map $f : A \rightarrow Y$ can be extended to X (i.e., whether there is a map $F : X \rightarrow Y$ whose restriction to A is f).

Lifting of maps: Let $f : A \rightarrow X$ and $p : Y \rightarrow X$ be maps. Decide whether there is a map $F : A \rightarrow Y$ such that $pF = f$.

Application: Inverse kinematics problems and tracking algorithms in robotics; see [Bak90] and [Section 48.1](#).

32.2 SIMPLICIAL COMPLEXES

Computation requires finite representation of topological spaces. Representing a space by a simplicial complex corresponds to the idea of building the space from simplices. Simplicial complexes may be considered as combinatorial objects, with a straightforward data structure for their representation. See also [Section 18.1](#).

GLOSSARY

Geometric simplex: A geometric k -simplex σ_k is the convex hull of a set A of $k + 1$ independent points $a_0, \dots, a_k$ in some Euclidean space $\mathbb{R}^d$ (so $d \geq k$). A is said to **span** the simplex σ_k . A simplex spanned by a subset A' of A is called a **face** of σ_k . The face is proper if $\emptyset \neq A' \neq A$. The **dimension** of the face is $|A'| - 1$. A 0-dimensional face is called a **vertex**, a 1-dimensional face is called an **edge**. The union σ_k^i , $0 \leq i \leq k$, of all faces of dimension at most i is called the **i -skeleton** of σ_k . In particular σ_k^0 is the set of vertices, and $\sigma_k^k = \sigma_k$. An **orientation** of σ_k is induced by an ordering of its vertices, denoted by $\langle a_0, \dots, a_k \rangle$, as follows: For any permutation π of $0, \dots, k$, the orientation $\langle a_{\pi(0)}, \dots, a_{\pi(k)} \rangle$ is equal to $(-1)^{\text{sign}(\pi)} \langle a_0, \dots, a_k \rangle$, where $\text{sign}(\pi)$ is the number of transpositions of π (so any simplex has two distinct orientations). If τ is a $(k-1)$ -dimensional face of σ , obtained by omitting the vertex a_i , then the **induced orientation** on τ is $(-1)^i \langle a_0, \dots, \hat{a}_i, \dots, a_k \rangle$, where the hat indicates omission of a_i .

Geometric simplicial complex K : A finite set of simplices in some Euclidean space $\mathbb{R}^m$, such that (i) if σ is a simplex of K and τ is a face of σ , then τ is a simplex of K , and (ii) if σ and τ are simplices of K , then $\sigma \cap \tau$ is either empty or a common face of σ and τ . The **dimension** of K is the maximum of the dimensions of its simplices. The **underlying space** of K , denoted by $|K|$, is the union of all simplices of K , endowed with the subspace topology of $\mathbb{R}^m$. The **i -skeleton** of K , denoted by K^i , is the union of all simplices of K of dimension at most i . A **subcomplex** L of K is a subset of K that is a simplicial complex.

Combinatorial simplicial complex: A pair $\mathcal{K} = (V, \Sigma)$, where V contains finitely many elements, called vertices, and Σ is a collection of subsets of V , called (combinatorial) simplices, with the property that any subset of a simplex is a simplex. The dimension of a simplex is one less than the number of vertices it contains. The dimension of $\mathcal{K}$ is the maximum of the dimensions of its simplices.

Geometric realization: A geometric simplicial complex K in $\mathbb{R}^m$ is called a geometric realization (in $\mathbb{R}^m$) of the combinatorial simplicial complex $\mathcal{K} = (V, \Sigma)$ if there is a 1-1 correspondence $f : V \rightarrow K^0$, such that $A \subset V$ is a simplex of $\mathcal{K}$ iff $f(A)$ spans a simplex of K . Furthermore $\mathcal{K}$ is called the **abstraction** of K .

Triangulation: A triangulation of a topological space X is a pair (K, h) , where K is a geometric simplicial complex and h is a homeomorphism from the underlying space $|K|$ to X .

Barycentric subdivision: The *barycenter* (center of mass) of a geometric k -simplex with vertices $a_0, \dots, a_k$ in $\mathbb{R}^m$ is the point $1/(k+1) \sum_{i=0}^k a_i$. The barycentric subdivision of a geometric simplicial complex K is defined inductively: (i) the barycentric subdivision of the 0-skeleton σ^0 is σ^0 itself; (ii) if σ is an i dimensional face of K , $i > 0$, then σ is subdivided into the collection of simplices $C(b, \tau)$, for all simplices τ in the barycentric subdivision of the $(i-1)$ -skeleton of σ . Here $C(b, \tau)$ is the convex hull of $b \cup \tau$ and b the barycenter of σ of σ .

FIGURE 32.2.1
Barycentric subdivision.

The (first) barycentric subdivision of a simplicial complex K is the simplicial complex $s(K)$ obtained by barycentric subdivision of all simplexes of K ; see Figure 32.2.1. The i th barycentric subdivision of K , $i > 1$, is defined inductively as $s(s^{i-1}(K))$. A simplicial complex L is called a **refinement** of K if $L = s^i(K)$, for some $i \geq 0$.

Simplicial map: A simplicial map between simplicial complexes K and L is a function $f : |K| \rightarrow |L|$ such that (i) if a is a vertex of K then $f(a)$ is a vertex of L ; (ii) if $a_0, \dots, a_k$ are vertices of a simplex of K , then the convex hull of $f(a_0), \dots, f(a_k)$ is a simplex of L (whose dimension may be less than k); and (iii) f is linear on each simplex: if $x = \sum_{i=0}^k \lambda_i a_i$ is a point in a simplex with vertices $a_0, \dots, a_k$, then $f(x) = \sum_{i=0}^k \lambda_i f(a_i)$.

Simplicial equivalence: Two simplicial complexes K and L are simplicially equivalent iff there are simplicial maps $f : |K| \rightarrow |L|$ and $g : |L| \rightarrow |K|$ such that gf is the identity on $|K|$ and fg is the identity on $|L|$.

Piecewise linear (PL)-equivalence: Two simplicial complexes K and L are called piecewise linearly equivalent (PL-equivalent, for short) if there is a refinement K' of K and L' of L such that K' and L' are simplicially equivalent.

Orientation of a simplicial manifold: An orientation of a simplicial complex K , whose underlying space is a d -manifold, is a choice of orientation for each simplex of K , such that, if τ is a $(d-1)$ -face of two distinct d -simplices σ_1 and σ_2 , then the orientation on τ induced by σ_1 is the opposite of the orientation induced by σ_2 . The manifold is called **orientable** if it has a triangulation that has an orientation, otherwise it is **nonorientable**.

Euler characteristic: (Combinatorial definition; cf. Section 32.4) The Euler characteristic of a simplicial d -complex K , denoted by $\chi(K)$, is the number $\sum_{i=0}^d (-1)^i \alpha_i$, where α_i is the number of i -simplices of K .

Polygonal schema for a surface: Let $\mathcal{M}_g(a_1, b_1, \dots, a_g, b_g)$ be a regular $4g$ -gon, whose successive edges are labeled $a_1, b_1, \bar{a}_1, \bar{b}_1, \dots, a_g, b_g, \bar{a}_g, \bar{b}_g$. Edge x is directed counterclockwise, edge $\bar{x}$ clockwise. The space obtained by identifying edges x and $\bar{x}$, as indicated by their direction, is a closed oriented surface, denoted by $\mathbb{M}_g$; see, e.g., [Sti93, Chapter 1.4]. This surface, called the orientable surface of genus g , is homeomorphic to a 2-sphere with g handles.

Let $\mathcal{N}_g(a_1, \dots, a_g)$ be the regular $2g$ -gon whose successive edges are labeled $a_1, a_1, \dots, a_g, a_g$. Identifying edges in pairs, as indicated by their oriented labels, yields a closed nonorientable surface, denoted by $\mathbb{N}_g$. This surface, called the nonorientable surface of genus g , is homeomorphic to a 2-sphere with g cross-caps.

The labeled polygon $\mathcal{M}_g$ ($\mathcal{N}_g$) is called the polygonal schema of $\mathbb{M}_g$ ($\mathbb{N}_g$). $\mathbb{M}_1$ is the **torus**, $\mathbb{N}_1$ is the **projective plane**, $\mathbb{N}_2$ is the **Klein bottle**.

Minimal triangulation: A triangulation of a surface is called minimal if it has no contractible edges (i.e., contracting an edge yields a subdivision that is not a triangulation).

EXAMPLES

1. A **graph** is a 1-dimensional simplicial complex. The complete graph with n vertices is the 1-skeleton of an $(n-1)$ -simplex: $K_n = \sigma_{n-1}^1$.
2. Every connected, compact 1-manifold is topologically equivalent to $\mathbb{S}^1$ or $\mathbb{I}$.
3. The Delaunay triangulation of a set of points in general position in $\mathbb{R}^d$ is a simplicial complex.

BASIC PROPERTIES

1. Every triangulation of an orientable manifold has an orientation (i.e., the definition of orientability does not depend on the particular triangulation).
2. The Euler characteristic is a homotopy (and hence a topological) invariant (cf. Section 32.4).
3. A simplicial 2-complex is (topologically equivalent to) a closed surface iff every edge is incident with two faces, and the faces around a vertex can be ordered as $f_0, \dots, f_{k-1}$ so that there is exactly one edge incident with both f_i and f_{i+1} (indices modulo k).
4. An oriented closed surface X is topologically equivalent to $\mathbb{S}^2$ if $\chi(X) = 2$, or to $\mathbb{M}_g$ if $\chi(X) \neq 2$, where g is uniquely determined by $\chi(X) = 2 - 2g$. A nonorientable closed surface X is topologically equivalent to $\mathbb{N}_g$, with $\chi(X) = 2 - g$. The number g is called the **genus** of the surface.
5. Every surface has finitely many minimal triangulations. (This number is 1 for $\mathbb{S}^2$, 2 for the projective plane, and 22 for the torus; cf. Section 21.2.)
6. A simplicial complex is a 3-manifold without boundary iff every 2-simplex is incident with exactly two 3-simplices and $\chi(M) = 0$. See [Fom91, p. 184].

7. Every combinatorial simplicial d -complex has a geometric realization in $\mathbb{R}^{2d+1}$.
8. Two geometric realizations K_1 and K_2 of a combinatorial simplicial complex $\mathcal{K}$ are simplicially equivalent (therefore the topology of K does not depend on the Euclidean space in which $\mathcal{K}$ is geometrically realized).
9. A simplicial map $f : |K| \rightarrow |L|$ is continuous. Hence both simplicial equivalence and PL-equivalence imply topological equivalence.
10. **Hauptvermutung:** Two simplicial complexes are PL-equivalent iff their underlying spaces are topologically equivalent. The Hauptvermutung is true if the underlying spaces are manifolds of dimension ≤ 3 , and open for manifolds of dimension exceeding 3. It is false for general simplicial complexes, see Milnor [Mil61]. (*Reidemeister torsion* is a PL-invariant, but not a topological invariant [DFN90, pp. 156, 372].)

ALGORITHMS, DATA STRUCTURES, AND COMPLEXITY

Representation of spaces: The *Delaunay complex* D_X is a geometric simplicial complex which is, under some conditions, homotopically (or even topologically) equivalent to a given subspace X of some Euclidean space $\mathbb{R}^d$. See [ES94]. For applications of simplicial complexes to geometric modeling, see [Ede94].

Classification of surfaces: The Euler characteristic and orientability of a triangulated surface with n simplices can both be computed in $O(n)$ time.

Polygonal schema for a surface of genus $g > 0$: Given a triangulation of a closed orientable (nonorientable) surface of genus $g > 0$ with n triangles, there is a sequence of $O(n)$ elementary transformations (called **cross-cap** or **handle normalizations**) that turns the triangulation into a polygonal schema of the form $\mathcal{M}_g(\mathcal{N}_g)$. This sequence of transformations can be computed in $O(n \log n)$ time [VY90].

Minimal triangulations of a surface: For a triangulation of a surface of genus g with n triangles, a sequence of $O(n)$ edge contractions leading to a minimal triangulation, can be computed in $O(n \log n)$ time [Sch91]. Therefore the classification problem for triangulated surfaces with n -triangles can be solved in $O(n)$ time; see property (4) above.

Isomorphism (simplicial equivalence): The homeomorphism problem for 2-complexes is equivalent to the graph-isomorphism problem [ÓWW00]. It is unknown whether the graph-isomorphism problem is solvable in polynomial time (in the size of the graphs). See [vL90].

PL-equivalence: Deciding whether two arbitrary simplicial d -manifolds are PL-equivalent is unsolvable for $d \geq 4$ [Sti93, Chapter 9].

OPEN PROBLEMS

1. Design an algorithm that determines whether a simplicial 3-manifold is topologically equivalent to $\mathbb{S}^3$. This is a hard problem; see [VKF74] for partial results.

2. Design an algorithm that computes all minimal triangulations for a surface of genus g .
3. Determine the minimal size of a triangulation for a triangulable d -manifold [BK87, Sar87].

32.3 CELL COMPLEXES

Although simplicial complexes are convenient representations of topological spaces from an algorithmic point of view, they usually have many simplices. If a representation with a smaller number of cells is desirable, CW-complexes seem appropriate. See also [Section 18.4](#).

GLOSSARY

Attaching cells to a space: Let X and Y be topological spaces, such that $X \subset Y$. We say that Y is obtained by attaching a (finite) collection of k -cells to X if $Y \setminus X$ is the disjoint union of a finite number of open k -balls $\{e_i^k \mid i \in I\}$, with the property that, for each i in the index set I , there is a map $f_i : \mathbb{B}^k \rightarrow \overline{e_i^k}$, called the **characteristic map** of the cell e_i^k , such that $f_i(\mathbb{S}^{k-1}) \subset X$ and the restriction $f_i|_{\mathbb{B}^k}$ is a homeomorphism $\mathbb{B}^k \rightarrow e_i^k$. (Note: $\mathbb{B}^k$ need not be homeomorphic to $\overline{e_i^k}$.)

Cell complex (CW complex): A (finite) CW-decomposition of a topological space X is a finite sequence

$$\emptyset = X^{-1} \subset X^0 \subset X^1 \subset \cdots \subset X^d = X \quad (32.3.1)$$

such that (i) X^0 is a finite set of points, called the 0-cells of X ; (ii) for $k > 0$, X^k is obtained from X^{k-1} by attaching a finite number of k -cells to X^{k-1} . The connected components of $X^k \setminus X^{k-1}$ are called the k -cells of X . The space X is called a (finite) CW-complex. The dimension of X is the maximal dimension of the cells of X . A finite CW-complex is called **regular** if the characteristic map of each cell is a homeomorphism. (“CW” stands for “Closure-finite with the Weak topology.”)

EXAMPLES AND ELEMENTARY PROPERTIES

1. The d -sphere ($d > 0$) is a CW-complex, obtained by attaching a d -cell to a point p (so $X^k = \{p\}$, for $0 \leq k < d$, and $X^d = \mathbb{S}^d$). This CW-complex is not regular: the characteristic map of the d -cell maps the boundary of $\mathbb{B}^d$ to a single point.
2. The **orientable surface** $\mathbb{M}_g$ of genus $g > 1$ is a CW-complex with one 0-cell, $2g$ 1-cells, and one 2-cell. Let the 1-cells be $a_1, b_1, \dots, a_g, b_g$, endowed with an orientation (direction). The characteristic map of the 2-cell is uniquely determined by attaching the labeled $4g$ -gon $\mathcal{M}_g(a_1, b_1, \dots, a_g, b_g)$ (cf. Section 32.2) to the 1-skeleton by mapping an edge to the 1-cell with the same

label, so that the directions of the edge and the 1-cell correspond. See [VY90]. The $2g$ 1-cells are curves on the surface, disjoint except at their common endpoint (which is the 0-cell). These curves are called **canonical generators** of the surface (see [Section 32.4](#) for a justification of this nomenclature). The total number of cells is $2g + 2$, whereas the total number of simplices in a triangulation is at least $10g - 10 + \Theta(\sqrt{g})$ [JR80].

3. The **nonorientable surface** $\mathbb{N}_g$ of genus $g > 1$ is a CW-complex, with one 0-cell, g 1-cells, and one 2-cell. The characteristic map of the 2-cell is obtained from the polygonal schema represented by the $2g$ -gon $\mathcal{N}_g(a_1, \dots, a_g)$.
4. A geometric simplicial complex is a regular CW-complex.
5. The dual map of a triangulation of a surface is a regular CW-complex, but not a simplicial complex.
6. Examples of CW-complexes arising in computational geometry are: arrangements of hyperplanes in $\mathbb{R}^d$ (after addition of a point at infinity), the visibility complex [PV93], the free space of a polygonal robot moving amid polygonal obstacles (see [SS83] and [Chapter 47](#) of this Handbook), and the zero-set of a generic polynomial defined on $\mathbb{S}^d \subset \mathbb{R}^{d+1}$.

ALGORITHMS AND DATA STRUCTURES

Representation: A data structure for the representation and manipulation of a finite, d -manifold CW-complex is described in [Bri93].

CW-decomposition of surfaces from triangulations: For a triangulated surface of genus g , with a total of n simplices, a set of canonical generators (cf. property (2)) can be computed in $O(gn)$ time, which is optimal in the worst case [VY90]. Two algorithms achieving this time complexity have been implemented; see [LPVV01].

Each of the g or $2g$ canonical generators is represented by a polygonal curve whose vertices are on the 1-skeleton, while its other points are in the interior of a 2-simplex. In some cases the total number of edges of a single generator is $O(n)$. This method can be used to construct covering surfaces of m sheets in time $O(gnm)$ time and space; see also [Section 32.4](#).

CW-decomposition in motion planning: A general method to solve motion planning problems is the construction of a cell decomposition (Equation 32.3.1) of the free space X of the robot, together with a **retraction** $r : X \rightarrow X^k$ of X onto a low-dimensional skeleton, such that there is a motion from initial position $x_0 \in X$ to final position $x_1 \in X$ iff there is a motion from $r(x_0)$ to $r(x_1)$. This may be regarded as a reduction of the degrees of freedom of the robot. Because in general the complexity of the motion planning problem is exponential in the number of degrees of freedom, this approach simplifies the problem. For more details on the cell decomposition method in motion planning, see [Section 47.1](#).

32.4 ALGEBRAIC TOPOLOGY

In algebraic topology one associates homotopy-invariant groups (homology and homotopy groups) to a space, and homotopy-invariant homomorphisms to maps

between spaces. In passing from topology to algebra one may lose information since topologically distinct spaces may give rise to identical algebraic invariants. However, one gains on the algorithmic side, since the algebraic counterpart of an intractable topological problem may be tractable.

32.4.1 SIMPLICIAL HOMOLOGY GROUPS

Historically speaking, simplicial homology groups were among the first invariants associated with topological spaces. They are conceptually and algorithmically appealing. Modern algebraic topology usually deals with singular and cellular homology groups, which are more convenient from a mathematical point of view.

GLOSSARY

Ordered simplex: Let the vertices of a simplicial complex K be ordered $v_0, \dots, v_m$. A k -simplex of K with vertices $v_{i_0}, \dots, v_{i_k}$, $i_0 < \dots < i_k$ is represented by the symbol $[v_{i_0}, \dots, v_{i_k}]$, and called an ordered simplex.

Simplicial chain: If G is an abelian group, then an (ordered) simplicial k -chain is a formal sum of the form $\sum_j a_j \sigma_j$, with $a_j \in G$ and σ_j the symbol of a k -simplex in K . With the obvious definition for addition, the set of all (ordered) simplicial k -chains forms a (free) abelian group $C_k(K, G)$, called the group of (ordered) simplicial k -chains of K . If $G = \mathbb{Z}$, the group of integers, an element of $C_k(K, G)$ is called an **integral k -chain**.

Boundary operator: The boundary operator $\partial_k : C_k(K, G) \rightarrow C_{k-1}(K, G)$ is defined as follows. For a single (ordered) k -simplex $\sigma = [v_{i_0}, \dots, v_{i_k}]$, let $\partial_k \sigma = \sum_{h=0}^k (-1)^h [v_{i_0}, \dots, \hat{v}_{i_h}, \dots, v_{i_k}]$, and then let ∂_k be extended linearly, viz., $\partial_k(\sum_j a_j \sigma_j) = \sum_j a_j \partial_k \sigma_j$. The boundary operator is a homomorphism of groups. It satisfies $\partial_k \partial_{k+1} = 0$.

Simplicial k -cycles: $Z_k(K, G) = \ker \partial_k$ is called the group of (ordered) simplicial k -cycles.

Simplicial k -boundaries: $B_k(K, G) = \text{im } \partial_{k+1}$ is called the group of (ordered) simplicial k -boundaries. Since the boundary of a boundary is 0, B_k is a subgroup of $Z_k(K, G)$.

Simplicial homology groups: The group $H_k(K, G) = Z_k(K, G)/B_k(K, G)$ is the k th (simplicial) homology group of K . This is a purely combinatorial object, since in fact it is defined for abstract simplicial complexes. If $G = \mathbb{Z}$, these groups are called **integral homology groups**, usually denoted by $H_k(K)$. If G is a field (such as $\mathbb{R}$), then $H_k(K, G)$ is a vector space.

Homology groups of a triangulable topological space: $H_k(X, G) = H_k(K, G)$, if K is a simplicial complex triangulating X . This definition is independent of the triangulation K : if $h_i : K_i \rightarrow X$, $i = 1, 2$, are two triangulations of X , then $H_k(K_1, G) = H_k(K_2, G)$.

Betti numbers: The k th Betti number $\beta_k(K)$ of a simplicial complex K is the dimension of the real vector space $H_k(K, \mathbb{R})$. (For an alternative definition, see [Bre93, Chapter IV.1].)

Euler characteristic: The Euler characteristic $\chi(K)$ of a simplicial d -complex K is defined by $\chi(K) = \sum_{i=0}^d (-1)^i \beta_i(K)$. This definition is equivalent to the one of Section 32.2.

EXAMPLES

1. The n -sphere ($n > 0$): $H_k(\mathbb{S}^n, \mathbb{Z}) = \mathbb{Z}$, if $k = 0$ or n , and 0 otherwise.
2. *Orientable surface*: For $g \geq 0$, $H_0(\mathbb{M}_g, G) = H_2(\mathbb{M}_g, G) = G$, $H_1(\mathbb{M}_g, G) = \oplus_{i=1}^{2g} G$, $H_k(\mathbb{M}_g, G) = 0$ for $k > 2$. Taking $G = \mathbb{R}$ we see that $\chi(\mathbb{M}_g) = 2 - 2g$.
3. *Nonorientable surface*: For $g \geq 0$, $H_0(\mathbb{N}_g, \mathbb{Z}) = \mathbb{Z}$, $H_1(\mathbb{N}_g, \mathbb{Z}) = \oplus_{i=1}^{g-1} \mathbb{Z} \oplus \mathbb{Z}_2$, $H_k(\mathbb{N}_g, \mathbb{Z}) = 0$ for $k \geq 2$. $H_0(\mathbb{N}_g, \mathbb{R}) = \mathbb{R}$, $H_1(\mathbb{N}_g, \mathbb{R}) = \oplus_{i=1}^{g-1} \mathbb{R}$, $H_2(\mathbb{N}_g, \mathbb{R}) = 0$. Hence, $\chi(\mathbb{N}_g) = 2 - g$.

BASIC PROPERTIES

1. Homology is a homotopy invariant: if X_1 and X_2 are homotopy-equivalent, then $H_k(X_1) = H_k(X_2)$ for all k . In particular, Betti numbers and the Euler characteristic are homotopy invariants.
2. For a simplicial d -complex K : $H_k(K, G) = 0$ for $k > d$.
3. Let $\alpha_i(K)$ be the number of i -simplices of a simplicial d -complex K . Then $\chi(K) = \sum_{i=0}^d (-1)^i \alpha_i(K)$. This justifies the definition of χ in Section 32.2.

COMPUTING BETTI NUMBERS AND HOMOLOGY GROUPS

See Table 32.4.1 for the algorithmic complexity of computing the Betti numbers of several important types of spaces. The paper [DG98] also presents a method of computing a basis for the first and second homology groups of a complex in $\mathbb{R}^3$ of size n , in time $O(\bar{g}n^2)$, where the integer $\bar{g}$ is an invariant of the complex, with $\bar{g} < n$.

Bounds on the sum of the Betti numbers of closed semialgebraic sets are given in [Bas99], as well as a single-exponential-time algorithm for computing the Euler characteristic of arbitrary closed semialgebraic sets.

TABLE 32.4.1 Complexity of computing Betti numbers.

TYPE OF SPACE	COMPLEXITY	SOURCE
Simplicial subcomplex of $\mathbb{S}^3$ of size n	$O(n\alpha(n))$	[DE95]
Simplicial complex in $\mathbb{R}^3$ of size n	$O(n)$	[DG98]
Sparse simplicial complex of size n	$O(n^2)$ (probabilistic)	[DC91]
Semialgebraic set, defined by m poly's (deg $\leq d$) on $\mathbb{R}^n$, n fixed	polynomial in m, d	[SS83]

32.4.2 HOMOTOPY GROUPS

Homotopy groups usually provide more information than homology groups, but are generally harder to compute. The main object is the fundamental group, whose computation requires some combinatorial group theory.

GLOSSARY

Fundamental group: The space of x_0 -based curves on X is endowed with a group structure by (group multiplication) $(u_1 \cdot u_2)(t) = u_1(2t)$, if $0 \leq t \leq \frac{1}{2}$, and $u_2(2t - 1)$ if $\frac{1}{2} \leq t \leq 1$, and (inverse) $u^{-1}(t) = u(1 - t)$.

This group structure can be extended to homotopy classes of x_0 -based curves: If u, v are homotopic, then u^{-1} and v^{-1} are homotopic, and if u_i and v_i , $i = 1, 2$, are homotopic, then $u_1 \cdot u_2$ and $v_1 \cdot v_2$ are homotopic (homotopies respect the basepoint x_0). The group of homotopy classes of closed x_0 -based curves is called the fundamental group (or, the **first homotopy group**) of (X, x_0) , and is denoted by $\pi_1(X, x_0)$. If X is connected, the definition is independent of the basepoint. Then the fundamental group is denoted by $\pi_1(X)$.

Combinatorial definition of the fundamental group: If X is a connected space with triangulation K and vertices $a_0, \dots, a_m$, then the fundamental group has generators g_{ij} , one per ordered 1-simplex $[a_i, a_j]$, and relations $g_{ij}g_{jk}g_{ik}^{-1} = 1$, one for each ordered 2-simplex $[a_i, a_j, a_k]$ [Mau70, Chapter 3]. See [Sti93] for an introduction to combinatorial group theory.

k th homotopy group: Let $s_0 \in \mathbb{S}^k$, for $k \geq 1$. The space of homotopy classes of basepoint-preserving maps $(\mathbb{S}^k, s_0) \rightarrow (X, x_0)$ can be endowed with a group structure. The group is called the k th homotopy group of (X, x_0) , and is denoted by $\pi_k(X, x_0)$.

Word problem for a group G : Given a (finitely generated) group generated by $g_1, \dots, g_k$ (the alphabet), and a finite set of relations of the form $g_1^{m_1} \cdots g_k^{m_k} = 1$ (rewrite rules) with $m_i \in \mathbb{Z}$, decide whether a given word of the form $g_1^{n_1} \cdots g_k^{n_k}$ represents the unit element 1.

Covering space: A continuous map $p : Y \rightarrow X$ is a covering map if every point $x \in X$ has a connected neighborhood U such that for each connected component V of $p^{-1}(x)$ the restriction of p to V is a homeomorphism $V \rightarrow U$. Y is called a covering space of X . If the cardinality n of $p^{-1}(U)$ is finite, Y is called an n -sheeted cover of X . This number is the same for all $x \in X$.

Universal covering space: A connected covering space Y of X is called universal if $\pi_1(Y) = 0$.

EXAMPLES

1. *The n -sphere* ($n > 0$): $\pi_1(\mathbb{S}^n, s_0) = \mathbb{Z}$ if $n = 1$, and 0 otherwise.
2. *Orientable surface of genus $g \geq 1$:* $\pi_1(\mathbb{M}_g)$ is generated by $2g$ generators $a_1, b_1, \dots, a_g, b_g$, with the single relation $a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1} = 1$.
3. *Nonorientable surface of genus $g \geq 1$:* $\pi_1(\mathbb{N}_g)$ is generated by g generators $a_1, \dots, a_g$, with the single relation $a_1 a_1 \cdots a_g a_g = 1$.
4. *Universal covering space:* The universal covering space of $\mathbb{S}^1$ is $\mathbb{R}$, with covering map $p : \mathbb{R} \rightarrow \mathbb{S}^1$ defined by $p(t) = (\cos t, \sin t)$. The universal covering space of the projective plane $\mathbb{P}$ is $\mathbb{S}^2$, the covering map being antipodal identification. The plane is the universal covering space of $\mathbb{M}_g$ and $\mathbb{N}_g$, $g > 0$.

BASIC PROPERTIES

1. The homotopy groups are homotopy invariants.
2. The first integral homology group is the abelianized fundamental group.
3. The fundamental group of a simplicial complex is the fundamental group of its 2-skeleton.
4. For every finitely generated group G there is a finite simplicial 2-complex K and a 4-manifold M such that $\pi_1(K) = G$ and $\pi_1(M) = G$.
5. Homotopy invariants are topological invariants, but not vice versa. For example, the *lens spaces* $L(5, 1)$ and $L(5, 2)$ are not homotopy-equivalent, but do have isomorphic homology and homotopy groups [Bre93, Chapter VI].
6. Let Y be a universal covering space of X with covering map $p : Y \rightarrow X$, and let $y_0 \in Y$ and $x_0 = p(y_0) \in X$. Every curve $c : \mathbb{I} \rightarrow X$ with $c(0) = x_0$ has a unique lift $\bar{c} : \mathbb{I} \rightarrow Y$ with $\bar{c}(0) = y_0$. Furthermore, a closed curve c is contractible in X iff $\bar{c}$ is a closed curve in Y , i.e., $\bar{c}(1) = y_0$ [Sti93, Chapter 6]. This is the basis of Dehn's algorithm for the contractibility problem on surfaces (see below).

ALGORITHMS AND COMPLEXITY

Undecidability of homeomorphism problem: The word problem for general groups is undecidable. Hence the contractibility problem for general simplicial 2-complexes, and for manifolds of dimension ≥ 4 , is undecidable [Sti93]. A slight variation even proves that the homeomorphism problem for 4-manifolds is undecidable.

Contractibility problem for surfaces: Determine whether a curve with k edges on a triangulated surface $\mathbb{M}_g$ of size n is contractible, and, if so, construct a contraction.

Dey and Schipper [DS95] implement Dehn's algorithm in $O(n + k \log g)$ time and $O(n + k)$ space by constructing a finite portion of the covering surface of $\mathbb{M}_g$, for $g > 1$, and determining whether the lift of the curve to the covering space is closed. These algorithms can also be applied to solving the homotopy problem for curves on a surface.

The paper [DG99] presents an algorithmic solution of the word problem for fundamental groups of the orientable surfaces $\mathbb{M}_g$, if $g \neq 2$, and of the nonorientable surfaces $\mathbb{N}_g$, if $g \neq 3, 4$. This algorithm yields a method to decide whether a curve on such a surface is contractible in $O(n + k)$ time and space, which is optimal.

Representation problem: There is an algorithm that decides whether a homotopy class of curves contains a simple closed curve. The algorithm of [Chi72] can be turned into a polynomial-time algorithm using methods similar to those of [Sch92] and [VY90]. (Poincaré had already given a condition for a *homology* class of a curve on a surface to contain a simple closed curve. This can also be turned into a polynomial algorithm along similar lines.)

Homotopy of polygonal paths among points in the plane: Several algorithms determine whether two polygonal paths in the plane with n points removed

are homotopic. Hershberger and Snoeyink [HS94b] construct part of the covering space to compute minimum length curves that are homotopy-equivalent to a given curve, in $\Theta(n^2)$ time, where n is the number of point-shaped holes and the input curve consists of at most n edges. Cabello, Liu, Mantler, and Snoeyink [CLMS02] present an $O(n \log n)$ algorithm to test whether two *simple* paths, with the same endpoints, are homotopic. See [Section 27.2](#).

32.5 EMBEDDING SIMPLICIAL COMPLEXES

Embeddability problems are important for their own sake, but also for computations. Especially important algorithmically is the problem of embedding a simplicial complex in a Euclidean space of lowest dimension. See also [Section 21.1](#).

GLOSSARY

Simplicial embedding of a simplicial complex K in simplicial complex L : A simplicial map $f : |K| \rightarrow |L|$ that is a topological embedding.

Geometric embedding of a simplicial complex K in $\mathbb{R}^d$: A simplicial equivalence $f : K \rightarrow L$, where L is a geometric simplicial complex in $\mathbb{R}^d$.

Piecewise-linear (PL) embedding of a simplicial complex K in a simplicial complex L : A simplicial embedding of a refinement K' of K in a refinement L' of L . If L is a geometric simplicial complex in $\mathbb{R}^d$, we say that K can be PL-embedded in $\mathbb{R}^d$.

PL-minimality: A simplicial complex is PL-minimal in $\mathbb{R}^d$ if it is not PL-embeddable in $\mathbb{R}^d$, but every proper subcomplex can be PL-embedded in $\mathbb{R}^d$.

Genus of a graph: The orientable (nonorientable) genus of a graph G is the minimal genus of an orientable (nonorientable) surface in which G is PL-embeddable.

Book: A book with p pages is a simplicial complex consisting of p triangles sharing a common edge (and nothing else).

Page number of a graph: Minimal number of pages of a book in which the graph is PL-embeddable.

32.5.1 PL-EMBEDDINGS

BASIC RESULTS

1. A simplicial d -complex that is topologically embeddable in $\mathbb{R}^{2d}$ is also PL-embeddable in $\mathbb{R}^{2d}$ [Web67].
2. For $d \geq 3$, a simplicial d -complex K is PL-embeddable in $\mathbb{R}^{2d}$ iff its *van Kampen obstruction class* $o(K) = 0$. ($o(K)$ is an element of the $2d$ th cohomology group of the symmetric product of K minus the diagonal; see [vK33, Sha57].) If K is a triangulation of a d -manifold, then $o(K) = 0$, so K can be embedded in $\mathbb{R}^{2d}$ [Whi44].

3. **Kuratowski's theorem:** a graph G is PL-embeddable in the plane iff K_5 and $K_{3,3}$ are not PL-embeddable in G . The graphs K_5 and $K_{3,3}$ are called **forbidden minors** for planarity.
4. Every orientable triangulated surface can be PL-embedded in $\mathbb{R}^3$. Every nonorientable triangulated surface can be PL-embedded in $\mathbb{R}^4$, but not in $\mathbb{R}^3$ (for a simple proof of the latter, see [Mae93]).
5. Kuratowski's theorem can be rephrased by saying that K_5 and $K_{3,3}$ are the only PL-minimal 1-complexes in $\mathbb{R}^2$. For each $n \geq 2$ and each d , with $n+1 \leq d \leq 2n$, there are countably many nonhomeomorphic n -complexes that are all PL-minimal in $\mathbb{R}^d$ [Zak69].
6. There is a finite set of forbidden minors for PL-embeddability in a surface of fixed genus g [RS90].
7. The page-number of a graph is $O(g)$ [HI92].

ALGORITHMS AND COMPLEXITY

PL-embeddability of graphs: It can be decided in $O(n \log n)$ time whether a graph with n vertices is planar (PL-embeddable in the plane). In $O(n \log n)$ time a geometric embedding in the plane can be constructed [HT74].

Graph genus: The graph genus problem is NP-complete [Tho89].

OPEN PROBLEMS

1. Give an efficient algorithm that computes the van Kampen obstruction $o(K)$ for a simplicial d -complex K with a total of n simplices. Find an algorithm that constructs a PL-embedding (of reasonable complexity) for K in case $o(K) = 0$.
2. Design an efficient algorithm that determines whether a simplicial d -complex can be PL-embedded in $\mathbb{R}^k$, for $d \leq k < 2d$.

32.5.2 GEOMETRIC EMBEDDINGS

MAIN RESULTS

1. Every simplicial d -complex can be geometrically embedded in $\mathbb{R}^{2d+1}$.
2. Every simplicial 1-complex (graph) that is PL-embeddable in $\mathbb{R}^2$ can be geometrically embedded in $\mathbb{R}^2$ (**Fáry's theorem**).
3. For each $d \geq 2$ there is a simplicial d -complex that is PL-embeddable in $\mathbb{R}^{d+1}$, but not geometrically embeddable in $\mathbb{R}^{d+1}$ [Duk70].
4. All minimal triangulations of the 2-sphere and the torus can be geometrically embedded in $\mathbb{R}^3$ [BW93]. All minimal triangulations of the projective plane can be geometrically embedded in $\mathbb{R}^4$ [BW93].

ALGORITHMS

Geometric embeddability of a graph: It can be decided in $O(n \log n)$ time whether a simplicial 1-complex (graph) with n cells (edges and vertices) can be geometrically embedded in the plane. If such an embedding exists, it can be constructed in $O(n \log n)$ time [HT74].

OPEN PROBLEMS

1. Can every minimal triangulation (see [Section 32.2](#)) of the surface of genus g be geometrically embedded in $\mathbb{R}^3$ (cf. [BW93])?
 2. Design an efficient (polynomial-time) algorithm that determines whether a simplicial d -complex can be geometrically embedded in $\mathbb{R}^k$, for $d \leq k \leq 2d$.
 3. Prove or disprove: If a simplicial d -complex is PL-embeddable in $\mathbb{R}^{2d}$, then it is geometrically embeddable in $\mathbb{R}^{2d}$.
 4. Is there a constant c such that the c th barycentric subdivision of any simplicial complex K whose underlying space can be PL-embedded in $\mathbb{R}^d$, can be geometrically embedded in $\mathbb{R}^d$? Recall that there are examples of simplicial complexes that are PL-embeddable in $\mathbb{R}^d$, but not geometrically embeddable.
-

32.5.3 KNOTS

GLOSSARY

Knot: A PL-embedding of a polygon in $\mathbb{R}^3$.

Spanning surface of a knot: A PL-embedded orientable surface in $\mathbb{R}^3$, whose boundary is the knot (also called a *Seifert surface*).

Trivial knot: A knot with a spanning surface that is PL-equivalent to a disk.

Genus of a knot: Minimum possible genus of a spanning surface. (The genus of a spanning surface is the genus of the closed orientable surface obtained by attaching a disk—cf. Section 32.3—along the boundary of the spanning surface. In particular, a trivial knot has genus 0.)

ALGORITHMS AND COMPLEXITY

1. A spanning surface for a polygonal knot with n vertices can be constructed in $O(n^2)$ time (Seifert's construction [Liv93]).
2. There is an algorithm that solves the **knot triviality** problem (or, unknotting problem), i.e., that decides whether a polygonal knot with n vertices is trivial, in $O(\exp(cn^2))$ time and $O(n^2 \log n)$ space, for some positive constant c (the Haken-Hemion unknottedness algorithm; see [Hem92]). The Jaco-Tollefson

unknottedness algorithm [JT95] decides this question in at most $O(\exp(c'n))$ time and $O(n^2 \log n)$ space, for some positive constant c' . The knot triviality problem is in **NP**, [HLP99].

3. The genus problem for a polygonal knot is in **PSPACE** [HLP99].

OPEN PROBLEM

Knot triviality: Is the knot triviality problem NP-complete?

32.6 IMMERSIONS

GLOSSARY

Immersion: Let K and L be simplicial complexes. A PL-map $f : |K| \rightarrow |L|$ is called an immersion if it is locally injective (i.e., every point $p \in |K|$ has a neighborhood in $|K|$ on which f is 1–1). We say that $|K|$ is immersed in $|L|$. An immersion of $|K|$ in $\mathbb{R}^d$ is defined similarly.

Regular equivalence of immersions: Two immersions f_0 and f_1 of $|K|$ in $|L|$ (or $\mathbb{R}^d$) are regularly equivalent if there is a homotopy F , between f_0 and f_1 , defined on $|K| \times \mathbb{I}$, such that f_t , defined by $f_t(x) = F(x, t)$, is an immersion of $|K|$ in $|L|$ (or $\mathbb{R}^d$).

Winding number: Consider a polygon P with n vertices, immersed in the plane. Let its exterior angles $\theta_1, \dots, \theta_n$, be measured with sign. The winding number of P is $w(P) = \frac{1}{2\pi} \sum_{i=1}^n \theta_i \in \mathbb{Z}$ (the total number of turns of its tangent vector). P may be considered as the image of a PL-immersion $c : \mathbb{S}^1 \rightarrow \mathbb{R}^2$, for which we define $w(c) = w(P)$.

BASIC RESULTS

1. Every PL-embedding is an immersion.
2. Every simplicial d -manifold can be immersed in $\mathbb{R}^{2d-1}$ [Whi44].
3. Two immersions $c_1, c_2 : \mathbb{S}^1 \rightarrow \mathbb{R}^2$ are regularly equivalent iff $w(c_1) = w(c_2)$ (a theorem of Whitney-Graustein).
4. There are two regular equivalence classes of immersions $\mathbb{S}^1 \rightarrow \mathbb{S}^2$, viz the curves that go once and twice along the equator of $\mathbb{S}^2$.
5. Smale [Sma58a] associates with each immersion $c : \mathbb{S}^1 \rightarrow \mathbb{M}_g$ an element $W(c)$ of the fundamental group of the unit tangent bundle $S^1(\mathbb{M}_g)$ of $\mathbb{M}_g$ that is a complete invariant for the regular equivalence class of c . This element $W(c)$ may be considered the generalization of the winding number of an immersion of $\mathbb{S}^1$ in $\mathbb{R}^2$. For related definitions, see [Chi72, MC93].
6. All immersions of $\mathbb{S}^2$ in $\mathbb{R}^3$ are regularly equivalent. See [Sma58b] and [Fra87, Phi66] for pictures and constructions.

7. More generally, there are 4^g regular equivalence classes of immersions of an oriented closed surface in $\mathbb{R}^3$ [JT66]. See [Phi66] for pictures of the 4 classes of immersions of the torus $\mathbb{M}_1$ in $\mathbb{R}^3$.

ALGORITHMS

Kinkfree deformations of immersed curves in $\mathbb{R}^2$: If $w(P_1) = w(P_2)$ for planar polygons P_1 and P_2 with a total of n vertices, there is a sequence of $O(n)$ “elementary” moves that realizes a regular equivalence between P_1 and P_2 . This sequence can be computed in $O(n \log n)$ time [Veg89]. This algorithm can be adapted to construct a regular equivalence between two polygonal curves on $\mathbb{S}^2$.

Regular closed curves on $\mathbb{M}_g$, $g > 0$: There is an algorithm that determines in polynomial time whether two PL-immersions $\mathbb{S}^1 \rightarrow \mathbb{M}_g$ are regularly equivalent [Chi72, MC93].

OPEN PROBLEMS

1. *Regular deformations of curves on a surface:* Design an optimal algorithm that determines whether two PL-immersions $\mathbb{S}^1 \rightarrow \mathbb{M}_g$ are regularly equivalent, and, if so, construct such an equivalence.
2. *Immersions of $\mathbb{S}^2$ in $\mathbb{R}^3$:* Design an efficient algorithm that constructs a regular equivalence between two arbitrary PL-immersions of $\mathbb{S}^2$ in $\mathbb{R}^3$.
3. *Immersions of $\mathbb{M}_g$ in $\mathbb{R}^3$:* Design an algorithm that determines whether two immersions of $\mathbb{M}_g$ in $\mathbb{R}^3$ are regularly equivalent. Extend the method to the construction of such an equivalence.

32.7 MORSE THEORY

Finite dimensional Morse theory deals with the relation between the topology of a smooth manifold and the critical points of smooth real-valued functions on the manifold. It is the basic tool for the solution of fundamental problems in differential topology. Recently, basic notions from Morse theory have been used in the study of the geometry and topology of large molecules.

GLOSSARY

Differential of a smooth map between Euclidean spaces: A function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is called **smooth** if it has derivatives of all orders. A map $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is called smooth if its component functions are smooth. The **differential** of φ at $q \in \mathbb{R}^n$ is the **linear map** $d\varphi_q : \mathbb{R}^n \rightarrow \mathbb{R}^m$ defined as follows. For $v \in \mathbb{R}^n$, let $\alpha : I \rightarrow \mathbb{R}^n$, with $I = (-\varepsilon, \varepsilon)$ for some positive ε , be defined by $\alpha(t) = \varphi(q + tv)$; then $d\varphi_q(v) = \alpha'(0)$. If $\varphi(x_1, \dots, x_n) = (\varphi_1(x_1, \dots, x_n), \dots, \varphi_m(x_1, \dots, x_n))$, then the differential $d\varphi_q$ is represented by the **Jacobian matrix**

$$\begin{pmatrix} \frac{\partial \varphi_1}{\partial x_1}(q) & \cdots & \frac{\partial \varphi_1}{\partial x_n}(q) \\ \vdots & & \vdots \\ \frac{\partial \varphi_m}{\partial x_1}(q) & \cdots & \frac{\partial \varphi_m}{\partial x_n}(q) \end{pmatrix}.$$

Submanifold of $\mathbb{R}^n$: If $m \leq n$, a subset M of $\mathbb{R}^n$ is an m -dimensional smooth submanifold of $\mathbb{R}^n$ if, for each $p \in M$, there is an open set V in $\mathbb{R}^n$ containing p , and a map $\varphi : U \rightarrow M \cap V$ from an open subset U in $\mathbb{R}^m$ onto $V \cap M$, such that (i) φ is a smooth homeomorphism and (ii) the differential $d\varphi_q : \mathbb{R}^m \rightarrow \mathbb{R}^n$ is injective for each $q \in U$. The map φ is called a **parametrization** of M at p .

Tangent space of a manifold: A smooth curve through a point p on a smooth submanifold M of $\mathbb{R}^n$ is a smooth map $\alpha : I \rightarrow \mathbb{R}^n$, with $I = (-\varepsilon, \varepsilon)$ for some positive ε , satisfying $\alpha(t) \in M$ for $t \in I$ and $\alpha(0) = p$. A **tangent vector** of M at p is the tangent vector $\alpha'(0)$ of some smooth curve $\alpha : I \rightarrow M$ through p . The set $T_p M$ of all tangent vectors of M at p is the tangent space of M at p .

If $\varphi : U \rightarrow M$ is a smooth parametrization of M at p , with $0 \in U$ and $\varphi(0) = p$, then $T_p M$ is the m -dimensional subspace $d\varphi_0(\mathbb{R}^m)$ of $\mathbb{R}^n$, which passes through $\varphi(0) = p$. Let $\{e_1, \dots, e_m\}$ be the standard basis of $\mathbb{R}^m$, and define the tangent vector $\bar{e}_i \in T_p M$ by $\bar{e}_i = d\varphi_0(e_i)$. Then $\{\bar{e}_1, \dots, \bar{e}_m\}$ is a basis of $T_p M$.

Smooth function on a submanifold: A function $f : M \rightarrow \mathbb{R}$ on an m -dimensional smooth submanifold M of $\mathbb{R}^n$ is smooth at $p \in M$ if there is a smooth parametrization $\varphi : U \rightarrow M \cap V$, with U an open set in $\mathbb{R}^m$ and V an open set in $\mathbb{R}^n$ containing p , such that the function $f \circ \varphi : U \rightarrow \mathbb{R}$ is smooth. A function on a manifold is called smooth if it is smooth at every point of the manifold.

Critical point: A point $p \in M$ is a critical point of a smooth function $f : M \rightarrow \mathbb{R}$ if there is a local parametrization $\varphi : U \rightarrow \mathbb{R}^n$ of M at p , with $\varphi(0) = p$, such that 0 is a critical point of $f \circ \varphi : U \rightarrow \mathbb{R}$ (i.e., the differential of $f \circ \varphi$ at q is the zero function on $\mathbb{R}^n$). This condition does not depend on the particular parametrization. A real number $c \in \mathbb{R}$ is a **regular value** of f if $f(p) \neq c$ for all critical points p of f , and a **critical value** if $f^{-1}(c)$ contains a critical point of f .

Hessian at a critical point: Let M be a smooth submanifold of $\mathbb{R}^n$, and let $f : M \rightarrow \mathbb{R}$ be a smooth function. The Hessian of f at a critical point p is the quadratic form $H_p f$ on $T_p M$ defined as follows. For $v \in T_p M$, let $\alpha : (-\varepsilon, \varepsilon) \rightarrow M$ be a curve with $\alpha(0) = p$ and $\alpha'(0) = v$. Then

$$H_p f(v) = \left. \frac{d^2}{dt^2} \right|_{t=0} f(\alpha(t)).$$

Let $\varphi : U \rightarrow M$ be a smooth parametrization of M at p , with $0 \in U$ and $\varphi(0) = p$, and let $v = v_1 \bar{e}_1 + \cdots + v_m \bar{e}_m \in T_p M$, where $\bar{e}_i = d\varphi_0(e_i)$. Then

$$H_p f(v) = \sum_{i,j=1}^m \frac{\partial^2 (f \circ \varphi)}{\partial x_i \partial x_j}(0) v_i v_j.$$

In particular, the matrix of $H_f(p)$ with respect to this basis is

$$\begin{pmatrix} \frac{\partial^2(f \circ \varphi)}{\partial x_1^2}(0) & \cdots & \frac{\partial^2(f \circ \varphi)}{\partial x_1 \partial x_m}(0) \\ \vdots & & \vdots \\ \frac{\partial^2(f \circ \varphi)}{\partial x_1 \partial x_m}(0) & \cdots & \frac{\partial^2(f \circ \varphi)}{\partial x_m^2}(0) \end{pmatrix}. \quad (32.7.1)$$

Nondegenerate critical point: The critical point p of $f : M \rightarrow \mathbb{R}$ is nondegenerate if the Hessian $H_p f$ is nondegenerate. The **index** of the critical point p is the number of negative eigenvalues of the Hessian at p . If M is 2-dimensional, then a critical point of index 0, 1, or 2, is called a **minimum**, **saddle point**, or **maximum**, respectively.

Morse function: A smooth function on a manifold is a Morse function if all critical points are nondegenerate. The **k th Morse number** of a Morse function f , denoted by $\mu_k(f)$, is the number of critical points of f of index k .

EXAMPLES

1. $\mathbb{R}^m$ is a smooth submanifold of $\mathbb{R}^n$, for $m \leq n$. For $m < n$, we identify $\mathbb{R}^m$ with the subset $\{(x_1, \dots, x_n) \in \mathbb{R}^n \mid x_{m+1} = \dots = x_n = 0\}$ of $\mathbb{R}^n$.

2. The quadratic function $f : \mathbb{R}^m \rightarrow \mathbb{R}$ defined by

$$f(x_1, \dots, x_m) = -x_1^2 - \dots - x_k^2 + x_{k+1}^2 + \dots + x_m^2$$

is a Morse function, with a single critical point $(0, \dots, 0)$. This point is a nondegenerate critical point, since the Hessian matrix at this point is $\text{diag}(-2, \dots, -2, 2, \dots, 2)$, with k entries on the diagonal equal to -2 . In particular, the index of the critical point is k .

3. $\mathbb{S}^{m-1}$ is a smooth submanifold of $\mathbb{R}^m$. A smooth parametrization of $\mathbb{S}^{m-1}$ at $(0, \dots, 0, 1) \in \mathbb{S}^{m-1}$ is given by $\varphi : U \rightarrow \mathbb{R}^m$, with

$$U = \{(x_1, \dots, x_{m-1}) \in \mathbb{R}^{m-1} \mid x_1^2 + \dots + x_{m-1}^2 < 1\}$$

and

$$\varphi(x_1, \dots, x_{m-1}) = (x_1, \dots, x_{m-1}, \sqrt{1 - x_1^2 - \dots - x_{m-1}^2}).$$

In fact, φ is a parametrization at every point of the upper hemisphere, i.e., the intersection of $\mathbb{S}^{m-1}$ and the upper half space $\{(y_1, \dots, y_m) \mid y_m > 0\}$.

4. The **height function** on $\mathbb{S}^{m-1}$, defined by $f(y_1, \dots, y_m) = y_m$ for $(y_1, \dots, y_m) \in \mathbb{S}^{m-1}$, is a Morse function. With respect to the parametrization φ the expression of the height function is $f \circ \varphi(x_1, \dots, x_{m-1}) = \sqrt{1 - x_1^2 - \dots - x_{m-1}^2}$, so that the only critical point of f on the upper hemisphere is $(0, \dots, 0, 1)$. The Hessian matrix (32.7.1) is the diagonal matrix $\text{diag}(-1, -1, \dots, -1)$, so that $(0, \dots, 0, 1)$ is a critical point of index $n - 1$. Similarly, the other critical point is $(0, \dots, 0, -1)$, which is of index 0.

5. The torus M in $\mathbb{R}^3$, obtained by rotating a circle in the x, y -plane with center $(0, R, 0)$ and radius r around the x -axis, is a smooth 2-manifold. Let $U = \{(u, v) \mid -\pi/2 < u, v < 3\pi/2\} \subset \mathbb{R}^2$, and let the map $\varphi : U \rightarrow \mathbb{R}^3$ be defined by

$$\varphi(u, v) = (r \sin u, (R - r \cos u) \sin v, (R - r \cos u) \cos v).$$

Then φ is a parametrization at all points of M , except for points on one latitudinal and one longitudinal circle. The height function on M is the function $h : M \rightarrow \mathbb{R}$ defined by

$$\tilde{h}(u, v) = h(\varphi(u, v)) = (R - r \cos u) \cos v,$$

so that the singular points of h are as shown in Table 32.7.1.

TABLE 32.7.1 Singularities of the height function for a torus.

(u, v)	$\varphi(u, v)$	TYPE OF SINGULARITY
$(0, 0)$	$(0, 0, R - r)$	saddle point
$(0, \pi)$	$(0, 0, -R + r)$	saddle point
$(\pi, 0)$	$(0, 0, R + r)$	maximum
(π, π)	$(0, 0, -R - r)$	minimum

BASIC RESULTS

1. **Regular level sets.** Let M be an m -dimensional submanifold of $\mathbb{R}^n$, and let $f : M \rightarrow \mathbb{R}$ be a smooth function. If $c \in \mathbb{R}$ is a regular value of f , then $f^{-1}(c)$ is a regular $(m - 1)$ -dimensional submanifold of $\mathbb{R}^n$.

For $a \in \mathbb{R}$, let $M_a = \{q \in M \mid f(q) \leq a\}$. If f has no critical values in $[a, b]$, for $a < b$, then the subsets M_a and M_b of M are homotopy-equivalent.

2. **The Morse Lemma.** Let M be a smooth m -dimensional submanifold of $\mathbb{R}^n$, and let $f : M \rightarrow \mathbb{R}$ be a smooth function on M with a nondegenerate critical point p of index k . Then there is a smooth parametrization $\varphi : U \rightarrow M$ of M at p , with U an open neighborhood of $0 \in \mathbb{R}^m$ and $\varphi(0) = p$, such that

$$f \circ \varphi(x_1, \dots, x_m) = f(p) - x_1^2 - \cdots - x_k^2 + x_{k+1}^2 + \cdots + x_m^2.$$

In particular, a critical point of index 0 is a local minimum of f , whereas a critical point of index m is a local maximum of f .

3. **Abundance of Morse functions.** (i) *Morse functions are generic.* Every smooth compact submanifold of $\mathbb{R}^n$ has a Morse function. (In fact, if we endow the set $C^\infty(M)$ of smooth functions on M with the so-called Whitney topology, then the set of Morse functions on M is an open and dense subset of $C^\infty(M)$. In particular, there are Morse functions arbitrarily close to any smooth function on M .)

(ii) *Generic height functions are Morse functions.* Let M be an m -dimensional submanifold of $\mathbb{R}^{m+1}$ (e.g., a smooth surface in $\mathbb{R}^3$). For $v \in \mathbb{S}^m$, the **height function** $h_v : M \rightarrow \mathbb{R}$ with respect to direction v is defined by $h_v(p) = \langle v, p \rangle$. The set of v for which h_v is not a Morse function has measure zero in $\mathbb{S}^m$.

4. **Passing critical levels.** Let $f : M \rightarrow \mathbb{R}$ be a smooth Morse function with exactly one critical level in (a, b) , and let a and b be regular values of f . Then

M_b is homotopy-equivalent to M_a with a cell of dimension k attached (cf. Section 32.3), where k is the index of the critical point in $f^{-1}([a, b])$. See Figure 32.7.1.

FIGURE 32.7.1

Passing a critical level of index 1 corresponds to attaching a 1-cell. Here M is the 2-torus embedded in $\mathbb{R}^3$, in standard vertical position, and f is the height function with respect to the vertical direction. Left: M_a , for a below the critical level of the lower saddle point of f . Middle: M_a with a 1-cell attached to it. Right: M_b , for b above the critical level of the lower saddle point of f . This set is homotopy-equivalent to the set in the middle part of the figure.

5. **Morse inequalities.** Let f be a Morse function on a compact m -dimensional smooth submanifold of $\mathbb{R}^n$. For each k , $0 \leq k \leq m$, the k th Morse number of f dominates the k th Betti number of M :

$$\mu_k(f) \geq \beta_k(M).$$

The Morse numbers of f are related to the Betti numbers and the Euler characteristic of M by the following identity:

$$\sum_{k=1}^m (-1)^k \mu_k(f) = \sum_{k=1}^m (-1)^k \beta_k(M) = \chi(M).$$

33 COMPUTATIONAL REAL ALGEBRAIC GEOMETRY

Bhubaneswar Mishra

INTRODUCTION

Computational real algebraic geometry studies various algorithmic questions dealing with the *real solutions* of a system of equalities, inequalities, and inequations of polynomials over the real numbers. This emerging field is largely motivated by the power and elegance with which it solves a broad and general class of problems arising in robotics, vision, computer-aided design, geometric theorem proving, etc.

The algorithmic problems that arise in this context are formulated as decision problems for the *first-order theory of reals* and the related problems of *quantifier elimination* (Section 33.1). The associated geometric structures are then examined via an exploration of the *semialgebraic sets* (Section 33.2). Algorithmic problems for semialgebraic sets are considered next. In particular, Section 33.3 discusses real algebraic numbers and their representation, relying on such classical theorems as Sturm's theorem and Thom's lemma (Section 33.3). This discussion is followed by a description of semialgebraic sets using the concept of *cylindrical algebraic decomposition* (CAD) in both one and higher dimensions (Sections 33.4 and 33.5). This leads to brief descriptions of two algorithmic approaches for the decision and quantifier elimination problems (Section 33.6): namely, Collins's algorithm based on CAD, and some more recent approaches based on critical points techniques and on reducing the multivariate problem to easier univariate problems. These new approaches rely on the work of several groups of researchers: Grigor'ev and Vorobjov [Gri88, GV88], Canny [Can88a, Can90], Heintz et al. [HRS90], Renegar [Ren91, Ren92a, Ren92b, Ren92c], and Basu et al. [BPR96]. A few representative applications of computational algebra conclude this chapter (Section 33.7).

33.1 FIRST-ORDER THEORY OF REALS

The *decision problem* for the first-order theory of reals is to determine if a *Tarski sentence* in the first-order theory of reals is true or false. The *quantifier elimination problem* is to determine if there is a logically equivalent quantifier-free formula for an arbitrary Tarski formula in the first-order theory of reals. As a result of Tarski's work, we have the following theorem.

THEOREM 33.1.1 [Tar51]

- Let Ψ be a Tarski sentence. There is an effective decision procedure for Ψ .
- Let Ψ be a Tarski formula. There is a quantifier-free formula ϕ logically equiv-

alent to Ψ . If Ψ involves only polynomials with rational coefficients, then so does the sentence ϕ .

Tarski formulas are formulas in a first-order language (defined by Tarski in 1930 [Tar51]) constructed from equalities, inequalities, and inequations of polynomials over the reals. Such formulas may be constructed by introducing logical connectives and universal and existential quantifiers to the atomic formulas. *Tarski sentences* are Tarski formulas in which all variables are bound by quantification.

GLOSSARY

Term: A constant, variable, or term combining two terms by an arithmetic operator: $\{+, -, \cdot, /\}$. A constant is a real number. A variable assumes a real number as its value. A term contains finitely many such algebraic variables: $x_1, x_2, \dots, x_n$.

Atomic formula: A formula comparing two terms by a binary relational operator: $\{=, \neq, >, <, \geq, \leq\}$.

Quantifier-free formula: An atomic formula, a negation of a quantifier-free formula given by the unary Boolean connective $\{\neg\}$, or a formula combining two quantifier-free formulas by a binary Boolean connective: $\{\Rightarrow, \wedge, \vee\}$. *Example:* The formula $(x^2 - 2 = 0) \wedge (x > 0)$ defines the (real algebraic) number $+\sqrt{2}$.

Tarski formula: If $\phi(y_1, \dots, y_r)$ is a quantifier-free formula, then it is also a Tarski formula. All the variables y_i are **free** in ϕ . Let $\Phi(y_1, \dots, y_r)$ and $\Psi(z_1, \dots, z_s)$ be two Tarski formulas (with free variables y_i and z_i , respectively); then a formula combining Φ and Ψ by a Boolean connective is a Tarski formula with free variables $\{y_i\} \cup \{z_i\}$. Lastly, if Q stands for a quantifier (either universal $\forall$ or existential $\exists$) and if $\Phi(y_1, \dots, y_r, x)$ is a Tarski formula (with free variables x and y), then

$$(Q x) [\Phi(y_1, \dots, y_r, x)]$$

is a Tarski formula with only the y 's as free variables. The variable x is **bound** in $(Q x)[\Phi]$.

Tarski sentence: A Tarski formula with no free variable.

Example: $(\exists x) (\forall y) [y^2 - x < 0]$. This Tarski sentence is false.

Prenex Tarski formula: A Tarski formula of the form

$$(Q x_1) (Q x_2) \cdots (Q x_n) [\phi(y_1, y_2, \dots, y_r, x_1, \dots, x_n)],$$

where ϕ is quantifier-free. The string of quantifiers $(Q x_1) (Q x_2) \cdots (Q x_n)$ is called the **prefix** and ϕ is called the **matrix**.

Prenex form of a Tarski formula, Ψ : A prenex Tarski formula logically equivalent to Ψ . For every Tarski formula, one can find its prenex form using a simple procedure that works in four steps: (1) eliminate redundant quantifiers; (2) rename variables so that the same variable does not occur as free and bound; (3) move negations inward; and finally, (4) push quantifiers to the left.

Extension of a Tarski formula, $\Phi(y_1, \dots, y_r)$ with free variables $\{y_1, \dots, y_r\}$: The set of all $\langle \zeta_1, \dots, \zeta_r \rangle \in \mathbb{R}^r$ such that

$$\Phi(\zeta_1, \dots, \zeta_r) = \text{True}.$$

THE DECISION PROBLEM

The general *decision problem* for the first-order theory of reals is to determine if a given Tarski sentence is true or false. A particularly interesting special case of the problem is when all the quantifiers are existential. We refer to the decision problem in this case as the *existential problem* for the first-order theory of reals.

The general decision problem was shown to be decidable by Tarski [Tar51]. However, the complexity of Tarski's original algorithm could only be given by a very rapidly growing function of the input size (e.g., a function that could not be expressed as a bounded tower of exponents of the input size). The first algorithm with substantial improvement over Tarski's algorithm was due to Collins [Col75]; it has a doubly-exponential time complexity in the number of variables appearing in the sentence. Further improvements have been made by a number of researchers (Grigor'ev-Vorobjov [Gri88, GV88], Canny [Can88b, Can93], Heintz et al. [HRS89, HRS90], Renegar [Ren92a,b,c]) and most recently by Basu et al. [BPR98].

In the following, we assume that our Tarski sentence is presented in its prenex form:

$$(\mathcal{Q}_1 \mathbf{x}^{[1]}) (\mathcal{Q}_2 \mathbf{x}^{[2]}) \cdots (\mathcal{Q}_\omega \mathbf{x}^{[\omega]}) [\psi(\mathbf{x}^{[1]}, \dots, \mathbf{x}^{[\omega]})],$$

where the $\mathcal{Q}_i$'s form a sequence of alternating quantifiers (i.e., $\forall$ or $\exists$, with every pair of consecutive quantifiers distinct), with $\mathbf{x}^{[i]}$ a partition of the variables

$$\bigcup_{i=0}^{\omega} \mathbf{x}^{[i]} = \{x_1, x_2, \dots, x_n\} \triangleq \mathbf{x}, \quad \text{and} \quad |\mathbf{x}^{[i]}| = n_i,$$

and where ψ is a quantifier-free formula with atomic predicates consisting of polynomial equalities and inequalities of the form

$$g_i \left(\mathbf{x}^{[1]}, \dots, \mathbf{x}^{[\omega]} \right) \begin{matrix} \geq \\ \leq \end{matrix} 0, \quad i = 1, \dots, m.$$

Here, g_i is a multivariate polynomial (over $\mathbb{R}$ or $\mathbb{Q}$, as the case may be) of total degree bounded by d . There are a total of m such polynomials. The special case $\omega = 1$ reduces the problem to that of the existential problem for the first-order theory of reals.

If the polynomials of the basic equalities, inequalities, inequations, etc., are over the rationals, then we assume that their coefficients can be stored with at most L bits. Thus the arithmetic complexity can be described in terms of n , n_i , ω , m , and d , and the bit complexity will involve L as well.

Table 33.1.1 highlights a representative set of known bit-complexity results for the decision problem.

QUANTIFIER ELIMINATION PROBLEM

Formally, given a Tarski formula of the form,

$$\Psi(\mathbf{x}^{[0]}) = (\mathcal{Q}_1 \mathbf{x}^{[1]}) (\mathcal{Q}_2 \mathbf{x}^{[2]}) \cdots (\mathcal{Q}_\omega \mathbf{x}^{[\omega]}) [\psi(\mathbf{x}^{[0]}, \mathbf{x}^{[1]}, \dots, \mathbf{x}^{[\omega]})],$$

where ψ is a quantifier-free formula, the *quantifier elimination problem* is to construct another quantifier-free formula, $\phi(\mathbf{x}^{[0]})$, such that $\phi(\mathbf{x}^{[0]})$ holds if and

TABLE 33.1.1 Selected time complexity results.

GENERAL OR EXISTENTIAL	TIME COMPLEXITY	SOURCE
General	$L^3(md)2^{O(\sum n_i)}$	[Col75]
Existential	$L^{O(1)}(md)^{O(n^2)}$	[GV92]
General	$L^{O(1)}(md)^{(O(\sum n_i))^{4\omega-2}}$	[Gri88]
Existential	$L^{1+o(1)}(m)^{(n+1)}(d)^{O(n^2)}$	[Can88b, Can93]
General	$(L \log L \log \log L)(md)^{(2^{O(\omega)})\prod n_i}$	[Ren92a,b,c]
Existential	$(L \log L \log \log L)m(m/n)^n(d)^{O(n)}$	[BPR96]
General	$(L \log L \log \log L)(m)^{\prod(n_i+1)}(d)^{\prod O(n_i)}$	[BPR96]

only if $\Psi(\mathbf{x}^{[0]})$ holds. Such a quantifier-free formula takes the form

$$\phi(\mathbf{x}^{[0]}) \equiv \bigvee_{i=1}^I \bigwedge_{j=1}^{J_i} \left(f_{i,j}(\mathbf{x}^{[0]}) \geq 0 \right),$$

where $f_{i,j} \in \mathbb{R}[\mathbf{x}^{[0]}]$ is a multivariate polynomial with real coefficients.

Significantly improved bounds were given by Basu et al. [BPR96] and are summarized as follows:

$$\begin{aligned} I &\leq (m)^{\prod(n_i+1)}(d)^{\prod O(n_i)} \\ J_i &\leq (m)^{\prod_{i>0}(n_i+1)}(d)^{\prod_{i>0} O(n_i)}. \end{aligned}$$

The total degrees of the polynomials $f_{i,j}(\mathbf{x}^{[0]})$ are bounded by

$$(d)^{\prod_{i>0} O(n_i)}.$$

Nonetheless, comparing the above bounds to the bounds obtained in *semilinear geometry*, it appears that the “combinatorial part” of the complexity of both the formula and the computation could be improved to $(m)^{\prod_{i>0}(n_i+1)}$. As a consequence of some recent results of Basu [Bas99], the best bound for the size of the equivalent quantifier-free formula is now

$$I, J_i \leq (m)^{\prod_{i>0}(n_i+1)}(d)^{n'_0 \prod_{i>0} O(n_i)},$$

where $n'_0 = \min(n_0, \tau \prod_{i>0}(n_i+1))$ and τ is a bound on the number of free variables occurring in any polynomial in the original Tarski formula. The total degrees of the polynomials $f_{i,j}(\mathbf{x}^{[0]})$ are still bounded by

$$(d)^{\prod_{i>0} O(n_i)}.$$

Furthermore, the algorithmic complexity of Basu’s new procedure involves only $(m)^{\prod_{i>0}(n_i+1)}(d)^{n'_0 \prod_{i>0} O(n_i)}$ arithmetic operations.

Lower bound results for the quantifier elimination problem can be found in Davenport and Heintz [DH88]. They showed that for every n , there exists a Tarski

formula Ψ_n with n quantifiers, of length $O(n)$, and of constant degree, such that any quantifier-free formula ψ_n logically equivalent to Ψ_n must involve polynomials of

$$\text{degree} = 2^{2^{\Omega(n)}} \quad \text{and} \quad \text{length} = 2^{2^{\Omega(n)}}.$$

Note that in the simplest possible case (i.e., $d = 2$ and $n_i = 2$), upper and lower bounds are doubly exponential and match well. This result, however, does not imply a similar lower bound for the decision problems.

33.2 SEMIALGEBRAIC SETS

Every quantifier-free formula composed of polynomial inequalities and Boolean connectives defines a semialgebraic set. Thus, these semialgebraic sets play an important role in real algebraic geometry.

GLOSSARY

Semialgebraic set: A subset $S \subseteq \mathbb{R}^n$ defined by a set-theoretic expression involving a system of polynomial inequalities

$$S = \bigcup_{i=1}^I \bigcap_{j=1}^{J_i} \left\{ \langle \xi_1, \dots, \xi_n \rangle \in \mathbb{R}^n \mid \text{sgn}(f_{i,j}(\xi_1, \dots, \xi_n)) = s_{i,j} \right\},$$

where the $f_{i,j}$'s are multivariate polynomials over $\mathbb{R}$ and the $s_{i,j}$'s are corresponding sets of signs in $\{-1, 0, +1\}$.

Real algebraic set: A subset $Z \subseteq \mathbb{R}^n$ defined by a system of algebraic equations.

$$Z = \left\{ \langle \xi_1, \dots, \xi_n \rangle \in \mathbb{R}^n \mid f_1(\xi_1, \dots, \xi_n) = \dots = f_m(\xi_1, \dots, \xi_n) = 0 \right\},$$

where the f_i 's are multivariate polynomials over $\mathbb{R}$.

Semialgebraic map: A map $\theta : S \rightarrow T$, from a semialgebraic set $S \subseteq \mathbb{R}^m$ to a semialgebraic set $T \subseteq \mathbb{R}^n$, such that its graph $\{ \langle s, \theta(s) \rangle \in \mathbb{R}^{m+n} : s \in S \}$ is a semialgebraic set in $\mathbb{R}^{m+n}$. Note that projection, being linear, is a semialgebraic map.

TARSKI-SEIDENBERG THEOREM

Equivalently, semialgebraic sets can be defined as

$$S = \left\{ \langle \xi_1, \dots, \xi_n \rangle \in \mathbb{R}^n \mid \psi(\xi_1, \dots, \xi_n) = \text{True} \right\},$$

where $\psi(x_1, \dots, x_n)$ is a quantifier-free formula involving n algebraic variables. As a direct corollary of Tarski's theorem on quantifier elimination, we see that extensions of Tarski formulas are also semialgebraic sets.

While real algebraic sets are quite interesting and would be natural objects of study in this context, *they are not closed under projection onto a subspace*. Hence they tend to be unwieldy. However, *semialgebraic sets are closed under projection*. This follows from a more general result: the famous **Tarski-Seidenberg theorem** which is an immediate consequence of quantifier elimination, since images are described by formulas involving only existential quantifiers.

THEOREM 33.2.1 *Tarski-Seidenberg Theorem* [Sei74]
