Let S be a semialgebraic set in $\mathbb{R}^m$, and let $\theta : \mathbb{R}^m \rightarrow \mathbb{R}^n$ be a semialgebraic map. Then $\theta(S)$ is semialgebraic in $\mathbb{R}^n$.

In fact, semialgebraic sets can be defined simply as the smallest class of subsets of $\mathbb{R}^n$ containing real algebraic sets and closed under projection.

GLOSSARY

Connected component of a semialgebraic set: A maximal connected subset of a semialgebraic set. Semialgebraic sets have a finite number of connected components and these are also semialgebraic.

Semialgebraic decomposition of a semialgebraic set S : A finite collection $\mathcal{K}$ of disjoint connected semialgebraic subsets of S whose union is S . The collection of connected components of a semialgebraic set forms a semialgebraic decomposition. Thus, every semialgebraic set admits a semialgebraic decomposition.

Set of sample points for S : A finite number of points meeting every nonempty connected component of S .

Sign assignment: A vector of sign values of a set of polynomials at a point p . More formally, let $\mathcal{F}$ be a set of real multivariate polynomials in n variables. Any point $p = \langle \xi_1, \dots, \xi_n \rangle \in \mathbb{R}^n$ has a **sign assignment** with respect to $\mathcal{F}$ as follows:

$$\text{sgn}_{\mathcal{F}}(p) = \left\langle \text{sgn}(f(\xi_1, \dots, \xi_n)) \mid f \in \mathcal{F} \right\rangle.$$

A sign assignment induces an equivalence relation: Given two points $p, q \in \mathbb{R}^n$, we say

$$p \sim_{\mathcal{F}} q, \quad \text{if and only if} \quad \text{sgn}_{\mathcal{F}}(p) = \text{sgn}_{\mathcal{F}}(q).$$

Sign class of $\mathcal{F}$: An equivalence class in the partition of $\mathbb{R}^n$ defined by the equivalence relation $\sim_{\mathcal{F}}$.

Semialgebraic decomposition for $\mathcal{F}$: A finite collection of disjoint connected semialgebraic subsets $\{C_i\}$ such that each C_i is contained in some semialgebraic sign class of $\mathcal{F}$. That is, the sign of each $f \in \mathcal{F}$ is **invariant** in each C_i . The collection of connected components of the sign-invariant sets for $\mathcal{F}$ forms a semialgebraic decomposition for $\mathcal{F}$.

Cell decomposition for $\mathcal{F}$: A semialgebraic decomposition for $\mathcal{F}$ into finitely many disjoint semialgebraic subsets $\{C_i\}$ called **cells**, such that each cell C_i is homeomorphic to $\mathbb{R}^{\delta(i)}$, $0 \leq \delta(i) \leq n$. $\delta(i)$ is called the **dimension of the cell** C_i , and C_i is called a **$\delta(i)$ -cell**.

Cellular decomposition for $\mathcal{F}$: A cell decomposition for $\mathcal{F}$ such that the closure $\overline{C_i}$ of each cell C_i is a union of cells C_j : $\overline{C_i} = \bigcup_j C_j$.

CONNECTED COMPONENTS OF SEMIALGEBRAIC SETS

A consequence of the Milnor-Thom result [Mil64, Tho65] gives a bound for the number (the zeroth **Betti number**, $B_0(S)$) of connected components of a basic semialgebraic set S : the bound is polynomial in the number m and degree d of the polynomials defining S and singly exponential in the number of variables, n . The current best bound for $B_0(S)$ is due to Pollack and Roy [PR93]: $B_0(S) = O(md)^n$.

Most recent work of Basu ([Bas01], Theorem 4) provides even more precise information about the topological complexity of basic semialgebraic sets through the **higher-order Betti numbers**. While $B_0(S)$ measures the number of connected components of the semialgebraic set S , intuitively, $B_i(S)$ ($i > 0$) measures the number of i -dimensional holes in S . The following bound on B_i is due to Basu:

THEOREM 33.2.2

Let $S \subseteq \mathbb{R}^n$ be the set defined by the conjunction of m inequalities,

$$f_i(x_1, \dots, x_n) \geq 0, \quad f_i \in \mathbb{R}[x_1, \dots, x_n], \\ \text{degree}(f_i) \leq d, \quad 1 \leq i \leq m,$$

contained in a variety $V(Q)$ of real dimension n' , and

$$\text{degree}(Q) \leq d.$$

Then,

$$B_i(S) \leq m^{n'-i} O(d)^n.$$

A key problem in computational real algebraic geometry is to compute at least one point in each connected component of each nonempty sign assignment. An elegant solution to this problem is obtained by Collins's **cylindrical algebraic decomposition** (CAD), which is, in fact, a cell decomposition; see [Section 33.5](#) below. A related question is to provide a finitary representation for these sample points, e.g., each coordinate of the sample point may be a *real algebraic number*.

Currently, the best algorithm computing a finite set of points of bounded size that intersects *every connected component* of each nonempty sign condition is due to Basu et al. [BPR98] and has an arithmetic time-complexity of $m(m/n)^n d^{O(n)}$.

33.3 REAL ALGEBRAIC NUMBERS

Real algebraic numbers are real roots of rational univariate polynomials and provide finitary representation for some of the basic objects (e.g., sample points). Furthermore, we note that (1) real algebraic numbers have effective finitary representation, (2) field operations and polynomial evaluation on real algebraic numbers are efficiently (polynomially) computable, and (3) conversions among various representations of real algebraic numbers are efficiently (polynomially) computable. The key machinery used in describing and manipulating real algebraic numbers relies upon techniques based on the Sturm-Sylvester theorem, Thom's lemma, resultant construction, and various bounds for real root separation.

GLOSSARY

Real algebraic number: A real root α of a univariate polynomial $p(t) \in \mathbb{Z}[t]$ with integer coefficients.

Polynomial for α : A univariate polynomial p such that α is a real root of p .

Minimal polynomial of α : A univariate polynomial p of minimal degree defining α as above.

Degree of a nonzero real algebraic number: The degree of its minimal polynomial. By convention, the degree of the 0 polynomial is $-\infty$.

OPERATIONS ON REAL ALGEBRAIC NUMBERS

Note that if α and β are real algebraic numbers, then so are $-\alpha$, α^{-1} (assuming $\alpha \neq 0$), $\alpha + \beta$, and $\alpha \cdot \beta$. These facts can be constructively proved using the algebraic properties of a resultant construction.

THEOREM 33.3.1

The real algebraic numbers form a field.

A real algebraic number α can be represented by a polynomial for α and a component that identifies the root. There are essentially three types of information that may be used for this identification: *order* (where we assume the real roots are indexed from left to right), *sign* (by a vector of signs), or *interval* (an interval that contains exactly one root).

A classical technique due to Sturm and Sylvester shows how to compute the number of real roots of a univariate polynomial $p(t)$ in an interval $[a, b]$. One important use of this classical theorem is to compute a sequence of relatively small (nonoverlapping) intervals that isolate the real roots of p .

GLOSSARY

Sturm sequence of a pair of polynomials $p(t)$ and $q(t) \in \mathbb{R}[t]$:

$$\overline{\text{STURM}}(p, q) = \langle \hat{r}_0(t), \hat{r}_1(t), \dots, \hat{r}_s(t) \rangle,$$

where

$$\begin{aligned} \hat{r}_0(t) &= p(t) \\ \hat{r}_1(t) &= q(t) \\ &\vdots \\ \hat{r}_{i-1}(t) &= \hat{q}_i(t) \hat{r}_i(t) - \hat{r}_{i+1}(t), & \deg(\hat{r}_{i+1}) < \deg(\hat{r}_i) \\ &\vdots \\ \hat{r}_{s-1}(t) &= \hat{q}_s(t) \hat{r}_s(t). \end{aligned}$$

Number of variations in sign of a finite sequence $\vec{c}$ of real numbers: Number of times the entries change sign when scanned sequentially from left to right; denoted $\text{Var}(\vec{c})$.

For a vector of polynomials $\overline{P} = \langle p_1(t), \dots, p_m(t) \rangle$ and a real number a :

$$\text{Var}_a(\overline{P}) = \text{Var}(\overline{P}(a)) = \text{Var}(\langle p_1(a), \dots, p_m(a) \rangle).$$

Formal derivative: $p'(t) = D(p(t))$, where $D: \mathbb{R}[t] \rightarrow \mathbb{R}[t]$ is the (formal) derivative map, taking t^n to nt^{n-1} and $a \in \mathbb{R}$ (a constant) to 0.

STURM-SYLVESTER THEOREM

THEOREM 33.3.2 *Sturm-Sylvester Theorem* [Stu35, Syl53]

Let $p(t)$ and $q(t) \in \mathbb{R}[t]$ be two real univariate polynomials. Then, for any interval $[a, b] \subseteq \mathbb{R} \cup \{\pm\infty\}$ (where $a < b$):

$$\text{Var}[\overline{P}]_a^b = c_p[q > 0]_a^b - c_p[q < 0]_a^b,$$

where

$$\begin{aligned} \overline{P} &\triangleq \overline{\text{STURM}}(p, p'q), \\ \text{Var}[\overline{P}]_a^b &\triangleq \text{Var}_a(\overline{P}) - \text{Var}_b(\overline{P}), \end{aligned}$$

and $c_p[\mathcal{P}]_a^b$ counts the number of distinct real roots (without counting multiplicity) of p in the interval (a, b) at which the predicate $\mathcal{P}$ holds.

Note that if we take $S_p \triangleq \overline{\text{STURM}}(p, p')$ (i.e., $q = 1$) then

$$\begin{aligned} \text{Var}[S_p]_a^b &= c_p[\text{True}]_a^b - c_p[\text{False}]_a^b \\ &= \# \text{ of distinct real roots of } p \text{ in } (a, b). \end{aligned}$$

COROLLARY 33.3.3

Let $p(t)$ and $q(t)$ be two polynomials with coefficients in a real closed field K . For any interval $[a, b]$ as before, we have

$$\begin{bmatrix} 1 & 1 & 1 \\ 0 & 1 & -1 \\ 0 & 1 & 1 \end{bmatrix} \begin{bmatrix} c_p[q = 0]_a^b \\ c_p[q > 0]_a^b \\ c_p[q < 0]_a^b \end{bmatrix} = \begin{bmatrix} \text{Var}[\overline{\text{STURM}}(p, p')]_a^b \\ \text{Var}[\overline{\text{STURM}}(p, p'q)]_a^b \\ \text{Var}[\overline{\text{STURM}}(p, p'q^2)]_a^b \end{bmatrix}.$$

These identities as well as some related algorithmic results (the so-called BKR-algorithm) are based on results of Ben-Or et al. [BKR86] and their extensions by others. Using this identity, it is a fairly simple matter to decide the sign conditions of a single univariate polynomial q at the roots of a univariate polynomial p . It is possible to generalize this idea to decide the sign conditions of a sequence of univariate polynomials $q_0(t), q_1(t), \dots, q_n(t)$ at the roots of a single polynomial

$p(t)$ and hence give an efficient (both sequential and parallel) algorithm for the decision problem for Tarski sentences involving univariate polynomials. Further applications in the context of general decision problems are described below.

GLOSSARY

Fourier sequence of a real univariate polynomial $p(t)$ of degree n :

$$\overline{\text{FOURIER}}(p) = \langle p^{(0)}(t) = p(t), p^{(1)}(t) = p'(t), \dots, p^{(n)}(t) \rangle,$$

where $p^{(i)}$ is the i th derivative of p with respect to t .

Sign-invariant region of $\mathbb{R}$ determined by a sign sequence $\bar{s}$ with respect to $\overline{\text{FOURIER}}(p)$: The region $R(\bar{s})$ with the property that $\xi \in R(\bar{s})$ if and only if $\text{sgn}(p^{(i)}(\xi)) = s_i$.

THOM'S LEMMA

LEMMA 33.3.4 *Thom's Lemma* [Tho65]

Every nonempty sign-invariant region $R(\bar{s})$ (determined by a sign sequence $\bar{s}$ with respect to $\overline{\text{FOURIER}}(p)$) must be connected, i.e., consists of a single interval.

Let $\text{sgn}_{\xi}(\overline{\text{FOURIER}}(p))$ be the sign sequence obtained by evaluating the polynomials of $\overline{\text{FOURIER}}(p)$ at ξ . Then as an immediate corollary of Thom's lemma, we have:

COROLLARY 33.3.5

Let ξ and ζ be two real roots of a real univariate polynomial $p(t)$ of positive degree $n > 0$. Then $\xi = \zeta$, if

$$\text{sgn}_{\xi}(\overline{\text{FOURIER}}(p')) = \text{sgn}_{\zeta}(\overline{\text{FOURIER}}(p')).$$

REPRESENTATION OF REAL ALGEBRAIC NUMBERS

Let $p(t)$ be a univariate polynomial of degree d with integer coefficients. Assume that the distinct real roots of $p(t)$ have been enumerated as follows:

$$\alpha_1 < \alpha_2 < \dots < \alpha_{j-1} < \alpha_j = \alpha < \alpha_{j+1} < \dots < \alpha_l,$$

where $l \leq d = \deg(p)$. Then we can represent any of its roots uniquely and in a finitary manner.

GLOSSARY

Order representation of an algebraic number: A pair consisting of its polynomial p and its index j in the monotone sequence enumerating the real roots of p : $\langle \alpha \rangle_o = \langle p, j \rangle$. *Example:* $\langle \sqrt{2} + \sqrt{3} \rangle_o = \langle x^4 - 10x^2 + 1, 4 \rangle$.

Sign representation of an algebraic number: A pair consisting of its polynomial p and a sign sequence $\bar{s}$ representing the signs of its Fourier sequence evaluated at the root: $\langle \alpha \rangle_s = \langle p, \bar{s} = \text{sgn}_\alpha(\text{FOURIER}(p')) \rangle$. *Example:* $\langle \sqrt{2} + \sqrt{3} \rangle_s = \langle x^4 - 10x^2 + 1, (+1, +1, +1) \rangle$. The validity of this representation follows easily from Thom's lemma.

Interval representation of an algebraic number: A triple consisting of its polynomial p and the two endpoints of an isolating interval, (l, r) ($l, r \in \mathbb{Q}$, $l < r$), containing only α : $\langle \alpha \rangle_i = \langle p, l, r \rangle$. *Example:* $\langle \sqrt{2} + \sqrt{3} \rangle_i = \langle x^4 - 10x^2 + 1, 3, 7/2 \rangle$.

33.4 UNIVARIATE DECOMPOSITION

In the one-dimensional case, a semialgebraic set is the union of finitely many intervals whose endpoints are real algebraic numbers. For instance, given a set of univariate defining polynomials:

$$\mathcal{F} = \left\{ f_i(x) \in \mathbb{Q}[x] \mid i = 1, \dots, m \right\},$$

we may enumerate all the real roots of the f_i 's (i.e., the real roots of the single polynomial $F = \prod f_i$) as

$$-\infty < \xi_1 < \xi_2 < \dots < \xi_{i-1} < \xi_i < \xi_{i+1} < \dots < \xi_s < +\infty,$$

and consider the following finite set $\mathcal{K}$ of elementary intervals defined by these roots:

$$\begin{aligned} &[-\infty, \xi_1), [\xi_1, \xi_1], (\xi_1, \xi_2), \dots, \\ &(\xi_{i-1}, \xi_i), [\xi_i, \xi_i], (\xi_i, \xi_{i+1}), \dots, [\xi_s, \xi_s], (\xi_s, +\infty]. \end{aligned}$$

Note that $\mathcal{K}$ is, in fact, a cellular decomposition for $\mathcal{F}$. Any semialgebraic set S defined by $\mathcal{F}$ is simply the union of a subset of elementary intervals in $\mathcal{K}$. Furthermore, for each interval $C \in \mathcal{K}$, we can compute a sample point α_C as follows:

$$\alpha_C = \begin{cases} \xi_1 - 1, & \text{if } C = [-\infty, \xi_1); \\ \xi_i, & \text{if } C = [\xi_i, \xi_i]; \\ (\xi_i + \xi_{i+1})/2, & \text{if } C = (\xi_i, \xi_{i+1}); \\ \xi_s + 1, & \text{if } C = (\xi_s, +\infty]. \end{cases}$$

Now, given a first-order formula involving a single variable, its validity can be checked by evaluating the associated univariate polynomials at the sample points. Using the algorithms for representing and manipulating real algebraic numbers, we see that the bit complexity of the decision algorithm is bounded by $(Lmd)^{O(1)}$. The resulting cellular decomposition has no more than $2md + 1$ cells.

Using variants of the theorem due to Ben-Or et al. [BKR86], Thom's lemma, and some results on parallel computations in linear algebra, one can show that this univariate decision problem is "well-parallelizable," i.e., the problem is solvable by uniform circuits of bounded depth and polynomially many "gates" (simple processors).

33.5 MULTIVARIATE DECOMPOSITION

A straightforward generalization of the standard univariate decomposition to higher dimensions is provided by Collins's cylindrical algebraic decomposition [Col75]. In order to represent a semialgebraic set $S \subseteq \mathbb{R}^n$, we may assume recursively that we can construct a cell decomposition of its projection $\pi(S) \subseteq \mathbb{R}^{n-1}$ (also a semialgebraic set), and then decompose S as a union of the *sectors* and *sections* in the cylinders above each cell of the projection, $\pi(S)$. This also leads to a cell decomposition of S . One can further assign an algebraic sample point in each cell of S recursively in a straightforward manner.

If $\mathcal{F}$ is a set of polynomials defining the semialgebraic set $S \subseteq \mathbb{R}^n$, then at no additional cost, we may in fact compute a cell decomposition for $\mathcal{F}$ using the procedure described above. Such a decomposition leads to a *cylindrical algebraic decomposition* for $\mathcal{F}$.

GLOSSARY

Cylindrical algebraic decomposition (CAD): A recursively defined cell decomposition of $\mathbb{R}^n$ for $\mathcal{F}$. The decomposition is a cellular decomposition if the set of defining polynomials $\mathcal{F}$ satisfies certain nondegeneracy conditions.

In the recursive definition, the cells of n -dimensional CAD are constructed from an $(n-1)$ -dimensional CAD: Every $(n-1)$ -dimensional CAD cell C' has the property that the distinct real roots of $\mathcal{F}$ over C' vary continuously as a function of the points of C' .

Moreover, the following quantities remain invariant over a $(n-1)$ -dimensional cell: (1) the total number of complex roots of each polynomial of $\mathcal{F}$; (2) the number of distinct complex roots of each polynomial of $\mathcal{F}$; and (3) the total number of common complex roots of every distinct pair of polynomials of $\mathcal{F}$.

These conditions can be expressed by a set $\Phi(\mathcal{F})$ of at most $O(md)^2$ polynomials in $n-1$ variables, obtained by considering *principal subresultant coefficients* (PSC's). Thus, they correspond roughly to *resultants* and *discriminants*, and ensure that the polynomials of $\mathcal{F}$ do not intersect or “fold” in a cylinder over an $(n-1)$ -dimensional cell. The polynomials in $\Phi(\mathcal{F})$ are each of degree no more than d^2 .

More formally, an $\mathcal{F}$ -sign-invariant cylindrical algebraic decomposition of $\mathbb{R}^n$ is:

- **BASE CASE:** $n = 1$. A univariate cellular decomposition of $\mathbb{R}^1$ as in the previous section.
- **INDUCTIVE CASE:** $n > 1$. Let $\mathcal{K}'$ be a $\Phi(\mathcal{F})$ -sign-invariant CAD of $\mathbb{R}^{n-1}$. For each cell $C' \in \mathcal{K}'$, define an ***auxiliary polynomial*** $g_{C'}(x_1, \dots, x_{n-1}, x_n)$ as the product of those polynomials of $\mathcal{F}$ that do not vanish over the $(n-1)$ -dimensional cell, C' . The real roots of the auxiliary polynomial $g'_{C'}$ over C' give rise to a finite number (perhaps zero) of semialgebraic continuous functions, which partition the cylinder $C' \times (\mathbb{R} \cup \{\pm\infty\})$ into finitely many $\mathcal{F}$ -sign-invariant “slices.” The auxiliary polynomials are of degree no larger than md .

FIGURE 33.5.1

Sections and sectors “slicing” the cylinder over a lower dimensional cell.

Assume that the polynomial $g_{C'}(p', x_n)$ has l distinct real roots for each $p' \in C'$: $r_1(p'), r_2(p'), \dots, r_l(p')$, each r_i being a continuous function of p' . The following sectors and sections are cylindrical over C' (see Figure 33.5.1):

$$\begin{aligned} C_0^* &= \{ \langle p', x_n \rangle \mid p' \in C' \wedge x_n \in [-\infty, r_1(p')) \}, \\ C_1 &= \{ \langle p', x_n \rangle \mid p' \in C' \wedge x_n \in [r_1(p'), r_2(p')] \}, \\ C_1^* &= \{ \langle p', x_n \rangle \mid p' \in C' \wedge x_n \in (r_1(p'), r_2(p')) \}, \\ &\vdots \\ C_l^* &= \{ \langle p', x_n \rangle \mid p' \in C' \wedge x_n \in (r_l(p'), +\infty] \}. \end{aligned}$$

The n -dimensional CAD is thus the union of all the sections and sectors computed over the cells of the $(n-1)$ -dimensional CAD.

A straightforward recursive algorithm to compute a CAD follows from the above description.

CYLINDRICAL ALGEBRAIC DECOMPOSITION

If we assume that the dimension n is a fixed constant, then the preceding cylindrical algebraic decomposition algorithm is polynomial in $m = |\mathcal{F}|$ and $d = \deg(\mathcal{F})$. However, the algorithm can be easily seen to be doubly-exponential in n as the number of polynomials produced at the lowest dimension is $(md)^{2^{O(n)}}$, each of degree no larger than $d^{2^{O(n)}}$. The number of cells produced by the algorithm is also *doubly-exponential*. This bound can be seen to be tight by a result due to Davenport and Heintz [DH88], and is related to their lower bound for the quantifier elimination problem (Section 33.1).

CONSTRUCTING SAMPLE POINTS

Cylindrical algebraic decomposition provides a sample point in every sign-invariant connected component for $\mathcal{F}$. However, the total number of sample points generated is doubly-exponential, while the number of connected components of all sign

conditions is only singly-exponential. In order to avoid this high complexity (both algebraic and combinatorial) of a CAD, many recent techniques for constructing sample points use a single projection to a line instead of a sequence of cascading projections. For instance, if one chooses a height function carefully then one can easily enumerate its critical points and then associate at least two such critical points to every connected component of the semialgebraic set. From these critical points, it will be possible to create at least one sample point per connected component. Using Bézout's bound, it is seen that only a singly-exponential number of sample points is created, thus improving the complexity of the underlying algorithms.

However, in order to arrive at the preceding conclusion using critical points, one requires certain genericity conditions that can be achieved by symbolically deforming the underlying semialgebraic sets. These infinitesimal deformations can be handled by extending the underlying field to a field of *Puiseux series*. Many of the significant complexity improvements based on these techniques have been due to a careful choice of the symbolic perturbation schemes which results in keeping the number of perturbation variables small.

33.6 ALGORITHMIC APPROACHES

COLLINS'S APPROACH

The decision problem for the first-order theory of reals can be solved easily using a cylindrical algebraic decomposition. First consider the existential problem for a sentence with only existential quantifiers,

$$(\exists \mathbf{x}^{[0]}) [\psi(\mathbf{x}^{[0]})].$$

This sentence is true if and only if there is a $q \in C$, a sample point in the cell C ,

$$q = \alpha^{[0]} = \langle \alpha_1, \dots, \alpha_n \rangle \in \mathbb{R}^n,$$

such that $\psi(\alpha^{[0]})$ is true. Thus we see that the decision problem for the purely existential sentence can be solved by simply evaluating the matrix ψ over the finitely many sample points in the associated CAD. This also implies that the existential quantifiers could be replaced by finitely many disjunctions ranging over all the sample points. Note that the same arguments hold for any semialgebraic decomposition with at least one sample point per sign-invariant connected component.

In the general case, one can describe the decision procedure by means of a search process that proceeds *only on* the coordinates of the sample points in the cylindrical algebraic decomposition. This follows because a sample point in a cell acts as a representative for any point in the cell as far as the sign conditions are concerned.

Consider a Tarski sentence

$$(\mathcal{Q}_1 \mathbf{x}^{[1]}) (\mathcal{Q}_2 \mathbf{x}^{[2]}) \dots (\mathcal{Q}_\omega \mathbf{x}^{[\omega]}) [\psi(\mathbf{x}^{[1]}, \dots, \mathbf{x}^{[\omega]})],$$

with $\mathcal{F}$ the set of polynomials appearing in the matrix ψ . Let $\mathcal{K}$ be a cylindrical algebraic decomposition of $\mathbb{R}^n$ for $\mathcal{F}$. Since the cylindrical algebraic decomposition

produces a sequence of decompositions:

$$\mathcal{K}_1 \text{ of } \mathbb{R}^1, \mathcal{K}_2 \text{ of } \mathbb{R}^2, \dots, \mathcal{K}_n \text{ of } \mathbb{R}^n,$$

such that the each cell $C_{i-1,j}$ of $\mathcal{K}_i$ is cylindrical over some cell C_{i-1} of $\mathcal{K}_{i-1}$, the search progresses by first finding cells C_1 of $\mathcal{K}_1$ such that

$$(\mathcal{Q}_2 x_2) \cdots (\mathcal{Q}_n x_n) [\psi(\alpha_{C_1}, x_2, \dots, x_n)] = \text{True}.$$

For each C_1 , the search continues over cells C_{12} of $\mathcal{K}_2$ cylindrical over C_1 such that

$$(\mathcal{Q}_3 x_3) \cdots (\mathcal{Q}_n x_n) [\psi(\alpha_{C_1}, \alpha_{C_{12}}, x_3, \dots, x_n)] = \text{True},$$

etc. Finally, at the bottom level the truth properties of the matrix ψ are determined by evaluating at all the coordinates of the sample points.

This produces a tree structure, where each node at the $(i-1)$ th level corresponds to a cell $C_{i-1} \in \mathcal{K}_{i-1}$ and its children correspond to the cells $C_{i-1,j} \in \mathcal{K}_i$ that are cylindrical over C_{i-1} . The leaves of the tree correspond to the cells of the final decomposition $\mathcal{K} = \mathcal{K}_n$. Because we only have finitely many sample points, the universal quantifiers can be replaced by finitely many conjunctions and the existential quantifiers by disjunctions. Thus, we label every node at the $(i-1)$ th level “AND” (respectively, “OR”) if $\mathcal{Q}_i$ is a universal quantifier $\forall$ (respectively, $\exists$) to produce a so-called AND-OR tree. The truth of the Tarski sentence is thus determined by simply evaluating this AND-OR tree.

A quantifier elimination algorithm can be devised by a similar reasoning and a slight modification of the CAD algorithm described above.

NEW APPROACHES USING CRITICAL POINTS

In order to avoid the cascading projections inherent in Collins’s algorithm, the new approaches employ a single projection to a one-dimensional set by using critical points in a manner described above. As before, we start with a sentence with only existential quantifiers,

$$(\exists \mathbf{x}^{[0]}) [\psi(\mathbf{x}^{[0]})].$$

Let $\mathcal{F} = \{f_1, \dots, f_m\}$ be the set of polynomials appearing in the matrix ψ .

Under certain genericity conditions, it is possible to produce a set of sample points such that every sign-invariant connected component of the decomposition induced by $\mathcal{F}$ contains at least one such point. Furthermore, these sample points are described by a set of univariate polynomial sequences, where each sequence is of the form

$$p(t), q_0(t), q_1(t), \dots, q_n(t),$$

and encodes a sample point $\langle \frac{q_1(\alpha)}{q_0(\alpha)}, \dots, \frac{q_n(\alpha)}{q_0(\alpha)} \rangle$. Here α is a root of p . Now the decision problem for the existential theory can be solved by deciding the sign conditions of the sequence of univariate polynomials

$$f_1(q_1/q_0, \dots, q_n/q_0), \dots, f_m(q_1/q_0, \dots, q_n/q_0),$$

at the roots of the univariate polynomial $p(t)$. Note that we have now reduced a multivariate problem to a univariate problem and can solve this by the BKR approach.

In order to keep the complexity reasonably small, one needs to ensure that the number of such sequences is small and that these polynomials are of low degree. Assuming that the polynomials in $\mathcal{F}$ are in general position, one can achieve this and compute the polynomials p and q_i (for example, by the u -resultant method in Renegar's algorithm).

If the genericity conditions are violated, one needs to symbolically deform the polynomials and carry out the computations on these polynomials with additional perturbation parameters. The Basu-Pollack-Roy (BPR) algorithm differs from Renegar's algorithm primarily in the manner in which these perturbations are made so that their effect on the algorithmic complexity is controlled.

Next consider an existential Tarski formula of the form

$$(\exists \mathbf{x}^{[0]}) [\psi(\mathbf{y}, \mathbf{x}^{[0]})],$$

where $\mathbf{y}$ represents the free variables. If we carry out the same computation as before over the ambient field $\mathbb{R}(\mathbf{y})$, we get a set of *parameterized* univariate polynomial sequences, each of the form

$$p(\mathbf{y}, t), q_0(\mathbf{y}, t), q_1(\mathbf{y}, t), \dots, q_n(\mathbf{y}, t).$$

For a fixed value of $\mathbf{y}$, say $\bar{\mathbf{y}}$, the polynomials

$$p(\bar{\mathbf{y}}, t), q_0(\bar{\mathbf{y}}, t), q_1(\bar{\mathbf{y}}, t), \dots, q_n(\bar{\mathbf{y}}, t)$$

can then be used as before to decide the truth or falsity of the sentence

$$(\exists \mathbf{x}^{[0]}) [\psi(\bar{\mathbf{y}}, \mathbf{x}^{[0]})].$$

Also, one may observe that the *parameter space* $\mathbf{y}$ can be partitioned into semialgebraic sets so that all the necessary information can be obtained by computing at sample values $\bar{\mathbf{y}}$.

This process can be extended to ω blocks of quantifiers, by replacing each block of variables by a finite number of cases, each involving only one new variable; the last step uses a CAD method for these ω -many variables.

33.7 APPLICATIONS

Computational real algebraic geometry finds applications in robotics, vision, computer-aided design, geometric theorem proving, and other fields. Important problems in robotics include the kinematic modeling, the inverse kinematic solution, the computation of the workspace and workspace singularities, and the planning of an obstacle-avoiding motion of a robot in a cluttered environment—all arising from the algebro-geometric nature of robot kinematics. In solid modeling, graphics, and vision, almost all applications involve the description of surfaces, the generation of various auxiliary surfaces such as blending and smoothing surfaces, the classification of various algebraic surfaces, the algebraic or geometric invariants associated with a surface, the effect of various affine or projective transformations of a surface, the description of surface boundaries, and so on.

To give examples of the nature of the solutions demanded by various applications, we discuss a few representative problems from robotics, engineering, and computer science.

ROBOT MOTION PLANNING

Given the initial and desired configurations of a robot (composed of rigid subparts) and a set of obstacles, find a collision-free continuous motion of the robot from the initial configuration to the final configuration.

The algorithm proceeds in several steps. The first step translates the problem to **configuration space**, a parameter space modeled as a low-dimensional algebraic manifold (assuming that the obstacles and the robot subparts are bounded by piecewise algebraic surfaces). The second step computes the set of configurations that avoid collisions and produces a semialgebraic description of this so-called “free space” (subspaces of the configuration space). Since the initial and final configurations correspond to two points in the configuration space, we simply have to test whether they lie in the same connected component of the free space. If so, they can be connected by a piecewise algebraic path. Such a path gives rise to an obstacle-avoiding motion of the robot(s). This path planning process can be carried out using Collins’s CAD [SS83], yielding an algorithm with doubly-exponential time complexity (Theorem 40.1.1). A singly-exponential time complexity algorithm (the *roadmap algorithm*) has been devised by Canny [Can88a] (Theorem 40.1.2). The main idea of Canny’s algorithm is to determine a one-dimensional connected subset (called the “roadmap”) of each connected component of the free space. Once these roadmaps are available, they can be used to link up two points in the same connected component. The main geometric idea is to construct roadmaps starting from the critical sets of some projection function. The basic roadmap algorithm has been improved and extended by several researchers over the last decade (Heintz et al. [HRS90], Gournay and Risler [GR93], Grigor’ev and Vorobjov [Gri88, GV88], and Canny [Can88a, Can90]).

OFFSET SURFACE CONSTRUCTION IN SOLID MODELING

Given a polynomial $f(x, y, z)$, whose zeros define an algebraic surface in three-dimensional space, compute the envelope of a family of spheres of radius r whose centers lie on the surface f . Such a surface is called a (two-sided) **offset surface** of f .

Let $p = \langle x, y, z \rangle$ be a point on the offset surface and $q = \langle u, v, w \rangle$ be a **footprint** of p on f ; that is, q is the point at which a normal from p to f meets f . Let $\vec{t}_1 = \langle t_{1,1}, t_{1,2}, t_{1,3} \rangle$ and $\vec{t}_2 = \langle t_{2,1}, t_{2,2}, t_{2,3} \rangle$ be two linearly independent tangent vectors to f at the point q . Then, we see that the system of polynomial equations

$$\begin{aligned} (x - u)^2 + (y - v)^2 + (z - w)^2 - r^2 &= 0, \\ f(u, v, w) &= 0, \\ (x - u)t_{1,1} + (y - v)t_{1,2} + (z - w)t_{1,3} &= 0, \\ (x - u)t_{2,1} + (y - v)t_{2,2} + (z - w)t_{2,3} &= 0, \end{aligned}$$

describes a surface in the (x, y, z, u, v, w) six-dimensional space, which, when projected into the three-dimensional space with coordinates (x, y, z) , gives the offset surface in an implicit form. The offset surface is computed by simply eliminating the variables u, v, w from the preceding set of equations.

This approach (the **envelope method**) of computing the offset surface has

several problematic features: the method does not deal with self-intersection in a clean way and, sometimes, generates additional points not on the offset surface. For a discussion of these and several other related problems in solid modeling, see [Hof89] and [Chapter 56](#) of this Handbook.

GEOMETRIC THEOREM PROVING

Given a geometric statement consisting of a finite set of hypotheses and a conclusion,

$$\begin{array}{ll} \text{Hypotheses} & : f_1(x_1, \dots, x_n) = 0, \dots, f_r(x_1, \dots, x_n) = 0 \\ \text{Conclusion} & : g(x_1, \dots, x_n) = 0 \end{array}$$

decide whether the conclusion $g = 0$ is a consequence of the hypotheses $((f_1 = 0) \wedge \dots \wedge (f_r = 0))$.

Thus we need to determine whether the following universally quantified first-order sentence holds:

$$\left(\forall x_1, \dots, x_n \right) \left[\left((f_1 = 0) \wedge \dots \wedge (f_r = 0) \right) \Rightarrow g = 0 \right].$$

One way to solve the problem is by first translating it into the form: decide if the following existentially quantified first-order sentence is unsatisfiable:

$$\left(\exists x_1, \dots, x_n, z \right) \left[(f_1 = 0) \wedge \dots \wedge (f_r = 0) \wedge (gz - 1) = 0 \right].$$

When the underlying domain is assumed to be the field of real numbers, then we may simply check whether the following multivariate polynomial (in $x_1, \dots, x_n, z$) has no real root:

$$f_1^2 + \dots + f_r^2 + (gz - 1)^2.$$

If, on the other hand, the underlying domain is assumed to be the field of complex numbers (an algebraically closed field), then other tools from computational algebra are used (e.g., techniques based on Hilbert's Nullstellensatz). In the general setting, some techniques based on Ritt-Wu characteristic sets have proven very powerful. See [Cho88].

For another approach to geometric theorem proving, see [Section 59.4](#).

CONNECTION TO SEMIDEFINITE PROGRAMMING

Checking **global nonnegativity** of a function of several variables occupies a central role in many areas of applied mathematics, e.g., optimization problems with polynomial objectives and constraints, as in quadratic, linear and boolean programming formulations. These problems have been shown to be NP-hard in the most general setting, but do admit good approximations involving polynomial-time computable relaxations. (See Parilo [Par00]).

Provide checkable conditions or procedure for verifying the validity of the proposition

$$F(x_1, \dots, x_n) \geq 0, \quad \forall x_1, \dots, x_n,$$

where F is a multivariate polynomial in the ring of multivariate polynomials over the reals, $\mathbb{R}[x_1, \dots, x_n]$.

An obvious necessary condition for F to be globally nonnegative is that it has even degree. On the other hand, a rather simple sufficient condition for a real-valued polynomial $F(x)$ to be globally nonnegative is the existence of a **sum-of-squares decomposition**:

$$F(x_1, \dots, x_n) = \sum_i f_i^2(x_1, \dots, x_n), \quad f_i(x_1, \dots, x_n) \in \mathbb{R}[x_1, \dots, x_n].$$

Thus one way to solve the global nonnegativity problem is by finding a sum-of-squares decomposition. Note that since there exist globally nonnegative polynomials not admitting a sum-of-squares decomposition (e.g., the Motzkin form $x^4y^2 + x^2y^4 + z^6 - 3x^2y^2z^2$), the procedure suggested below does not give a solution to the problem in all situations.

The procedure can be described as follows: express the given polynomial $F(x_1, \dots, x_n)$ of degree $2d$ as a quadratic form in all the monomials of degree less than or equal to d :

$$F(x_1, \dots, x_n) = z^T Q z, \quad z = [1, x_1, \dots, x_n, x_1x_2, \dots, x_n^d],$$

where Q is a constant matrix to be determined. If the above quadratic form can be solved for a positive semidefinite Q , then $F(x_1, \dots, x_n)$ is globally nonnegative. Since the variables in z are not algebraically independent, the matrix Q is not unique, but lives in an affine subspace. Thus, we need to determine if the intersection of this affine subspace and the positive semidefinite matrix cone is nonempty. This problem can be solved by a **semidefinite programming** feasibility problem:

$$\begin{aligned} \text{trace}(zz^T Q) &= F(x_1, \dots, x_n), \\ Q &\succeq 0. \end{aligned}$$

The dimensions of the matrix inequality are $\binom{n+d}{d} \times \binom{n+d}{d}$ and is polynomial for fixed number of variables (n) or fixed degree (d). Thus our question reduces to efficiently solvable semidefinite programming (SDP) problems.

33.8 SOURCES AND RELATED MATERIAL

SURVEYS

[Mis93]: A textbook for algorithmic algebra covering Gröbner bases, characteristic sets, resultants, and real algebra. [Chapter 8](#) gives many details of the classical results in computational real algebra.

[CJ98]: An anthology of key papers in computational real algebra and real algebraic geometry. Contains reprints of the following papers cited in this chapter: [BPR98, Col75, Ren91, Tar51].

[AB88]: A special issue of the *J. Symbolic Comput.* on computational real algebraic geometry. Contains several papers ([DH88, Gri88, GV88] cited here) addressing many key research problems in this area.

[BR90]: A very accessible and self-contained textbook on real algebra and real algebraic geometry.

[BCR98]: A self-contained textbook on real algebra and real algebraic geometry.

[HRR91]: A survey of many classical and recent results in computational real algebra.

[Cha94]: A survey of the connections among computational geometry, computational algebra, and computational real algebraic geometry.

[Tar51]: Primary reference for Tarski's classical result on the decidability of elementary algebra.

[Col75]: Collins's work improving the complexity of Tarski's solution for the decision problem [Tar51]. Also, introduces the concept of cylindrical algebraic decomposition (CAD).

[Ren91]: A survey of some recent results, improving the complexity of the decision problem and quantifier elimination problem for the first-order theory of reals. This is mostly a summary of the results first given in a sequence of papers by Renegar [Ren92a,b,c].

[Lat91]: A comprehensive textbook covering various aspects of robot motion planning problems and different solution techniques. [Chapter 5](#) includes a description of the connection between the motion planning problem and computational real algebraic geometry.

[SS83]: A classic paper in robotics showing the connection between the robot motion planning problem and the connectivity of semialgebraic sets using CAD. Contains several improved algorithmic results in computational real algebra.

[Can88a]: Gives a singly-exponential time algorithm for the robot motion planning problem and provides complexity improvement for many key problems in computational real algebra.

[Hof89]: A comprehensive textbook covering various computational algebraic techniques with applications to solid modeling. Contains a very readable description of Gröbner bases algorithms.

[Cho88]: A monograph on geometric theorem proving using Ritt-Wu characteristic sets. Includes computer-generated proofs of many classical geometric theorems.

GEOMETRIC DATA STRUCTURES AND SEARCHING

34 POINT LOCATION

Jack Snoeyink

INTRODUCTION

A basic question for computer applications that employ geometric structures (e.g., for computer graphics, geographic information systems, robotics, and databases) is: “Where am I?” Given a set of disjoint geometric objects, the ***point-location problem*** asks for the object containing a query point. Instances of the problem vary in the dimension and type of objects and whether the set is static or dynamic. Solutions vary in preprocessing time, space used, and query time.

Point location has inspired several techniques for structuring geometric data, which we survey in this chapter. We begin with point location in one dimension (Section 34.1) or in one polygon (Section 34.2). In two dimensions, we look at how techniques of persistence, fractional cascading, trapezoid graphs, or hierarchical triangulations can lead to optimal methods for point location in static subdivisions (Section 34.3), at the current best methods for dynamic subdivisions (Section 34.4), and at practical methods (Section 34.5). There are fewer results on point location in higher dimensions; these we mention in (Section 34.6).

34.1 ONE-DIMENSIONAL POINT LOCATION

The simplest nontrivial instance of point location is list searching. The objects are points $x_1 \leq \dots \leq x_n$ on the real line, presented in arbitrary order, and the intervals between them, (x_i, x_{i+1}) for $1 \leq i < n$. The answer to a query q is the name of the object containing q .

The list-searching problem already illustrates several aspects of general point location problems.

GLOSSARY

Preprocessing/queries: If one assumes that many queries will ask for the same input, then resources can profitably be spent building data structures to facilitate the search. Three resources are commonly analyzed:

Query time: Computation time to answer a single query, given a point location data structure. Usually a worst-case upper bound, expressed as a function of the number of objects in the structure, n .

Preprocessing time: Time required to build a point location structure for n objects.

Space: Memory used by the point location structure for n objects.

Decomposable problem: A problem whose answer can be obtained from the

answers to the same problem on the sets of an arbitrary partition of the input [Ben79, BS80]. As initially stated, one-dimensional point location is not decomposable—taking subsets of the points gives different intervals. If, however, we choose to name each interval by its lower endpoint, then we can report (the lower endpoint of) the interval containing a query from the intervals in the subproblems—simply report the highest “lower endpoint” from the answers to queries on subsets. Most point location problems can be made decomposable and are easier to solve in such a form.

Dynamic point location: Maintaining a location data structure as points are inserted and deleted. The one-dimensional point location structures can be made dynamic without changing their asymptotic performances.

Randomized point location: Data structures whose preprocessing algorithms may make random choices in an attempt to avoid poor performance caused by pathological input data. Preprocessing and query times are reported as expectations over these random choices. Randomized algorithms make no assumptions on the input or query distributions. They often use a sample to obtain information about the input distribution, and can achieve good expected performance with simple algorithms.

Entropy bounds: If the probability of a query falling in region i is known to be p_i , then Shannon entropy $H = \sum_i -p_i \log_2(p_i)$ is a lower bound for expected query time, where here the expectation is over the query probability distribution.

LIST SEARCH AS ONE-DIMENSIONAL POINT LOCATION

Table 34.1.1 reports query time, preprocessing time, and space for five search methods. Linear search requires no additional data structure if the problem is decomposable. Binary search trees or randomized search trees [SA96, Pug90] require a total order and an ability to do comparisons. An adversary argument shows that these comparison-based query algorithms require $\Omega(\log n)$ comparisons. If the probability distribution for queries is known, then the lower bound on expected query time is H , and expected $H + 2$ can be achieved by weight-balanced trees [Meh77].

If the points are restricted to integers $[1, \dots, U]$, then van Emde Boas has shown how hashing techniques can be applied in stratified search trees to answer a query in $O(\log \log U)$ time. A useful method in practice is to partition the input range into b equal-sized buckets, and to answer a query by searching the bucket containing the query.

TABLE 34.1.1 List search as one-dimensional point location.

TECHNIQUE	QUERY	PREPROC	SPACE
Linear search	$O(n)$	none	data only
Binary search	$O(\log n)$	$O(n \log n)$	$O(n)$
Randomized tree	$O(\log n)$ expec	$O(n \log n)$ expec	$O(n)$
Weight-balance tree	$H+2$ expec	$O(n \log n)$	$O(n)$
van Emde Boas tree [vEKZ77]	$O(\log \log U)$	$O(n)$ expec	$O(n)$
Bucketing	$O(n)$	$O(n + b)$	$O(n + b)$

34.2 POINT-IN-POLYGON

The second simplest form of point location is to determine whether a query point q lies inside a given n -sided polygon P [Hai94]. Without preprocessing the polygon, one may use parity of the winding or crossing numbers: count intersections of a ray from q with the boundary of polygon P . Point q is inside P iff the number is odd. A query takes $O(n)$ time.

FIGURE 34.2.1

*Counting degenerate crossings:
eight crossings imply $q \notin P$.*

One must count carefully in degenerate cases when the ray passes through a vertex or edge of P . When the ray is horizontal, as in Figure 34.2.1, then edges of P can be considered to contain their lower but not their upper endpoints. Edges inside the ray can be ignored. This is consistent with the count obtained by perturbing the ray infinitesimally upward. Stewart [Ste91] further considered instances in which vertex and edge positions may be imprecise.

To obtain sublinear query times, preprocess the polygon P using the more general techniques of the next sections.

34.3 PLANAR POINT LOCATION: STATIC

Theoretical research has produced a number of planar point location methods that are optimal for comparison-based models: $O(n \log n)$ time to preprocess a planar subdivision with n vertices for $O(\log n)$ time queries using $O(n)$ space. Preprocessing time reduces to linear if the input is given in an appropriate format, and some preprocessing schemes have been parallelized (see [Chapter 42](#)).

We focus on the data structuring techniques used to reach optimality: persistence, fractional cascading, trapezoid graphs, and hierarchical triangulations.

In a planar subdivision, point location can be made decomposable by storing with each edge the name of the face immediately above. If one knows for each subproblem the edge below a query, then one can determine the edge directly below and report the containing face, even for an arbitrary partition into subproblems.

GLOSSARY

Planar subdivision: A partitioning of a region of the plane into point *vertices*, line segment *edges*, and polygonal *faces*.

Size of a planar subdivision: The number of vertices, usually denoted by n .

Euler's relation bounds the numbers of edges $e \leq 3n - 6$ and faces $f \leq 2n - 4$; often the constants are suppressed by saying that the number of vertices, edges, and faces are all $O(n)$.

Monotone subdivision: A planar subdivision whose faces are x -monotone polygons: i.e., the intersection of any face with any vertical line is connected.

Triangulation or trapezoidation: Planar subdivisions whose faces are triangles or whose faces are trapezoids whose parallel sides are all parallel.

Dual graph: A planar subdivision can be viewed as a graph with vertices joined by edges. The dual graph has a node for each face and an arc joining two faces if they share a common edge.

TABLE 34.3.1 A selection of the best static planar point location results for subdivision with n edges. Expectations are over decisions made by the algorithm; averages are over a query distribution with entropy H .

TECHNIQUE	QUERY	PREPROC	SPACE
Slab + persistence [ST86]	$O(\log n)$	$O(n \log n)$	$O(n)$
Separating chain + fractional cascade [EGS86]	$O(\log n)$	$O(n \log n)$	$O(n)$
Optimal query [SA00]	$\log_2 n + \sqrt{\log_2 n} + \Theta(1)$	$O(2^{2\sqrt{\log n}})$	$O(2^{2\sqrt{\log n}})$
+ struct. sharing	$\log_2 n + \sqrt{\log_2 n} + O(\log_2^{1/4} n)$	exp. $O(n \log n)$	exp. $O(n)$
Randomized [Mul90]	expected $O(\log n)$	exp. $O(n \log n)$	exp. $O(n)$
Weighted randomized [AMM01b]	average $(5 \ln 2)H + O(1)$	exp. $O(n \log n)$	exp. $O(n)$
Optimal entropy [AMM01a]	average $H + o(H)$	exp. $O(n \log n)$	$O(n \log^* n)$

PLANAR SEPARATOR THEOREM

The first optimal point location scheme is based on Lipton and Tarjan's **planar separator theorem** [LT80] that every planar graph of n nodes has a set of $O(\sqrt{n})$ nodes that partition it into roughly equal pieces. When applied to the dual graph of a planar subdivision, the nodes are a small set of faces that partition the remainder of the faces: simple quadratic-space methods can be used to determine which set of the partition needs to be searched recursively.

The fact that embedded graphs have small separators continues to be important in theoretical work. For example, Goodrich [Goo95] gave a linear-time construction of a family of planar separators in his parallel triangulation algorithm.

SLABS AND PERSISTENCE

By drawing a vertical line through every vertex, as shown in Figure 34.3.1(a), we obtain vertical **slabs** in which point location is almost one-dimensional. Two binary searches suffice to answer a query: one on x -coordinates for the slab containing q , and one on edges that cross that slab. Query time is $O(\log n)$, but space may be quadratic if all edges are stored with the slabs that they cross.

The location structures for adjacent slabs are similar. We could sweep from left to right to construct balanced binary search trees on edges for all slabs: As we sweep over the right endpoint of an edge, we remove the corresponding tree node. As we sweep over the left endpoint of an edge, we add a node. This takes $O(n \log n)$ total time and a linear number of node updates. To store all slabs in linear space, Sarnak and Tarjan [ST86] add to this the idea of *persistence*.

Rather than modifying a node to update the tree, copy the $O(\log n)$ nodes on the path from the root to this node, then modify the copies. This **node-copying persistence** preserves the former tree and gives access to a new tree (through the new root) that represents the adjacent slab. The total space for n trees is $O(n \log n)$. Figure 34.3.1(a) provides an illustration. The initial tree contains 8 and 1. (Recall that edges are named by the face immediately above.) Then 2, 3, and 7 are added, 8 is copied during rebalancing, but node 1 is not changed. When 6 is added, 7 is copied in the rebalancing, but the two subtrees holding 1, 2, 3, and 8 are not changed.

Limited node copying reduces the space to linear. Give each node spare left and right pointers and left and right time-stamps. Build a balanced tree for the initial slab. When a pointer is to be modified, use a spare and time-stamp it, if there is a spare available. Future searches can use the time-stamp to determine whether to follow the pointer or the spare. Otherwise, copy the node and modify its ancestor to point to the copy. If the slab location structures are maintained with $O(1)$ rotations per update, then the amortized cost of copying is also $O(1)$ per update.

Preprocessing takes $O(n \log n)$ time to sort by x coordinates and build either persistent data structure. To compare constants with other methods, the data structure has about 12 entries per edge because of extra pointers and copying. Searches take about $4 \log_2 N$ comparisons, where N is the number of edges that can intersect a vertical line; this is because there are two comparisons per node and “ $O(1)$ rotation” tree-balancing routines are balanced only to within a factor of two.

FIGURE 34.3.1

Optimal static methods: (a) Slab (persistent); (b) separating chain (fractional cascading).

SEPARATING CHAINS AND FRACTIONAL CASCADING

If a subdivision is monotone, then its faces can be totally ordered consistent with aboveness; in other words, we can number faces $1, \dots, f$ so that any vertical line encounters lower numbers below higher numbers. The *separating chain* between the faces $< k$ and those $\geq k$ is a monotone chain of edges [LP77]. Figure 34.3.1(b) shows all separating chains for a subdivision; the middle chain, $k = 5$, is shown darkest.

A balanced binary tree of separating chains can be used for point location: if query point q is above chain i and below chain $i + 1$, then q is in face i . To preserve linear space we need to avoid the duplication of edges in chains that can be seen in Figure 34.3.1(b).

Note that the separating chains that contain an edge are defined by consecutive integers; we can store the first and last with each edge. Then form a binary tree in which each subtree stores the separating chains from some interval—at each node, store the edges of the median chain that have not been stored higher in the tree, and recursively store the intervals below and above the median in the left and right subtrees respectively. The root, for example, stores all edges of the middle chain. Since no edge is stored twice, this data structure takes $O(n)$ space.

As we search the tree for a query point q , we keep track of the edges found so far that are immediately above and below q . (Initially, no edges have been found.) Now, the root of the subtree to search is associated with a separating chain. If that chain does not contain one of the edges that we know is above or below q , then we search the x -coordinates of edges stored at the node and find the one on the vertical line through q . We then compare against the separating chain and recursively search the left or right subtree. Thus, this separating chain method [LP77] inspects $O(\log n)$ tree nodes at a cost of $O(\log n)$ each, giving $O(\log^2 n)$ query time.

To reduce the query time, we can use fractional cascading [CG86, EGS86] for efficient search in multiple lists. As we traverse our search tree, at every node we search a list by x -coordinates. We can make all searches after the first take constant time, if we increase the total size of these lists by 50%. Pass every fourth x -coordinate from a child list to its parent, and establish connections so that knowing one's position in the parent list gives one's position in the child to within four nodes.

Preprocessing takes $O(n)$ time on a monotone subdivision; arbitrary planar subdivisions can be made monotone by plane sweep in $O(n \log n)$ time. One can trade off space and query time in fractional cascading, but typical constants are 8 entries per edge for a query time of $4 \log_2 n$.

TRAPEZOID GRAPH METHODS

Preparata's [Pre81] trapezoid method is a simple, practical method that achieves $O(\log n)$ query time at the cost of $O(n \log n)$ space. Its underlying search structure, the *trapezoid graph*, is the basis for important variations: randomized point location in optimal expected time and space, a recursive application giving exact worst-case optimal query time, and average-time point location achieving the entropy bound.

A trapezoid graph is a directed, acyclic graph (DAG) in which each nonleaf node ν is associated with a trapezoid τ_ν whose parallel sides are vertical and whose

top and bottom are either a single subdivision edge or are at infinity. Node ν splits τ_ν either by a vertical line through a subdivision vertex (a vertical node) or by a subdivision edge (a horizontal node). The root is associated with a trapezoid that contains the entire subdivision.

Most planar point location structures can be represented as trapezoid graphs, including the slab and separating chain methods. Bucketing and some triangulation methods do not, since they may make comparisons with coordinates or segments that are not in the input.

FIGURE 34.3.2

A subdivision with its trapezoid graph; circles indicate vertical splits at vertices, rectangles horizontal splits at edges, and leaves are numbered. Edges af , bf , and cf are cut and duplicated.

In Preparata's trapezoid method of point location, the trapezoid graph is a tree constructed top-down from the root. Figure 34.3.2 shows an example. If trapezoid τ_ν does not contain a subdivision vertex or intersect an edge, then node ν is a leaf. If every subdivision edge intersecting τ_ν has at least one endpoint inside τ_ν , then make ν a vertical node and split τ_ν by a vertical line through the median vertex. Otherwise, make ν a horizontal node and split τ_ν by the median of all edges cutting through τ_ν , and call ν a *horizontal split node*. This tree has depth (and query time) $3 \log n$ [SA00]. Experiments [EKA84] suggest that this method performs well, although its worst-case size and preprocessing time are $O(n \log n)$.

In a delightful paper, Seidel and Adamy [SA00] give the exact number of comparisons for point location in a planar subdivision of n edges by establishing a tight bound of $\log_2 n + \sqrt{\log_2 n} + \Theta(1)$ on the worst-case height of a trapezoid graph. (The paper has an extra factor of $O(\log_2 \log_2 n)$ that was removed by Seidel and Kirkpatrick [unpublished].) The lower bound uses a stack of $n/2$ horizontal lines that are each cut into two along a diagonal.

The upper bound divides a trapezoid into $t = 2\sqrt{\log_2 n}$ slabs and uses horizontal splits to define trapezoids with point-location subproblems to be solved recursively. Each subproblem with a location structure of depth d is given weight 2^d , and a weight-balanced trapezoid tree is constructed to determine the relevant subproblem for a query. Query time in this trapezoid tree is optimal. Preprocessing time is determined by the number of tree nodes, which is $O(n2^t)$.

They also show that $\Omega(n \log n)$ space is required for a trapezoid tree, but that space can be reduced to linear by using cuttings to make the trapezoid graph into a DAG.

A space-efficient trapezoid graph can be most easily built as the history graph

of the randomized incremental construction (RIC) of an arrangement of segments [Mul90] [Sei91]. (See [Chapter 40](#) for details on RICs.) RIC gives an expected optimal point location scheme: $O(\log n)$ expected query time, $O(n \log n)$ expected preprocessing time, and $O(n)$ expected space, where the expectation is taken over random choices made by the construction algorithm.

Arya et al. [AMM01b] showed that a weighted randomized construction gives expected query times satisfying entropy bounds. Suppose that we have a planar subdivision with regions of constant complexity, such as trapezoids or triangles, and that we know the probability p_i of a query falling in the i th region. The entropy $H = \sum_i -p_i \log_2 p_i$.

For a constant K , assign to a subdivision edge that is incident on regions with total probability P the weight $\lceil K P n \rceil$, and perform a randomized incremental construction. The use of integral weights ensures that ratios of weights are bounded by $O(n)$, which is important to achieve query time bounded by $O(H)$.

Entropy-preserving cuttings can be used to give a method whose query time of $H + o(H)$ approaches the optimal entropy bound [AMM01a], at the cost of increased space and programming complexity.

TRIANGULATIONS

Kirkpatrick [Kir83] developed the second optimal method for point location specifically for triangulations. This is not a restriction, since any planar subdivision can be triangulated, although it can be an added complication to do so.

FIGURE 34.3.3

Hierarchical triangulation.

This scheme creates a hierarchy of subdivisions in which all faces, including the outer face, are triangles. Like Lipton and Tarjan’s method, hierarchical triangulation suffers from large constant factors, but the ideas are still of theoretical and practical importance. It has become an important tool for problems on convex polyhedra (see [Chapter 38](#)), terrain representation, and mesh simplification.

In every planar triangulation, one can find (in linear time) an independent set of low-degree vertices that consists of a constant fraction of all vertices. In Figure 34.3.3 these are circled and, in the next picture, are removed and the shaded hole is retriangulated if necessary. Repeating this “coarsening” operation a logarithmic number of times gives a constant-size triangulation.

To locate the triangle containing a query point q , start by finding the triangle in the coarsest triangulation, at right in Figure 34.3.3. Knowing the hole (shaded) that this triangle came from, one need only replace the missing vertex and check the incident triangles to locate q in the previous, finer triangulation.

Given a triangulation, preprocessing takes $O(n)$ time, but the hidden constants on time and space are large. For example, choosing the independent set by greedily taking vertices in order of increasing degree up to 10 guarantees 1/6th of the vertices [SvK97], which leads to a data structure with $12n$ triangles in which a query could take $35 \log_2 n$ comparisons.

OPEN PROBLEMS

1. Develop a data structure for point location in a planar subdivision that simultaneously achieves linear space and $H + o(H)$ query time.
2. Splay trees [ST85] achieve $O(m + mH)$ query time for m queries (if each element is queried at least once). Can one develop a “self-adjusting” data structure for 2D point location with similar query time?

34.4 PLANAR POINT LOCATION: DYNAMIC

In dynamic planar point location, the subdivision can be updated by adding or deleting vertices and edges. Unlike the static case, algorithms that match the performance of one-dimensional point location have not yet been found. Again, we focus on the data structures used by the best methods, summarized in [Table 34.4.1](#).

GLOSSARY

Updates: A dynamic planar subdivision is most commonly updated by inserting or deleting a vertex or edge. Update time usually refers to the worst-case time for a single insertion or deletion.

Chain insertion/deletion: Some methods support insertion or deletion of a chain of k vertices and edges, so that this is faster than doing k insertions or k deletions.

Vertex expansion/contraction: Updating a planar subdivision by splitting a vertex into two vertices joined by an edge, or the inverse: contracting an edge and merging the two endpoints into one. This operation, supported by the “primal/dual spanning tree” (discussed below), is important for point location in 3D subdivisions.

Amortized update time: When times are reported as amortized, then an individual operation may be expensive, but the total time for k operations, starting from an empty data structure, will take at most k times the amortized bound.

I/O efficient algorithm: An algorithm whose asymptotic number of I/O operations is minimal. Model parameters are problem size N , disk block size B and memory size M , with typically $B \leq \sqrt{M}$. Sorting requires $O((N/B) \log_B N)$ time.

TABLE 34.4.1 Dynamic point location results.

TECHNIQUE	QUERY	UPDATE	SPACE	UPDATES SUPPORTED

TRAPEZOID METHOD

Preparata's trapezoid method [Pre81], which stores a binary tree on subdivision edges as described in Section 34.3, can be made dynamic. It preserves its optimal $O(\log n)$ query time, as well as retaining its suboptimal $O(n \log n)$ space.

To allow updates in $O(\log^2 n)$ time, Chiang and Tamassia [CT92, CPT96] store the tree on subdivision edges in a *link-cut* tree [ST83], which supports in $O(\log n)$ time the operation of linking two trees by adding an arc, and the inverse, cutting an arc to make two trees.

DYNAMIC INTERVAL TREE

An *interval tree* storing segments can be defined recursively: the root stores segments that cross a given vertical line ℓ ; segments to the left (right) are stored in an interval tree that is the left (right) child of the root. To locate a query point q , one must search down the interval tree, answering the following subproblem at $O(\log n)$ nodes: Given a set of segments S that intersect a common line ℓ , which segment is immediately below q ?

Cheng and Janardan [CJ92] solve this subproblem by a priority-tree search, which allows them to use the interval tree for dynamic point location. In an interval tree node, store the segments in a binary search tree ordered along ℓ , and store in each subtree a pointer to the "priority segment" with endpoint farthest left of ℓ . (Priority must also be stored on the right.) At each level of the search tree, only two candidate subtrees may contain the segment below q —the ones whose priority segments are immediately above and below q . Figure 34.4.1(a) illustrates a case in which the search continues in the two shaded subtrees.

Performing this search in each node of the interval tree leads to $O(\log^2 n)$ query time using $O(n)$ space. Constants are moderate, with only 4 or 5 entries per edge and 6 comparisons per search step. Updates take $O(\log n)$ time with larger constants; they must maintain tree balance and segment priorities.

Baumgarten et al. [BJM94] use fractional cascading on blocks of $O(\log^2 n)$ segments in each interval tree node to speed up queries to $O(\log n \log \log n)$, at the cost of slowing insertions to $O(\log n \log \log n)$ amortized, and deletions to $O(\log^2 n)$. This is a surprising development because fractional cascading requires a global order that is difficult to establish in interval tree techniques.

FIGURE 34.4.1

Dynamic methods: (a) *Priority search (interval tree)*; (b) *primal/dual spanning tree*.

PRIMAL/DUAL SPANNING TREE

A monotone subdivision has a *monotone spanning tree* in which all root-to-leaf paths are monotone. Each edge not in the tree closes a cycle and defines a monotone polygon.

In any planar graph whose faces are simple polygons, the duals of edges not in the spanning tree form a dual spanning tree of faces, as in Figure 34.4.1(b). Goodrich and Tamassia [GT91] use a centroid decomposition of the dual tree to guide comparisons with monotone polygons in the primal tree. The centroid edge, which breaks the dual tree into two nearly-equal pieces, is indicated in Figure 34.4.1(b). The primal edge creates the shaded monotone polygon; if the query is inside then we recursively explore the corresponding piece of the dual tree. Using link-cut trees, the centroid decomposition can be maintained in logarithmic time per update, giving a dynamic point-location structure with $O(\log^2 n)$ query time.

In the static setting, fractional cascading can turn this into an optimal point location method. Dynamic fractional cascading can be used to reduce the dynamic query time and to obtain $O(1)$ amortized update time.

The dual nature of the structure supports insertion and deletion of dual edges, which correspond to expansion and contraction of vertices. These are needed to support static 3D point location via persistence. Furthermore, a k -vertex monotone chain can be inserted/deleted in $O(\log n + k)$ time.

SEPARATING CHAINS

The separating chain method was the first to be made fully dynamic [PT89]. Although both its asymptotics and its constant factors are larger than other methods, it has been made I/O-efficient [AV00]. This is an impressive theoretical accomplishment, but simpler algorithms that assume that the input is somewhat evenly distributed in the plane will be more practical.

OPEN PROBLEMS

1. Improve dynamic planar point location to simultaneously attain $O(n)$ space

and $O(\log n)$ query and update time, or establish a lower bound.

2. Can persistent data structures be made dynamic? The fact that data are copied seems to work against maintaining a data structure under insertions and deletions.

34.5 PLANAR POINT LOCATION: COMMON PRACTICE

Programming complexity and nonnegligible asymptotic constants mean that optimal point location techniques are used less than might be expected. See [TV01] for a study of geometric algorithm engineering that uses point location schemes as its example.

PICK HARDWARE

Graphic workstations employ special “pick hardware” that draws objects on the screen and returns a list of objects that intersect a query pixel. The hardware imposes a minimum time of about 1/30th of a second on a pick operation, but hundreds of thousands of polygons may be considered in this time.

BUCKETING AND SPATIAL INDEX STRUCTURES

Because data in practical applications tend to be evenly distributed, bucketing techniques are far more effective [AEI⁺85, EKA84] than worst-case analysis would predict. For problems in two and three dimensions, a uniform grid will often trim data to a manageable size.

Adaptive data structures for more general spatial indexing, such as k -d trees, quadtrees, BANG files, R-trees, and their relatives [Sam90], can be used as filters for point location—these techniques are common in databases and geographic information systems.

SUBDIVISION WALKING

Applications that store planar subdivisions with their adjacency relations, such as geographic information systems, can walk through the regions of the subdivision from a known position p to the query q .

To walk a subdivision with $O(n)$ edges, compute the intersections of $\overline{pq}$ with the current region and determine if q is inside. If not, let q' denote the intersection point closest to q . Advance to the region incident to q' that contains a point in the interior of $\overline{q'q}$ and repeat. In the worst case, this walk takes $O(n)$ time. The application literature typically claims $O(\sqrt{n})$ time, which is the average number of intersections with a line under the assumption that vertices and edges of the subdivision are evenly distributed. When combined with bucketing or hierarchical data structures (for example, maintaining a regular grid or quadtree with known positions and starting from the closest to answer a query), walking is an effective, practical location method.

For triangulations, the algorithm walking $\overline{pq}$ is easy to implement. Guibas and Stolfi's [GS85] incremental Delaunay triangulation uses an even simpler walk from edge to edge, but this depends on an acyclicity theorem (Sections 20.4 and 22.1) that does not hold for arbitrary triangulations. A robust walk should remember its starting point and handle vertices on the traversed segment as if they had been perturbed consistently.

There have been several recent analyses of *Jump & Walk* schemes in triangulations [DPT02, DLM99, DMZ98]. Devroye et al. [DLM99] show expected query times of $O(n^{1/4})$ for a scheme that keeps $n^{1/4}$ points with known locations, and walks from the nearest to find a query. In their experiments, the combination of a 2D search tree with walking performed the best. Devillers' hierarchical Delaunay [Dev02] uses an idea that applies to other triangulations as well: maintain a hierarchy of triangulations using small samples (e.g., 3% [Dev98]) and then walk from a vertex located in one level to find a vertex in the next level. This is implemented in the CGAL library [BDP⁺02].

34.6 LOCATION IN HIGHER DIMENSIONS

In higher dimensions, known point location methods do not achieve both linear space and logarithmic query time. Linear space can be attained by relatively straightforward linear search, such as the point-in-polygon test.

Logarithmic time, or $O(d \log n)$ time, can be obtained by projection [DL76]: project the $d - 2$ faces of a subdivision to an arrangement in $d - 1$ dimensions and recursively build a point location structure for the arrangement in the projection. Knowing the cell in the projection gives a list of the possible faces that project to that cell, so an additional logarithmic search can return the answer. The worst-case space required is $O(n^{2^d})$.

Because point location is decomposable, batching can trade space for time: preprocessing n/k groups of k facets into structures with $S(k)$ space and $Q(k)$ time gives, in total, $O(nS(k)/k)$ space and $O(nQ(k)/k)$ query time.

Clever ways of batching can lead to better structures. Randomized methods can often reduce the dependence on dimension from doubly- to singly-exponential, since random samples can be good approximations to a set of geometric objects. They can also be used with objects that are implicitly defined.

We should mention that convex polyhedra can be preprocessed using the Dobkin-Kirkpatrick hierarchy (Section 34.3) so that the point-in-convex-polyhedron test does take $O(n)$ space and $O(\log n)$ query time.

THREE-DIMENSIONAL POINT LOCATION

Dynamic location structures can be used for static spatial point location in one higher dimension by employing persistence. If one swept a plane through a subdivision of three-space into polyhedra, one could see the intersection as a dynamic planar subdivision in which vertices (intersections of the sweep plane with edges) move along linear trajectories. Whenever the sweep plane passes through a vertex in space, vertices in the plane may join and split.

Goodrich and Tamassia's primal/dual method supports the necessary opera-

tions to maintain a point location structure for the sweeping plane. Using node-copying to make the structures persistent gives an $O(n \log n)$ space structure that can answer queries in $O(\log^2 n)$ time. Preprocessing takes $O(n \log n)$ time.

Devillers et al. [DPT02] tested several approaches to subdivision walking for Delaunay tetrahedralization, and established the practical effectiveness of the hierarchical Delaunay in three dimensions as well.

RECTILINEAR SUBDIVISIONS

Restricting attention to rectilinear (orthogonal) subdivisions permits better results via data structures for orthogonal range search. The *skewer tree*, a multidimensional interval tree, gives static point location among n rectangular prisms with $O(n)$ space and $O(\log^{d-1} n)$ query time after $O(n \log n)$ preprocessing [EHH86].

In dimensions two and three, stratified trees and perfect hashing [DKM⁺94] can be used to obtain $O((\log \log U)^{d-1})$ query time in a fixed universe $[1, \dots, U]$, or $O(\log n)$ query time in general. Iacono and Langerman [IL00] use “justified hyperrectangles” to obtain $O(\log \log U)$ query times in every dimension d , but the space and preprocessing time, which are $O(fn \log \log U)$ and $O(fn \log U \log \log U)$, respectively, depend on a *fatness parameter* f that equals the average ratio of the d th power of smallest dimension to volume of all hyperrectangles in the subdivision.

POINT LOCATION AMONG ALGEBRAIC VARIETIES

Chazelle and Sharir [CS90] consider point location in a general setting, among n algebraic varieties of constant maximum degree b in d -dimensional Euclidean space. They augment Collins’s cylindrical algebraic decomposition to obtain an $O(n^{2^{d-1}})$ -space, $O(\log n)$ -query time structure after $O(n^{2^{d+6}})$ preprocessing. Hidden constants depend on the degrees of projections and intersections, which can be b^{4^d} .

This method provides a general technique to obtain subquadratic solutions to optimization problems that minimize a function $\{F(a, b) \mid a \in A, b \in B\}$, where $F(a, b)$ has a constant-size algebraic description. For a fixed b , F is algebraic in a . Thus, small batches of points from B can be preprocessed in subquadratic time, and each a can be tested against each batch, again in subquadratic time.

OPEN PROBLEMS

1. Find an optimal method for static (or dynamic) point location in a 3D subdivision with n vertices and $O(n)$ faces: $O(n)$ space and $O(\log n)$ query time.
2. In a subdivision of a d -dimensional rectangular prism into n prisms, is there an optimal $O(\log n)$ -query, $O(n)$ -space point location method? The constants hidden by the big- O may depend on d . Under a pointer model of computation, this is already open for $d = 3$.

RANDOMIZED POINT LOCATION

TABLE 34.6.1 Randomized point location in arrangements.

TECHNIQUE	OBJECTS	QUERY	PREPROC	SPACE
Random sample [Cla87]	hyperplanes	$O(c^d \log n)$ exp	$O(n^{d+1+\epsilon})$ exp	$O(n^{d+\epsilon})$
Derandomized [CF94]	hyperplanes	$O(c^d \log n)$	$O(n^{2d+1})$	$O(n^d)$
Random sample [MS91]	dyn hpl $d \leq 4$	$O(\log n)$ exp	$O(n^{d+\epsilon})$ exp	$O(n^{d+\epsilon})$
Epsilon nets [Mei93]	hyperplanes	$O(d^5 \log n)$ exp	$O(n^{d+1+\epsilon})$ exp	$O(n^{d+\epsilon})$

The techniques of [Chapter 40](#) can lead to good point location methods when a random sample of a set of objects can be used to approximate the whole. Arrangements of hyperplanes in dimension d are a good example. A random sample of hyperplanes divides space into cells intersected by few hyperplanes; recursively sampling in each cell gives a point location structure for the arrangement. Table 34.6.1 lists the performance of some randomized point location methods for hyperplanes. Query time can be traded for space by choosing larger random samples.

The randomized incremental construction algorithms of Chapter 40 are simple because they naturally build randomized point location structures along with the objects that they aim to construct [Mul93, Sei93]. These have good “tail bounds” and work well as insertion-only location structures.

Randomized point location structures can be made fully dynamic by lazy deletion and randomized rebuild techniques [dBS95, MS91]; they maintain good expected performance if random elements are chosen for insertion and deletion. That is, the sequence of insertions and deletions may be specified, but the elements are to be chosen independently of their roles in the data structure.

IMPLICIT POINT LOCATION

In some applications of point location, the objects are not given explicitly. A planar motion planning problem may ask whether a start and a goal point are in the same cell of an arrangement of constraint segments or curves, without having explicit representations of all cells.

Consider a simple example: an arrangement of n lines, which defines nearly n^2 bounded cells. Without storing all cells, we can determine whether two points p and q are in the same cell by preprocessing $\sqrt{n}$ subarrangements of $\sqrt{n}$ lines ($O(n\sqrt{n})$ cells in all) and making sure that p and q are together in each subarrangement. If the lines are put into batches by slope, then within the same asymptotic time, an algorithm can return the pair of lines defining the lowest vertex as a unique cell name.

Implicit location methods are often seen as special cases of range queries ([Chapter 36](#)) or vertical ray shooting [[Aga91](#)]. [Table 34.6.2](#) lists results on implicit location among line segments, which depend upon tools discussed in Chapters 36, 37, and 40, specifically random sampling, ϵ -net theory, and spanning trees with low stabbing number.

TABLE 34.6.2 Implicit point location results for arrangements of n line segments.

TECHNIQUE	QUERY	PREPROC	SPACE
Span tree lsn [Aga92]	$O(\sqrt{n} \log^2 n)$	$O(n^{3/2} \log^\omega n)$	$O(n \log^2 n)$
Batch sp tree [AvK94]	$O\left((n/\sqrt{s}) \log^2(n/\sqrt{s}) + \log n\right)$	$O\left((sn(\log(n/\sqrt{s}) + 1)^{2/3})\right)$	$n \sqrt{\log n} \leq s \leq n^2$

35 COLLISION AND PROXIMITY QUERIES

Ming C. Lin and Dinesh Manocha

INTRODUCTION

In a geometric context, a collision or proximity query reports information about the relative configuration or placement of two objects. Some of the common examples of such queries include checking whether two objects overlap in space, or whether their boundaries intersect, or computing the minimum Euclidean separation distance between their boundaries. Hundreds of papers have been published on different aspects of these queries in computational geometry and related areas such as robotics, computer graphics, virtual environments, and computer-aided design. These queries arise in different applications including robot motion planning, dynamic simulation, haptic rendering, virtual prototyping, interactive walkthroughs, computer gaming, and molecular modeling. For example, a large-scale virtual environment, e.g., a walkthrough, creates a model of the environment with virtual objects. Such an environment is used to give the user a sense of presence in a synthetic world and it should make the images of both the user and the surrounding objects feel solid. The objects should not pass through each other, and objects should move as expected when pushed, pulled, or grasped; see Fig. 35.0.1. Such actions require fast and accurate collision detection between the geometric representations of both real and virtual objects. Another example is rapid prototyping, where digital representations of mechanical parts, tools, and machines, need to be tested for interconnectivity, functionality, and reliability. In Fig. 35.0.2, the motion of the pistons within the combustion chamber wall is simulated to check for tolerances and verify the design.

This chapter provides an overview of different queries and the underlying algorithms. It includes algorithms for collision detection and distance queries among convex polytopes (Section 35.1), nonconvex polygonal models (Section 35.2), penetration depth queries (Section 35.3), curved objects (Section 35.4), dynamic queries (Section 35.5), and large environments composed of multiple objects (Section 35.6). Finally, it briefly describes different software packages available to perform some of the queries (Section 35.7).

PROBLEM CLASSIFICATION

Collision Detection: Checks whether two objects overlap in space or their boundaries share at least one common point.

Separation Distance: Length of the shortest line segment joining two sets of points, A and B :

$$\text{dist}(A, B) = \min_{a \in A} \min_{b \in B} |a - b|.$$

FIGURE 35.0.1

A hand reaching toward a chair on a virtual porch, at top. The corresponding image of the user in the real world is shown on the bottom. Darkened finger tips indicate contacts between the user's hand and the virtual chair.

Hausdorff distance: Maximum deviation of one set from the other:

$$\text{haus}(A, B) = \max_{a \in A} \min_{b \in B} |a - b|.$$

Spanning Distance: Maximum distance between the points of two sets:

$$\text{span}(A, B) = \max_{a \in A} \max_{b \in B} |a - b|.$$

Penetration Depth: Minimum distance needed to translate one set to make it disjoint from the other:

$$\text{pen}(A, B) = \text{minimum } \|\mathbf{v}\| \text{ such that } \min_{a \in A} \min_{b \in B} |\mathbf{a} - \mathbf{b} + \mathbf{v}| > 0.$$

There are two forms of collision detection query: **Boolean** and **enumerative**. The Boolean distance query computes whether the two sets have at least one point in common. The enumerative form yields some representation of the intersection set.

There are at least three forms of the distance queries: exact, approximate, and Boolean. The exact form asks for the exact distance between the objects. The approximate form yields an answer within some given error tolerance of the true measure—the tolerance could be specified as a relative or absolute error. The Boolean form reports whether the exact measure is greater or less than a given value. Furthermore, the norm by which distance is defined may be varied. The Euclidean norm is the most common, but in principle other norms are possible, such as the L_1 and L_∞ norms.

Each of these queries can be augmented by adding the element of time. If the trajectories of two objects are known, then the next time can be determined at which a particular Boolean query (collision, separation distance, or penetration) will become TRUE or FALSE. In fact, this “time-to-next-event” query can have exact,

FIGURE 35.0.2

In this virtual prototyping application, the motion of the pistons is simulated to check for tolerances by performing distance queries.

TABLE 35.0.1 Classification of Proximity Queries.

CRITERIA	TYPES
Report	Boolean, exact, approximate, enumerative
Measure	Separation, span, Hausdorff, penetration, collision
Multiplicity	2-body, n -body
Temporality	Static, dynamic
Representation	Polyhedra, convex objects, implicit, parametric, NURBS, quadrics, set-theoretic combinations
Dimension	2,3, d

approximate, and Boolean forms. These queries are called *dynamic queries*, whereas the ones that do not use motion information are called *static queries*. In the case where the motion of an object can not be represented as a closed-form function of time, the underlying application often performs static queries at specific time steps in the application.

These measures, as defined above, apply only to pairs of sets. However, some applications work with many objects, and need to find the proximity information among all or a subset of the pairs. Thus, most of the query types listed above have associated N -body variants.

Finally, the primitives can be represented in different forms. They may be convex polytopes, general polygonal models, curved models represented using parametric or implicit surfaces, set-theoretic combination of objects, etc. Different set of algorithms are known for each representation. A classification of proximity queries based on these criteria is shown in [Table 35.1.1](#).

35.1 CONVEX POLYTOPES

In this section, we give a brief survey of algorithms for collision detection and separation-distance computation between a pair of convex polytopes. A number of algorithms with good asymptotic performance have been proposed. The algorithm with the current best runtime for Boolean collision queries takes $O(\log^2 n)$ time, where n is the number of features [DK90]. It precomputes the Dobkin-Kirkpatrick (DK) hierarchy for each polytope and uses it to perform the query. In practice, three classes of algorithms are commonly used for convex polytopes: linear programming, Minkowski sums, and tracking closest features based on Voronoi diagrams.

LINEAR PROGRAMMING

The problem of checking whether two convex polytopes intersect or not can be posed as a linear programming (LP) problem. In particular, two convex polytopes do not overlap if and only if there exists a separation plane between them. The coefficients of the separation plane equation are treated as unknowns. Linear constraints result by requiring that all vertices of the first polytope lie in one halfspace of this plane and those of the other polytope lie in the other halfspace. The linear programming algorithms are used to check whether there is any feasible solution to the given set of constraints. Given the fixed dimension of the problem, some of the well-known linear programming algorithms (e.g., [Sei90]; cf. Chapter 45) can be used to perform the Boolean collision query in expected linear-time. By caching the last pair of witness points to compute the new separating planes, Chung and Wang [CW96] proposed an iterative method that can quickly update the separating axis or the separating vector in nearly “constant time” in dynamic applications with high motion coherence.

MINKOWSKI SUMS AND CONVEX OPTIMIZATION

Collision and distance queries can be performed based on the Minkowski sum of two objects. It has been shown [CC86] that the minimum separation distance between two objects is the same as the minimum distance from the origin of the *Minkowski sums* of A and $-B$ to the surface of the sums. The Minkowski sum is also referred to as the *translational C-space obstacle* (TCSO). While the Minkowski sum of two convex polytopes can have $O(n^2)$ features [DHKS93], a fast algorithm for separation-distance computation based on convex optimization that exhibits linear-time performance in practice has been proposed by Gilbert et al. [GJK88], also known as the GJK algorithm. It uses pairs of vertices from each object that define simplices within each polytope and a corresponding simplex in the TCSO. Initially the simplex is set randomly and the algorithm refines it using local optimization, until it computes the closest point on the TCSO from the origin of the Minkowski sums. The algorithm assumes that the origin is not inside the TCSO.

FIGURE 35.1.1

A walk across external Voronoi region of Object A. Vertex V_b of Object B lies in the Voronoi region of E_a .

TRACKING CLOSEST FEATURES USING GEOMETRIC LOCALITY AND MOTION COHERENCE

Lin and Canny [LC91] proposed a distance-computation algorithm between non-overlapping convex polytopes. Often referred to as the LC algorithm, it tracks the closest features between the polytopes. This is the first approach that explicitly takes advantages of motion coherence and geometric locality. The features may correspond to a vertex, face, or an edge on each polytope. It precomputes the external Voronoi region for each polytope. At each time step, it starts with a pair of features and checks whether they are the closest features, based on whether they lie in each other's Voronoi region. If not, it performs a local walk on the boundary of each polytope until it finds the closest features. See Figure 35.1.1. In applications with high motion coherence, the local walk typically takes nearly “constant time” in practice. Typically the number of neighbors for each feature of a polytope is constant and the extent of “local walk” is proportional to the amount of the relative motion undergone by the polytopes.

Mirtich [Mir98] further optimized this algorithm by proposing a more robust variation that avoids some geometric degeneracies during the local walk, without sacrificing the accuracy or correctness of the original algorithm.

Guibas et al. [GHZ99] proposed an approach that exploits both coherence of motion using LC and hierarchical representations by Dobkin and Kirkpatrick [DK90] to reduce the runtime dependency on the amount of the local walks.

Ehmann and Lin [EL00] modified the LC algorithm and used an error-bounded level-of-detail (LOD) hierarchy to perform different types of proximity queries, using the progressive refinement framework (cf. [Chapter 54](#)). The implementation of this technique, “multi-level Voronoi Marching,” outperforms the existing libraries for collision detection between convex polytopes. It also uses an initialization technique based on directional lookup using hashing, resembling that of [DZ93].

By taking the similar philosophy as LC, Cameron [Cam97] presented an extension to the basic GJK algorithm by exploiting motion coherence and geometric locality in terms of connectivity between neighboring features. The algorithm tracks

the *witness points*, a pair of points from the two objects that realize the minimum separation distance between them. Rather than starting from a random simplex in the TCSO, the algorithm starts with the witness points from the previous iteration and performs hill climbing to compute a new set of witness points for the current configuration. The running time of this algorithm is a function of the number of refinement steps that the algorithm performs.

TABLE 35.1.1 Algorithms for convex polytopes.

METHOD	FEATURES
DK	$O(\log^2 n)$ query time, collision query only
LP	Linear running time, collision query
GJK	Linear-time behavior in practice, collision and separation-distance queries
LC	Expected constant-time in coherent environments, collision and separation-distance queries

KINETIC DATA STRUCTURES

Recently a new class of algorithms using “kinetic data structures” (or KDS for short) have been proposed for collision detection between moving convex polygons and polyhedra [BEG⁺99, EGSZ99, KSS02] (cf. [Chapter 50](#)). These algorithms are based on the formal framework of KDS to keep track of closest features of polytopes during their motion and exploits motion coherence and geometric locality. The performance of KDS-based algorithms is separation sensitive, and may depend on the amount of the minimum distance between the objects during their motion, relative to their size. The type of motion includes straight-line linear motion, translation along an algebraic trajectory, or algebraic rigid motion (including both rotation and translation).

35.2 GENERAL POLYGONAL MODELS

Algorithms for collision and separation-distance queries between general polygon models can be classified based whether they assume closed polyhedral models, or are represented as a collection of polygons. The latter, also referred to as “polygon soups,” make no assumption related to the connectivity among different faces or whether they represent a closed set.

Some of the most common algorithms for collision detection and separation-distance computation use spatial partitioning or bounding volume hierarchies (BVHs). The spatial subdivisions are a recursive partitioning of the embedding space, whereas bounding volume hierarchies are based on a recursive partitioning of the primitives of an object. These algorithms are based on the divide-and-conquer paradigm. Examples of spatial partitioning hierarchies include k-D trees

and octrees [Sam89], R-trees and their variants [HKM95], cone trees, BSPs [NAT90] and their extensions to multi-space partitions [WG91]. The BVHs use bounding volumes (BVs) to bound or contain sets of geometric primitives, such as triangles, polygons, curved surfaces, etc. In a BVH, BVs are stored at the internal nodes of a tree structure. The root BV contains all the primitives of a model, and children BVs each contain separate partitions of the primitives enclosed by the parent. Leaf node BVs typically contain one primitive. In some variations, one may place several primitives at a leaf node, or use several volumes to contain a single primitive. BVHs are used to perform collision and separation-distance queries. These include sphere-trees [Hub95, Qui94], AABB-trees [BKSS90, HKM95, PML97], OBB-trees [GLM96, BCG⁺96, Got00], spherical shell-trees [KPLM98, KGL⁺98], k -DOP-trees [HKM96, KHM⁺98], SSV-trees [LGLM99], multiresolution hierarchies [OL03], and convex hull-trees [EL01], as shown in Table 35.2.1.

TABLE 35.2.1 Types of bounding volume hierarchies.

NAME	TYPE OF BOUNDING VOLUME
Sphere-tree	Sphere
AABB-tree	Axis-aligned bounding box (AABB)
OBB-Tree	Oriented bounding box (OBB)
Spherical shell-tree	Spherical shell
k -DOP-tree	Discretely oriented polytope defined by k vectors (k -DOP)
SSV-Tree	Swept-sphere volume (SSV)
Convex hull-tree	Convex polytope

COLLISION DETECTION

Collision queries are performed by traversing the BVHs. Two models are compared by recursively traversing their BVHs in tandem. Each recursive step tests whether BVs A and B , one from each hierarchy, overlap. If they do not, the recursion branch is terminated. But if A and B overlap, the enclosed primitives may overlap and the algorithm is applied recursively to their children. If A and B are both leaf nodes, the primitives within them are compared directly.

SEPARATION-DISTANCE COMPUTATION

The structure of the separation-distance query is very similar to the collision query. As the query proceeds, the smallest distance found from comparing primitives is maintained in a variable δ . At the start of the query, δ is initialized to ∞ , or to the distance between an arbitrary pair of primitives. Each recursive call with BVs A and B must determine if some primitive within A and some primitive within B are closer than, and therefore will modify, δ . The call returns trivially if BVs A and B are farther than the current δ , as this precludes any primitives within them being closer than δ . Otherwise the algorithm is applied recursively to its children. For

FIGURE 35.2.1

$\mathbf{L}$ is a separating axis for OBBs A and B because projection onto $\mathbf{L}$ renders them disjoint intervals.

leaf nodes it computes the exact distance between the primitives, and if the new computed distance is less than δ , it updates δ .

To perform an approximate distance query, the distance between BVs A and B is used as a lower limit to the exact distances between their primitives. If this bound prevents δ from being reduced by more than the acceptable tolerance, that recursion branch is terminated.

QUERIES ON BOUNDING VOLUMES

Algorithms for collision detection and distance computation need to perform the underlying queries on the BVHs, including whether two BVs overlap, or computing the separation distance between them. The performance of the overall proximity query algorithm is governed largely by the performance of the subalgorithms used for proximity queries on a pair of BVs.

A number of specialized and highly optimized algorithms have been proposed to perform these queries on different BVs. It is relatively simple to check whether two spheres overlap. Two AABBs can be checked for overlap by comparing their dimensions along the three axes. The separation distance between them can be computed based on the separation along each axis. The overlap test can be easily extended to k -DOPs, where their projections are checked along the k fixed axis [KHM⁺98].

An efficient algorithm to test two OBBs for overlap based on the separating axis theorem (SAT) has been presented in [GLM96, Got00]. It computes the projection of each OBB along 15 axes in 3D. The 15 axes are computed from the face normals of the OBBs (6 face normals) and by taking the cross-products of the edges of the OBBs (9 cross-products). It is shown that two OBBs overlap if and only if their projection along each of these axes overlap. Furthermore, an efficient algorithm that performs overlap tests along each axis has been described. In practice, it can take anywhere from 80 to 240 arithmetic operations to check whether two OBBs overlap. The computation is robust and works well in practice [GLM96]. Figure 35.2.1 shows one of the separating axis tests for two rectangles in 2D.

Algorithms based on different *swept-sphere volumes* (SSVs) have been presented in [LGLM99]. Three types of SSVs are suggested: point swept-sphere (PSS), line swept-sphere (LSS), and a rectangular swept-sphere (RSS). Each BV is formu-

lated by taking the Minkowski sum of the underlying primitive—a point, line, or a rectangle in 3D, respectively—with a sphere. Algorithms to perform collision or distance queries between these BVs can be formulated as computing the distance between the underlying primitives. Larsen et al. [LGLM99] have presented an efficient and robust algorithm to compute distance between two rectangles in 3D (as well rectangles degenerating to lines and points). Moreover, they used priority directed search and primitive caching to lower the number of bounding volume tests for separation-distance computations.

In terms of higher-order bounding volumes, fast overlap tests based on spherical shells have been presented in [KPLM98, KGL⁺98]. Each spherical shell corresponds to a portion of the volume between two concentric spheres. The overlap test between two spherical shells takes into account their structure and reduces to checking whether there is a point contained in a circle that lies in the positive halfplane defined by two lines. The two lines and the circles belong to the same plane.

PERFORMANCE OF BOUNDING VOLUME HIERARCHIES

The performance of BVHs on proximity queries is governed by a number of design parameters, including techniques to build the trees, the maximum number of children per node, and the choice of BV type. An additional design choice is the descent rule. This is the policy for generating recursive calls when a comparison of two BVs does not prune the recursion branch. For instance, if BVs A and B failed to prune, one may recursively compare A with each of the children of B , B with each of the children of A , or each of the children of A with each of the children of B . This choice does not affect the correctness of the algorithm, but may impact the performance. Some of the commonly used algorithms assume that the BVHs are binary trees and each primitive is a single triangle or a polygon. The cost of performing the proximity query is given as [GLM96, LGLM99]:

$$T = N_{bv} \times C_{bv} + N_p \times C_p,$$

where T is the total cost function for proximity queries, N_{bv} is the number of bounding volume pair operations, and C_{bv} is the total cost of a BV pair operation, including the cost of transforming each BV for use in a given configuration of the models, and other per BV-operation overhead. N_p is the number of primitive pairs tested for proximity, and C_p is the cost of testing a pair of primitives for proximity (e.g., overlaps or distance computation).

Typically, for tight-fitting bounding volumes, e.g., oriented bounding boxes (OBBs), N_{bv} and N_p are relatively small, whereas C_{bv} is relatively high. In contrast, C_{bv} is low while N_{bv} and N_p may be larger for simple BV types like spheres and axis-aligned bounding boxes (AABBs). Due to these opposing trends, no single BV yields optimum performance for proximity queries in all situations.

35.3 PENETRATION-DEPTH COMPUTATION

In this section, we briefly review *penetration depth* (PD) computation algorithms between convex polytopes and general polyhedral models. The PD of two inter-

FIGURE 35.3.1

Penetration depth is applied to virtual exploration of a digestive system using haptic interaction to feel and examine different parts of the model. The distance computation and penetration depth computation algorithms are used for disjoint (D) and penetrating (P) situations, respectively, to compute the forces at the contact areas.

penetrating objects A and B is defined as the minimum translation distance that one object undergoes to make the interiors of A and B disjoint. It can be also defined in terms of the TCSO. When two objects are overlapping, the origin of the Minkowski sum of A and $-B$ is contained inside the TCSO. The penetration depth corresponds to the minimum distance from the origin to the surface of TCSO [Cam97]. PD computation is often used in motion planning [HKL⁺98], contact resolution for dynamic simulation [MZ90, ST96] and force computation in haptic rendering [KOLM02]. Fig. 35.3.1 shows a haptic rendering application of penetration-depth and separation-distance computation. For example, computation of dynamic response in penalty-based methods often needs to perform PD queries for imposing the nonpenetration constraint for rigid body simulation. In addition, many applications, such as motion planning and dynamic simulation, require a continuous distance measure when two (nonconvex) objects collide for a well-posed computation.

Several algorithms for PD computation involve computing Minkowski sums and the closest point on its surface from the origin. The worst-case complexity of the overall PD algorithm is dominated by computing Minkowski sums, which can be $\Omega(n^2)$ for convex polytopes and $\Omega(n^6)$ for general (or nonconvex) polyhedral models [DHKS93]. Given the complexity of Minkowski sums, many approximation algorithms have been proposed in the literature for fast PD estimation.

CONVEX POLYTOPES

Dobkin et al. [DHKS93] proposed a hierarchical algorithm to compute the directional PD using Dobkin and Kirkpatrick polyhedral hierarchy. For any direction d , it computes the directional penetration depth in $O(\log n \log m)$ time for polytopes with m and n vertices. Agarwal et al. [AGHP⁺00] designed a randomized approach to compute the PD values [AGHP⁺00], achieving $O(m^{\frac{3}{4}+\epsilon}n^{\frac{3}{4}+\epsilon} + m^{1+\epsilon} + n^{1+\epsilon})$ expected time for any positive constant ϵ . Cameron [Cam97] presented an exten-

sion to the GJK algorithm [GJK88] to compute upper and lower bounds on the PD between convex polytopes. Bergen further elaborated this idea in an expanding polytope algorithm [Ber01]. The algorithm iteratively improves the result of the PD computation by expanding a polyhedral approximation of the Minkowski sums of two polytopes. Kim et al. [KLM02] presented an incremental algorithm that marches toward a “locally optimal” solution by walking on the surface of the Minkowski sum. The surface of the TCSO is implicitly computed by constructing a local Gauss map and performing a local walk on the polytopes.

POLYHEDRAL MODELS

Algorithms for penetration-depth estimation between general polygonal models are based on discretization of the object space containing the objects, or use of digital geometric algorithms that perform computations on a finite resolution grid. Fisher and Lin [FL01] presented a PD estimation algorithm based on the distance-field computation using the fast marching level-set method. It is applicable to all polyhedral objects as well as deformable models, and it can also check for self-penetration. Hoff et al. [HZLM01, HZLM02] proposed an approach based on performing discretized computations on graphics rasterization hardware. It uses multi-pass rendering techniques for different proximity queries between general rigid and deformable models, including penetration depth estimation. Kim et al. [KLM02] presented a fast approximation algorithm for general polyhedral models using a combination of object-space as well as discretized computations. Given the global nature of the PD problem, it decomposes the boundary of each polyhedron into convex pieces, computes the pairwise Minkowski sums of the resulting convex polytopes and uses graphics rasterization hardware to perform the closest-point query up to a given discretized resolution. The results obtained are refined using a local walking algorithm. To further speed up this computation and improve the estimate, the algorithm uses a hierarchical refinement technique that takes advantage of geometry culling, model simplification, accelerated ray-shooting, and local refinement with greedy walking. The overall approach combines discretized closest-point queries with geometry culling and refinement at each level of the hierarchy. Its accuracy can vary as a function of the discretization error.

OTHER METRICS

Other metrics to characterize the intersection between two objects include the *growth distance* defined by Gilbert and Ong [GO94]. This is a consistent distance measure regardless of whether the objects are disjoint or overlapping; it differs from the PD between two interpenetrating convex objects.

35.4 SPLINE AND ALGEBRAIC OBJECTS

Most of the algorithms highlighted above are limited to polygonal objects. In many applications of geometric and solid modeling, curved objects whose boundaries are described using rational splines or algebraic equations are used (cf. [Chapter 53](#)).

Algorithms to perform different proximity queries on these objects may be classified by subdivision methods, tracing methods, and analytic methods. See [Pra86, Hof89, Man92] for surveys. Next, we briefly enumerate these methods.

SUBDIVISION METHODS

All subdivision methods for parametric surfaces work by recursively subdividing the domain of the two surface patches in tandem, and examining the spatial relationship between patches [LR80]. Depending on various criteria, the domains are further subdivided and recursively examined, or the given recursion branch is terminated. In all cases, whether it is the intersection curve or the distance function, the solution is known only to some finite precision.

TRACING METHODS

The tracing method begins with a given point known to be on the intersection curve [BFJP87, MC91, KM97]. Then the intersection curve is traced in sufficiently small steps until the edge of the patch is found, or until the curve loops back to itself. In practice, it is easy to check for intersections with a patch boundary, but difficult to know when the tracing point has returned to its starting position. Frequently this is posed as an initial-value differential equations problem [KPW90], or as solving a system of algebraic equations [MC91, KM97, LM97]. At the intersection point on the surfaces, the intersection curve must be mutually orthogonal to the normals of the surfaces. Consequently, the vector field which the tracing point must follow is given by the cross product of the normals.

ANALYTIC METHODS

Analytic methods usually involve implicitizing one of the parametric surfaces—obtaining an implicit representation of the model [SAG84, MC92]. The parametric surface is a mapping from (u, v) -space to (x, y, z) -space, and the implicit surface is a mapping from (x, y, z) -space to $\mathbb{R}$. Substituting the parametric functions $f_x(u, v)$, $f_y(u, v)$, $f_z(u, v)$ for x, y, z of the implicit function leads to a scalar function in u and v . The locus of roots of this scalar function map out curves in the (u, v) plane which are the preimages of the intersection curve [KPP90, MC91, KM97, Sar83]. Based on its representation as an algebraic plane curve, efficient algorithms have been proposed by a number of researchers [AB88, KM97, KCMh99].

35.5 DYNAMIC QUERIES

In this section we give a brief overview of algorithms used to perform *dynamic queries*. Unlike static queries, which check for collisions or perform separation-distance queries at discrete instances, these algorithms use continuous techniques based on the object motion to compute the time of first collision.

Many algorithms assume that the motion of the objects can be expressed as a closed-form function of time. Cameron [Cam90] has presented algorithms that

pose the problem as interference computation in a 4-dimensional space. Given a parametric representation of each object's boundary as well as its motion, Herzen et al. [HBZ90] presented a collision detection algorithm that subdivides the domain of the surface, including the time dimension. They use Lipschitz conditions, based on bounds on the various derivatives of the mapping, to compute bounds on the extent of the resulting function. The bounds are used to check two objects for overlap. Snyder et al. [Sea93] improved the runtime performance of this algorithm by introducing more conditions that prune the search space for collisions and combined it with interval arithmetic [Moo79].

Other continuous techniques use the object motion to estimate the time of first contact. For prespecified trajectories consisting of a sequence of individual translations and rotations about an arbitrary axis, Boyse [Boy79] presented an algorithm for detecting and analyzing collisions between a moving and a stationary objects. Canny [Can86] described an algorithm for computing the exact points of collision for objects that are simultaneously translating and rotating. It can deal with any path in the space that can be expressed as a polynomial function of time. Given bounds on the maximum velocity and acceleration of the objects are known, Lin [Lin93] presented a scheduling scheme that maintains a priority queue and sorts the object based on approximate time to collision. The approximation is computed from the separation distance as well as from bounds on velocity and acceleration. Redon et al. [RKC00] proposed an algorithm that replaces the unknown motion between two discrete instances by an arbitrary rigid motion. It reduces the problem of computing the time of collision to computing a root of a univariate cubic polynomial.

35.6 LARGE ENVIRONMENTS

Large environments are composed of multiple moving objects. Different methods have been proposed to overcome the bottleneck of $O(n^2)$ pairwise tests in an environment composed of n objects. The problem of performing proximity queries in large environments is typically divided into two parts [Hub95, CLMP95]: the *broad phase*, in which we identify the pair of objects on which we need to perform different proximity queries, and the *narrow phase*, in which we perform the exact pairwise queries. An architecture for multi-body collision detection algorithm is shown in [Figure 35.6.1](#). In this section, we present a brief overview of algorithms used in the broad phase.

The simplest algorithms for large environments are based on spatial subdivisions. The space is divided into cells of equal volume, and at each instance the objects are assigned to one or more cells. Collisions are checked between all object pairs belonging to each cell. In fact, Overmars presented an efficient algorithm based on hash table to efficiently perform point location queries in fat subdivisions [Ove92] (see also [Chapter 34](#)). This approach works well for sparse environments in which the objects are uniformly distributed through the space. Another approach operates directly on 4D volumes swept out by object motion over time [Cam90]. Efficient algorithms for maintenance and self-collision testing for kinematic chains composed of multiple links have been presented in [LSHL02].

Several algorithms compute an axis-aligned bounding box (AABB) for each

FIGURE 35.6.1

Typically, the object's motion is constrained by collisions with other objects in the simulated environment. Depending on the outcome of the proximity queries, the resulting simulation computes an appropriate response.

Architecture for Multi-body Collision Detection

object, based on their extremal points along each direction. Given n bounding boxes, they check which boxes overlap in space. A number of efficient algorithms are known for the static version of this problem. In 2D, the problem reduces to checking 2D intervals for overlap using interval trees and can be performed in $O(n \log n + s)$ where s is the total number of intersecting rectangles [Ede83]. In 3D, algorithms of complexity $O(n \log^2 n + s)$ complexity are known, where s is the number of overlapping pairwise bounding boxes [HSS83, HD82]. Algorithms for N -body proximity queries in dynamic environments are based on the **sweep and prune** approach [CLMP95]. This incrementally computes the AABBs for each object and checks them for overlap by computing the projection of the bounding boxes along each dimension, and sorting the interval endpoints using insertion sort or bubble sort [MD76, Bar92, CLMP95]. In environments where the objects make relatively small movements between successive frames, the lists can be sorted in expected linear time, leading to expected-time $O(n + m)$, where m is the number of overlapping intervals along any dimension. These algorithms are limited to environments where objects undergo rigid motion. Govindaraju et al. [GRLM03] have presented a general algorithm for large environments composed of rigid as well as nonrigid motion. This algorithm uses graphics hardware to prune the number of objects that are in close proximity and eventually checks for overlapping triangles between the objects. In practice, it works well in large environments composed of nonrigid and breakable objects. However, its accuracy is governed by the resolution of the rasterization hardware.

OUT-OF-CORE ALGORITHMS

In many applications, it may not be possible to load a massive geometric model composed of millions of primitives in the main memory for interactive proximity queries. In addition, algorithms based on spatial partitioning or bounding volume hierarchies also add additional memory overhead. Thus, it is important to develop proximity-query algorithms that use a relatively small or bounded memory footprint.

Wilson et al. [WLML99] presented an out-of-core algorithm to perform collision and separation-distance queries on large environments. It uses *overlap graphs* to exploit locality of computation. For a large model, the algorithm automatically encodes the proximity information between objects and represents it using an overlap graph. The overlap graph is computed off-line and preprocessed using graph partitioning, object decomposition, and refinement algorithms. At run time it traverses localized subgraphs and orders the computations to check the corresponding geometry for proximity tests, as well as pre-fetch geometry and associated hierarchical data structures. To perform interactive proximity queries in dynamic environments, the algorithm uses the BVHs, modifies the localized subgraph(s) on the fly, and takes advantage of spatial and temporal coherence.

35.7 PROXIMITY QUERY PACKAGES

Many systems and libraries have been developed for performing different proximity queries. These include:

I-COLLIDE: I-COLLIDE is an interactive and exact collision-detection system for environments composed of convex polyhedra or union of convex pieces. The system is based on the LC incremental distance computation algorithm [LC91] and an algorithm to check for collision between multiple moving objects [CLMP95]. It takes advantage of temporal coherence. <http://gamma.cs.unc.edu/I-COLLIDE>.

RAPID: RAPID is a robust and accurate interference detection library for a pair of unstructured polygonal models. It is applicable to polygon soups—models which contain no adjacency information and obey no topological constraints. It is based on OBBTrees and uses a fast overlap test based on Separating Axis Theorem to check whether two OBBs overlap [GLM96]. <http://gamma.cs.unc.edu/OBB/OBBT.html>

V-COLLIDE: V-COLLIDE is a collision detection library for large dynamic environments [HLC⁺97], and unites the N -body processing algorithm of I-COLLIDE with the pair processing algorithm of RAPID. Consequently, it is designed to operate on large numbers of static or moving polygonal objects, and the models may be unstructured. <http://gamma.cs.unc.edu/V-COLLIDE>

Enhanced GJK Algorithm: It is a library for distance computation based on the enhanced GJK algorithm [GJK88] developed by Cameron [Cam97]. It takes advantage of temporal coherence between successive frames. <http://www.comlab.ox.ac.uk/oucl/users/stephen.cameron/distances.html>

SOLID: SOLID is a library for interference detection of multiple 3D polygonal objects undergoing rigid motion. The shapes used by SOLID are polygon soups. The library exploits frame coherence by maintaining a set of pairs of proxi-

mate objects using incremental sweep and pruning on hierarchies of axis-aligned bounding boxes. Though slower for close proximity scenarios, its performance is comparable to that of V-COLLIDE in other cases. <http://www.win.tue.nl/cs/tt/gino/solid>

PQP: PQP, a Proximity Query Package, supports collision detection, separation-distance computation or tolerance verification. It uses OBBTree for collision queries and a hierarchy of swept-sphere volumes to perform distance queries [LGLM99]. It assumes that each object is a collection of triangles and can handle polygon soup models. <http://gamma.cs.unc.edu/SSV>

SWIFT: SWIFT a library for collision detection, distance computation, and contact determination between 3D polygonal objects undergoing rigid motion. It assumes that the input primitives are convex polytopes or a union of convex pieces. The underlying algorithm is based on a variation of LC [EL00]. The resulting system is faster, more robust, and more memory efficient than I-COLLIDE. <http://gamma.cs.unc.edu/SWIFT>

SWIFT++: SWIFT++ a library for collision detection, approximate and exact distance computation, and contact determination between closed and bounded polyhedral models. It decomposes the boundary of each polyhedra into convex patches and precomputes a hierarchy of convex polytopes [EL01]. It uses the SWIFT library to perform the underlying computations between the bounding volumes. <http://gamma.cs.unc.edu/SWIFT++>

QuickCD: QuickCD is a general-purpose collision detection library, capable of performing exact collision detection on complex models. The input model is a collection of triangles, with assumptions on the structure or topologies of the model. It precomputes a hierarchy of k -DOPs for each object and uses them to perform fast collision queries [KHM⁺98]. <http://www.ams.sunysb.edu/~jklosow/quickcd/QuickCD.html>

OPCODE: OPCODE is a collision detection library between general polygonal models. It uses a hierarchy of AABBs. It is memory efficient in comparison to RAPID, SOLID, or QuickCD. <http://www.codercorner.com/Opcode.htm>

DEEP: DEEP estimates the penetration depth and the associated penetration direction between two overlapping convex polytopes. It uses an incremental algorithm the computes a “locally optimal solution” by walking on the surface of the Minkowski sum of two polytopes [KLM02]. <http://gamma.cs.unc.edu/DEEP>

PIVOT: PIVOT computes generalized proximity information between arbitrary objects using graphics hardware. It uses multipass rendering techniques and accelerated distance computation, and provides an approximate solution for different proximity queries. These include collision detection, distance computation, local penetration depth, contact region and normals, etc. [HZLM01, HZLM02]. It involves no preprocessing and can handle deformable models. <http://gamma.cs.unc.edu/PIVOT>

36 RANGE SEARCHING

Pankaj K. Agarwal

INTRODUCTION

Range searching is one of the central problems in computational geometry, because it arises in many applications and a variety of geometric problems can be formulated as range-searching problems. A typical range-searching problem has the following form. Let S be a set of n points in $\mathbb{R}^d$, and let $\mathcal{R}$ be a family of subsets of $\mathbb{R}^d$; elements of $\mathcal{R}$ are called *ranges*. We wish to preprocess S into a data structure, so that for a query range γ , the points in $S \cap \gamma$ can be reported or counted efficiently. Typical examples of ranges include rectangles, halfspaces, simplices, and balls. If we are only interested in answering a single query, it can be done in linear time, using linear space, by simply checking each point of S whether it lies in the query range. However, most of the applications call for querying the same set S several times (perhaps with periodic insertions and deletions), in which case we would like to answer a query faster by preprocessing S into a data structure.

Range counting and range reporting are just two instances of range-searching queries. Other examples include *emptiness queries*, in which one wants to determine whether $S \cap \gamma = \emptyset$, and *optimization queries*, in which one wants to choose a point with certain property (e.g., a point in γ with the largest x_1 -coordinate). In order to encompass all different types of range-searching queries, a general range-searching problem can be defined as follows.

Let $(\mathbf{S}, +)$ be a commutative semigroup. For each point $p \in S$, we assign a weight $w(p) \in \mathbf{S}$. For any subset $S' \subseteq S$, let $w(S') = \sum_{p \in S'} w(p)$, where addition is taken over the semigroup. For a query range $\gamma \in \mathcal{R}$, we wish to compute $w(S \cap \gamma)$. For example, counting queries can be answered by choosing the semigroup to be $(\mathbb{Z}, +)$, where $+$ denotes standard integer addition, and setting $w(p) = 1$ for every $p \in S$; emptiness queries by choosing the semigroup to be $(\{0, 1\}, \vee)$ and setting $w(p) = 1$; reporting queries by choosing the semigroup to be $(2^S, \cup)$ and setting $w(p) = \{p\}$; and optimization queries by choosing the semigroup to be $(\mathbb{R}, \max)$ and choosing $w(p)$ to be, for example, the x_1 -coordinate of p .

We can, in fact, define a more general (decomposable) *geometric searching* problem. Let S be a set of *objects* in $\mathbb{R}^d$ (e.g., points, hyperplanes, balls, or simplices), $(\mathbf{S}, +)$ a commutative semigroup, $w : S \rightarrow \mathbf{S}$ a weight function, $\mathcal{R}$ a set of ranges, and $\diamond \subseteq S \times \mathcal{R}$ a “spatial” relation between objects and ranges. Then for a range $\gamma \in \mathcal{R}$, we want to compute $\sum_{p \diamond \gamma} w(p)$. Range searching is a special case of this general searching problem in which S is a set of points in $\mathbb{R}^d$ and $\diamond = \in$. Another widely studied searching problem is *intersection searching*, where $p \diamond \gamma$ if p intersects γ . As we will see below, range-searching data structures are useful for many other geometric searching problems.

The performance of a data structure is measured by the time spent in answering a query, called the *query time*, by the *size* of the data structure, and by the time constructed in the data structure, called the *preprocessing time*. Since the data structure is constructed only once, its query time and size are generally more

important than its preprocessing time. If a data structure supports insertion and deletion operations, its *update time* is also relevant. We should remark that the query time of a range-reporting query on any reasonable machine depends on the output size, so the query time for a range-reporting query consists of two parts — *search time*, which depends only on n and d , and *reporting time*, which depends on n , d , and the output size. Throughout this chapter we will use k to denote the output size.

We assume that d is a small fixed constant, and that big- O and big- Ω notation hide constants depending on d . The dependence on d of the performance of almost all the data structures mentioned in this survey is exponential, which makes them unsuitable in practice for large values of d .

The size of any range-searching data structure is at least linear, since it has to store each point (or its weight) at least once, and the query time in any reasonable model of computation such as pointer machines, RAMs, or algebraic decision trees is $\Omega(\log n)$ even when $d = 1$. Therefore, we would like to develop a linear-size data structure with logarithmic query time. Although near-linear-size data structures are known for orthogonal range searching in any fixed dimension that can answer a query in polylogarithmic time, no similar bounds are known for range searching with more complex ranges such as simplices or disks. In such cases, we seek a tradeoff between the query time and the size of the data structure — How fast can a query be answered using $O(n \text{polylog}(n))$ space, how much space is required to answer a query in $O(\text{polylog}(n))$ time, and what kind of tradeoff between the size and the query time can be achieved?

This chapter is organized as follows. In Section 36.1 we describe various models of computation that are used for range searching. In Section 36.2 we review the orthogonal range-searching data structures, and in Section 36.3 we review simplex range-searching data structures. Section 36.4 surveys other variants and extensions of range searching, including multilevel data structures and kinetic range searching. In Section 36.5, we study intersection-searching problems, which can be regarded as a generalization of range searching. Finally, Section 36.6 explores several optimization queries.

36.1 MODELS OF COMPUTATION

Most geometric algorithms and data structures are implicitly described in the familiar *random access machine* (RAM) model, or the **real RAM** model. In the traditional RAM model, memory cells can contain arbitrary $(\log n)$ -bit integers, which can be added, multiplied, subtracted, divided (computing $\lfloor x/y \rfloor$), compared, and used as pointers to other memory cells in constant time. In a real RAM, we also allow memory cells to store arbitrary real numbers (such as coordinates of points). We allow constant-time arithmetic on and comparisons between real numbers, but we do not allow conversion between integers and reals. In the case of range searching over a semigroup other than the integers, we also allow memory cells to contain arbitrary values from the semigroup, but only the semigroup-addition operations can be performed on them.

Many range-searching data structures are described in the more restrictive **pointer-machine** model. The main difference between RAM and pointer-machine models is that on a pointer machine, a memory cell can be accessed only through

a series of pointers, while in the RAM model, any memory cell can be accessed in constant time. In the basic pointer-machine model, a data structure is a directed graph with outdegree 2; each node is associated with a label, which is an integer between 0 and n . Nonzero labels are indices of the points in S , and the nodes with label 0 store auxiliary information. The query algorithm traverses a portion of the graph and for each point in the query range it identifies at least one node that stores the index of that point. Chazelle [Cha88b] defines several generalizations of the pointer-machine model that are more appropriate for answering counting and semigroup queries. In Chazelle's generalized pointer-machine models, nodes are labeled with arbitrary $O(\log n)$ -bit integers. In addition to traversing edges in the graph, the query algorithm is also allowed to perform various arithmetic operations on these integers. An *elementary* pointer machine (called EPM) can perform addition and comparisons between integers; an *arithmetic* pointer machine (called APM) can perform subtraction, multiplication, integer division, and shifting ($x \mapsto 2^x$).

If the input is too large to fit into main memory, then the data structure must be stored in secondary memory—on disk, for example—and portions of it must be moved into main memory when needed to answer a query. In this case the bottleneck in query and preprocessing time is the time spent in transferring data between main and secondary memory. A commonly used model is the standard *two-level* memory model, in which one assumes that data is stored in secondary memory in blocks of size B , where B is a parameter. Each access to secondary memory transfers one block (i.e., B words), and we count this as one input/output (I/O) operation. The size of a data structure is the number of blocks required to store it in secondary memory, and the query (resp. preprocessing) time is defined as the number of I/O operations required to answer a query (resp. to construct the structure). Under this model, the size of any data structure is at least n/B , and the range-reporting query time is at least $\log_B n + k/B$. There have been various extensions of this model, including the so-called *cache-oblivious* model in which one does not know the value of B and the goal is to minimize I/O as well as the total work performed.

Most lower bounds, and a few upper bounds, are described in the so-called ***semigroup arithmetic model***, which was originally introduced by Fredman [Fre81a] and refined by Yao [Yao85]. In this model, a data structure can be regarded informally as a set of precomputed partial sums in the underlying semigroup. The size of the data structure is the number of sums stored, and the query time is the minimum number of semigroup operations required (on the precomputed sums) to compute the answer to a query. The query time ignores the cost of various auxiliary operations, including the cost of determining which of the precomputed sums should be added to answer a query. Unlike the pointer-machine model, the semigroup model allows immediate access, at no cost, to any precomputed sum.

The informal model we have just described is much too powerful. For example, in this semigroup model, the optimal data structure for range-counting queries consists of the $n + 1$ integers $0, 1, \dots, n$. To answer a counting query, we simply return the correct answer; since no additions are required, we can answer queries in zero “time,” using a “data structure” of only linear size! We need the notion of a ***faithful*** semigroup to circumvent this problem. A commutative semigroup $(\mathbf{S}, +)$ is faithful if for each $n > 0$, for any sets of indices $I, J \subseteq \{1, \dots, n\}$ where $I \neq J$, and for every sequence of positive integers α_i, β_j ($i \in I, j \in J$), there are semigroup

values $s_1, s_2, \dots, s_n \in \mathbf{S}$ such that $\sum_{i \in I} \alpha_i s_i \neq \sum_{j \in J} \beta_j s_j$. For example, $(\mathbb{Z}, +)$, $(\mathbb{R}, \min)$, $(\mathbb{N}, \gcd)$, and $(\{0, 1\}, \vee)$ are faithful, but $(\{0, 1\}, + \bmod 2)$ is not faithful.

Let $S = \{p_1, p_2, \dots, p_n\}$ be a set of objects, $\mathbf{S}$ a faithful semigroup, $\mathcal{R}$ a set of ranges, and $\diamond$ a relation between objects and ranges. (Recall that in the standard range-searching problem, the objects in S are points, and $\diamond$ is containment.) Let $x_1, x_2, \dots, x_n$ be a set of n variables over $\mathbf{S}$, each corresponding to a point in S . A *generator* $g(x_1, \dots, x_n)$ is a linear form $\sum_{i=1}^n \alpha_i x_i$, where α_i 's are nonnegative integers, not all zero. (In practice, the coefficients α_i are either 0 or 1.) A *storage scheme* for $(S, \mathbf{S}, \mathcal{R}, \diamond)$ is a collection of generators $\{g_1, g_2, \dots, g_s\}$ with the following property: For any query range $\gamma \in \mathcal{R}$, there is a set of indices $I_\gamma \subseteq \{1, 2, \dots, s\}$ and a set of labeled nonnegative integers $\{\beta_i \mid i \in I_\gamma\}$ such that the linear forms

$$\sum_{p_i \diamond \gamma} x_i \quad \text{and} \quad \sum_{i \in I_\gamma} \beta_i g_i$$

are identically equal. In other words, the equation

$$\sum_{p_i \diamond \gamma} w(p_i) = \sum_{i \in I_\gamma} \beta_i g_i(w(p_1), w(p_2), \dots, w(p_n))$$

holds for *any* weight function $w : S \rightarrow \mathbf{S}$. (Again, in practice, $\beta_i = 1$ for all $i \in I_\gamma$.) The size of the smallest such set I_γ is the query time for γ ; the time to actually choose the indices I_γ is ignored. The space used by the storage scheme is measured by the number of generators. There is no notion of preprocessing time in this model.

The semigroup model is formulated slightly differently for off-line range-searching problems. Here we are given a set of weighted points S and a finite set of query ranges $\mathcal{R}$, and we want to compute the total weight of the points in each query range. This is equivalent to computing the product Aw , where A is the incidence matrix of the points and ranges, and w is the vector of weights. In the off-line semigroup model, introduced by Chazelle [Cha97, Cha01], an algorithm can be described as a circuit with one input for every point and one output for every query range, where every gate performs a binary semigroup addition. The running time of the algorithm is the total number of gates.

A serious weakness of the semigroup model is that it does not allow subtractions even if the weights of points belong to a group. Therefore, we will also consider the **group model**, in which both additions and subtractions are allowed [Cha98].

Almost all geometric range-searching data structures are constructed by subdividing space into several regions with nice properties and recursively constructing a data structure for each region. Range queries are answered with such a data structure by performing a depth-first search through the resulting recursive space partition. The **partition-graph** model, introduced by Erickson [Eri96a, Eri96b], formalizes this divide-and-conquer approach, at least for simplex range searching data structures. The partition graph model can be used to study the complexity of emptiness queries, unlike the semigroup arithmetic and pointer machine models, in which such queries are trivial.

We conclude this section by noting that most of the range-searching data structures discussed in this paper (halfspace range-reporting data structures being a notable exception) are based on the following general scheme. Given a point set S , the structure precomputes a family $\mathcal{F} = \mathcal{F}(S)$ of *canonical subsets* of S and store the weight $w(C) = \sum_{p \in C} w(p)$ of each canonical subset $C \in \mathcal{F}$. For a query range γ , the query procedure determines a partition $\mathcal{C}_\gamma = \mathcal{C}(S, \gamma) \subseteq \mathcal{F}$ of $S \cap \gamma$ and adds

the weights of the subsets in $\mathcal{C}_\gamma$ to compute $w(S \cap \gamma)$. We will refer to such a data structure as a *decomposition scheme*.

There is a close connection between the decomposition schemes and the storage schemes of the semigroup arithmetic model described earlier. Each canonical subset $C = \{p_i \mid i \in I\} \in \mathcal{F}$, where $I \subseteq \{1, 2, \dots, n\}$, corresponds to the generator $\sum_{i \in I} x_i$. How exactly the weights of canonical subsets are stored and how $\mathcal{C}_\gamma$ is computed depends on the model of computation and on the specific range-searching problem. In the semigroup (or group) arithmetic model, the query time depends only on the number of canonical subsets in $\mathcal{C}_\gamma$, regardless of how they are computed, so the weights of canonical subsets can be stored in an arbitrary manner. In more realistic models of computation, however, some additional structure must be imposed on the decomposition scheme in order to efficiently compute $\mathcal{C}_\gamma$. In a *hierarchical decomposition scheme*, the weights are stored in a tree T . Each node v of T is associated with a canonical subset $C_v \in \mathcal{F}$, and the children of v are associated with subsets of C_v . Besides the weight of C_v , some auxiliary information is also stored at v , which is used to determine whether $C_v \in \mathcal{C}_\gamma$ for a query range γ . If the weight of each canonical subset can be stored in $O(1)$ memory cells and if we can determine in $O(1)$ time whether $C_w \in \mathcal{C}_\gamma$ where w is a descendent of a given node v , we call the hierarchical decomposition scheme *efficient*. The total size of an efficient decomposition scheme is simply $O(|\mathcal{F}|)$. For range-reporting queries, in which the “weight” of a canonical subset is the set itself, the size of the data structure is reduced to $O(|\mathcal{F}|)$ by storing the canonical subsets implicitly. Finally, let $r > 1$ be a parameter, and set $\mathcal{F}_i = \{C \in \mathcal{F} \mid r^{i-1} \leq |C| \leq r^i\}$. We call a hierarchical decomposition scheme *r-convergent* if there exist constants $\alpha \geq 1$ and $\beta > 0$ so that the degree of every node in T is $O(r^\alpha)$ and for all $i \geq 1$, $|\mathcal{F}_i| = O((n/r^i)^\alpha)$ and, for all query ranges γ , $|\mathcal{C}_\gamma \cap \mathcal{F}_i| = O((n/r^i)^\beta)$, i.e., the number of canonical subsets in the data structure and in any query output decreases exponentially with their size. We will see below in [Section 36.4](#) that *r-convergent* hierarchical decomposition schemes can be cascaded together to construct multilevel structures that answer complex geometric queries.

To compute $\sum_{p_i \in \gamma} w(p_i)$ for a query range γ using a hierarchical decomposition scheme T , a query procedure performs a depth-first search on T , starting from its root. At each node v , using the auxiliary information stored at v , the procedure determines whether γ contains C_v , whether γ intersects C_v but does not contain C_v , or whether γ is disjoint from C_v . If γ contains C_v , then C_v is added to $\mathcal{C}_\gamma$ (rather, the weight of C_v is added to a running counter). Otherwise, if γ intersects C_v , the query procedure identifies a subset of children of v , say $\{w_1, \dots, w_a\}$, so that the canonical subsets $C_{w_i} \cap \gamma$, for $1 \leq i \leq a$, form a partition of $C_v \cap \gamma$. Then the procedure searches each w_i recursively. The total query time is $O(\log n + |\mathcal{C}_\gamma|)$, provided constant time is spent at each node visited.

36.2 ORTHOGONAL RANGE SEARCHING

In d -dimensional orthogonal range searching, the ranges are d -rectangles, each of the form $\prod_{i=1}^d [a_i, b_i]$ where $a_i, b_i \in \mathbb{R}$. This is an abstraction of *multikey searching*. For example, the points of S may correspond to employees of a company, each coordinate corresponding to a key such as age, salary, experience, etc. Queries of the form, e.g., “report all employees between the ages of 30 and 40 who earn more

than \$30,000 and who have worked for more than 5 years,” can be formulated as orthogonal range-reporting queries. Because of its numerous applications, orthogonal range searching has been studied extensively. In this section we review recent data structures and lower bounds.

UPPER BOUNDS

Most orthogonal range-searching data structures are based on *range trees*, introduced by Bentley [Ben80]. For a set S of n points in $\mathbb{R}^2$, the range tree T of S is a minimum-height binary tree with n leaves whose i th leftmost leaf stores the point of S with the i th smallest x -coordinate. Each interior node v of T is associated with a canonical subset $C_v \subseteq S$ containing the points stored at leaves in the subtree rooted at v . Let a_v (resp. b_v) be the smallest (resp. largest) x -coordinate of any point in C_v . The interior node v stores the values a_v and b_v and the set C_v in an array sorted by the y -coordinates of its points. The size of T is $O(n \log n)$, and it can be constructed in time $O(n \log n)$. The range-reporting query for a rectangle $q = [a_1, b_1] \times [a_2, b_2]$ can be answered by traversing T as follows. Suppose we are at a node v . If v is a leaf, then we report the point stored at v if it lies inside q . If v is an interior node and the interval $[a_v, b_v]$ does not intersect $[a_1, b_1]$, there is nothing to do. If $[a_v, b_v] \subseteq [a_1, b_1]$, we report all the points of C_v whose y -coordinates lie in the interval $[a_2, b_2]$, by performing a binary search. Otherwise, we recursively visit both children of v . The query time of this procedure is $O(\log^2 n + k)$, which can be improved to $O(\log n + k)$, using *fractional-cascading* (Section 34.3).

The size of the data structure can be reduced to $O(n \log n / \log \log n)$, without affecting the asymptotic query time, by constructing a range tree with $O(\log n)$ fanout and storing additional auxiliary structures at each node [Cha86]. If the query rectangles are “3-sided rectangles” of the form $[a_1, b_1] \times [a_2, \infty]$, then one can use a *priority search tree* of size $O(n)$ to answer a planar range-reporting query in time $O(\log n + k)$ [McC85]; see [AE99] for a few other special cases in which the storage can be reduced to linear. All these structures can be implemented in the elementary pointer-machine model and can be dynamized using the standard partial-rebuilding technique [Ove83]. If the preprocessing time of the data structure is $P(n)$, then a point can be inserted into or deleted from the data structure in $O((P(n)/n) \log n)$ amortized time. The update time can be made worst-case using the known deamortization techniques [DR91]. If we have a data structure for answering d -dimensional range-reporting queries, one can construct a $(d+1)$ -dimensional range-reporting structure in the EPM model, using multilevel range trees (see Section 36.4), by paying a $\log n$ factor in storage, preprocessing time, and query time.

If we use the RAM model, a set S of n points in $\mathbb{R}^2$ can be preprocessed into a data structure of size $O(n \log^\epsilon n)$ so that all k points lying inside a query rectangle can be reported in $O(\log n + k)$ time. Mortensen [Mor03] has developed a data structure of size $O(n \log n / \log \log n)$ that can answer a range query in $O(\log n + k)$ time and can insert or delete a point in $O(\log n)$ time. If the points lie on a $n \times n$ grid in the plane, then a query can be answered in $O(\log \log n + k)$ time using $O(n \log^\epsilon n)$ storage or in time $O((\log \log n)^2 + k \log \log n)$ using $O(n \log \log n)$ storage. For points in $\mathbb{R}^3$, a query can be answered in $O(\log n + k)$ time using $O(n \log^{1+\epsilon} n)$ storage. As for the data structures in the pointer-machine model, the range reporting data structures in the RAM model can be extended to higher dimensions by paying

a $\log n$ factor in storage and query time for each dimension. Alternatively, a d -dimensional data structure can be extended to a $(d+1)$ -dimensional data structure by paying a $\log^{1+\epsilon} n$ factor in storage and a $\log n / \log \log n$ factor in the query time.

TABLE 36.2.1 Upper bounds known on orthogonal range reporting.

d	MODEL	$S(n)$	$Q(n)$
$d = 2$	RAM	n	$\log n + k \log^\epsilon(2n/k)$
	RAM	$n \log \log n$	$\log n + k \log \log(4n/k)$
	RAM	$n \log^\epsilon n$	$\log n + k$
	APM	n	$k \log(2n/k)$
	EPM	n	$k \log^2(2n/k)$
	EPM	$\frac{n \log n}{\log \log n}$	$\log n + k$
$d = 3$	RAM	$n \log^{1+\epsilon} n$	$\log n + k$
	EPM	$n \log^3 n$	$\log n + k$

The two-dimensional range tree described earlier can be used to answer a range counting query in $O(\log n)$ time using $O(n \log n)$ storage. However, if we use the RAM model in which we assume that each word stores $\log n$ bits, the size can be reduced to $O(n)$ by compressing the auxiliary information stored at each node [Cha88b].

TABLE 36.2.2 Upper bounds known on orthogonal semigroup range searching.

MODEL	$S(n)$	$Q(n)$
arithmetic	m	$\frac{n \log n}{\log(2m/n)}$
RAM	n	$\log^{2+\epsilon} n$
RAM	$n \log \log n$	$\log^2 n \log \log n$
RAM	$n \log^\epsilon n$	$\log^2 n$
APM	n	$\log^3 n$
EPM	n	$\log^4 n$

LOWER BOUNDS

Fredman [Fre80, Fre81a] was the first to prove nontrivial lower bounds on orthogonal range searching, but he considered the framework in which the points could be inserted and deleted dynamically. He showed that a mixed sequence of n insertions, deletions, and queries takes $\Omega(n \log^d n)$ time. These bounds were extended by Willard [Wil89] to a group model, under some restrictions. Chazelle proved lower bounds for the static version of orthogonal range searching, which almost match the best upper bounds known [Cha90b]. The following theorem summarizes his main result.

THEOREM 36.2.1 *Chazelle* [Cha90b]

Let $(\mathbf{S}, \oplus)$ be a faithful semigroup, let d be a constant, and let n and m be parameters. Then there exists a set S of n weighted points in $\mathbb{R}^d$, with weights from $\mathbf{S}$, such that the worst-case query time, under the semigroup model, for an orthogonal range-searching data structure that uses m units of storage is $\Omega((\log n / \log(2m/n))^{d-1})$.

Theorem 36.1.1 holds even if the queries are quadrants instead of rectangles. In fact, this lower bound applies to answering the dominance query for a randomly chosen query point; in this sense the above theorem gives a lower bound on the average-case complexity of the query time. It should be pointed out that Theorem 36.1.1 assumes the weights of points in S to be a part of the input. That is, the data structure is not tailored to a special set of weights, and it should work for any set of weights. It is conceivable that a faster algorithm can be developed for answering orthogonal range-counting queries, exploiting the fact that the weight of each point is 1 in this case. None of the known algorithms are able to exploit this fact, however.

A rather surprising result of Chazelle [Cha90a] shows that the size of any data structure on a pointer machine that answers a d -dimensional range-reporting query in $O(\log^c n + k)$ time, for any constant c , is $\Omega(n(\log n / \log \log n)^{d-1})$. Notice that this lower bound is greater than the known upper bound for answering two-dimensional reporting queries on the RAM model.

These lower bounds do not hold for off-line orthogonal range searching, where given a set of n weighted points in $\mathbb{R}^d$ and a set of n rectangles, one wants to compute the weight of points in each rectangle. Chazelle [Cha97] proved that the off-line version takes $\Omega(n(\log n / \log \log n)^{d-1})$ time in the semigroup model and $\Omega(n \log \log n)$ time in the group model. For $d = \Omega(\log n)$ (resp. $d = \Omega(\log n / \log \log n)$), the lower bound for the off-line range-searching problem in the group model can be improved to $\Omega(n \log n)$ (resp. $\Omega(n \log n / \log \log n)$) [CL01]. The close connection between the lower bounds on range searching and the “discrepancy” of set systems is discussed in [Chapter 44](#).

SECONDARY MEMORY STRUCTURES

I/O-efficient orthogonal range-searching structures have received much attention recently because of massive data sets in spatial databases. The main idea underlying these structures is to construct high-degree trees instead of binary trees. For example, variants of B-trees are used to answer one-dimensional range-searching queries [Sam90]. Arge et al. [ASV99] developed an external priority search tree so that a 3-sided-rectangle-reporting query can be answered in $O(\log_B \nu + \kappa)$ I/Os using $O(\nu)$ storage, where $\nu = n/B$ and $\kappa = k/B$. The main ingredient of their algorithm is a data structure that can store B^2 points using $O(B)$ blocks and can report all points lying inside a 3-sided rectangle in $O(1 + \kappa)$ I/Os. Combining their external priority search tree with Chazelle’s data structure for range reporting [Cha86], they construct an external range tree that uses $O(\nu \log_B \nu / \log \log_B \nu)$ blocks and answers a two-dimensional rectangle reporting query in time $O(\log_B n + \kappa)$. By extending the ideas proposed in [Cha90a], it can be shown that any secondary-memory data structure that answers a range-reporting query using $O(\log_B^c \nu + \kappa)$ I/Os requires $\Omega(\nu \log_B \nu / \log \log_B n)$ storage. Govindrajan et al. [GAA03] have shown that a two-

dimensional range counting query can be answered in $O(\log_B \nu)$ I/Os using $O(\nu)$ blocks of storage, assuming that each word can store $\log n$ bits.

TABLE 36.2.3 Secondary-memory structures for orthogonal range searching. Here $\beta(n) = \log \log \log_B \nu$.

d	RANGE	$Q(n)$	$S(n)$
$d = 1$	interval	$\log_B \nu + \kappa$	ν
$d = 2$	3-sided rect	$\log_B \nu + \kappa$	ν
	rectangle	$\log_B \nu + \kappa$	$\nu \log_B \nu / \log \log_B \nu$
$d = 3$	octant	$\beta(\nu, B) \log_B \nu + \kappa$	$\nu \log \nu$
	box	$\beta(\nu, B) \log_B \nu + \kappa$	$\nu \log^4 \nu$

LINEAR-SIZE DATA STRUCTURES

None of the data structures described above are used in practice, even in two dimensions, because of the polylogarithmic overhead in their size. For a data structure to be used in real applications, its size should be at most cn , where c is a very small constant, the time to answer a typical query should be small—the lower bounds mentioned earlier imply that we cannot hope for small worst-case bounds—and it should support insertions and deletions of points. Keeping these goals in mind, a plethora of data structures have been proposed.

The most widely used data structures for answering one-dimensional range queries are B-trees and their variants. Since a B-tree requires a linear order on the input elements, several techniques such as lexicographic ordering, bit interleaving, and space-filling curves have been used to define a linear ordering on points in higher dimensions in order to store them in a B-tree. A more efficient approach to answer high-dimensional range queries is to construct a recursive partition of space, typically into rectangles, and to construct a tree induced by this partition. The simplest example of this type of data structure is the **quadtrees** in the plane. A quadtree is a 4-way tree, each of whose nodes is associated with a square R_v . R_v is partitioned into four equal-size squares, each of which is associated with one of the children of v . The squares are partitioned until at most one point is left inside a square. A range-search query can be answered by traversing the quadtree in a top-down fashion. Because of their simplicity, quadtrees are one of the most widely used data structures for a variety of problems. One disadvantage of quadtrees is that arbitrarily many levels of partitioning may be required to separate tightly clustered points. Finkel and Bentley [FB74] described a variant of the quad tree for range searching, called a *point quadtree*, in which each node is associated with a rectangle and the rectangle is partitioned into four rectangles by choosing a point in the interior and drawing horizontal and vertical lines through that point. Typically the point is chosen so that the height of the tree is $O(\log n)$. In order to minimize the number of disk accesses, one can partition the square into many squares (instead of four) by a drawing either a uniform or a nonuniform grid. The **grid file** data structure, introduced by Nievergelt et al. [NHS84], is based on this idea.

Quadtrees and their variants construct a grid on a rectangle containing all the

input points. One can instead partition the enclosing rectangle into two rectangles by drawing a horizontal or a vertical line and partitioning each of the two rectangles independently. This is the idea behind the ***k-d-tree*** data structure of Bentley [Ben75]. In particular, a *k-d-tree* is a binary tree, each of whose nodes v is associated with a rectangle R_v . If R_v does not contain any point in its interior, v is a leaf. Otherwise, R_v is partitioned into two rectangles by drawing a horizontal or vertical line so that each rectangle contains at most half of the points; splitting lines are alternately horizontal and vertical. In order to minimize the number of disk accesses, Robinson [Rob81] generalized a *k-d-tree* to a ***kd-B-tree***, in which one constructs a B-tree instead of a binary tree on the recursive partition of the enclosing rectangle, so all leaves of the tree are at the same level and each node has between $B/2$ and B children. The rectangles associated with the children are obtained by splitting R_v recursively, as in a *k-d-tree*. A simple top-down approach to construct a *kd-B-tree* requires $O(\nu \log_2 \nu)$ I/Os, but the preprocessing cost can be reduced to $O(\nu \log_B \nu)$ I/Os using a more sophisticated approach [AAPV01].

If points are dynamically inserted into a *k-d-tree* or *kd-B-tree*, then some of the nodes may have to be split, an expensive operation because splitting a node may require reconstructing the entire subtree rooted at that node. A few variants of *k-d-trees* have been proposed that can update the structure in $O(\text{polylog} n)$ time and can answer a query in $O(\sqrt{n} + k)$ time. On the practical side, many variants of *kd-B-trees* have also been proposed to minimize the number of splits, to optimize the space, and to improve the query time, most notably ***buddy trees*** [SRF87] and ***hB-trees*** [LS90, ELS97]. A *buddy tree* is a combination of quad- and *kd-B-trees* in the sense that rectangles are split into sub-rectangles only at some specific locations, which simplifies the split procedure. If points are in degenerate position, then it may not be possible to split a square into two halves by a line. Lomet and Salzberg [LS90] circumvent this problem by introducing a new data structure, called an ***hB-tree***, in which the region associated with a node is allowed to be $R_1 \setminus R_2$ where R_1 and R_2 are rectangles. A more refined version of this data structure, known as an ***hB^{II}-tree***, is presented in [ELS97].

All the data structures described in this section for d -dimensional range searching construct a recursive partition of $\mathbb{R}^d$. There are other data structures that construct a hierarchical cover of $\mathbb{R}^d$, most popular of which is the ***R-tree***, originally introduced by Guttman [Gut84]. An *R-tree* is a B-tree, each of whose nodes stores a set of rectangles. Each leaf stores a subset of input points, and each input point is stored at exactly one leaf. For each node v , let R_v be the smallest rectangle containing all the rectangles stored at v ; R_v is stored at the parent of v (along with the pointer to v). R_v induces the subspace corresponding to the subtree rooted at v , in the sense that for any query rectangle intersecting R_v , the subtree rooted at v is searched. Rectangles stored at a node are allowed to overlap. Although allowing rectangles to overlap helps reduce the size of the data structure, answering a query becomes more expensive. Guttman suggests a few heuristics to construct an *R-tree* so that the overlap is minimized. Several better heuristics for improving the performance minimizing the overlap have been proposed, including *R*-* and *Hilbert-R-trees*. An *R-tree* also may be constructed on a set of rectangles. Agarwal et al. [AdBG⁺02] showed how to construct an *R-tree* on a set of n rectangles in $\mathbb{R}^d$ so that all k rectangles intersecting a query rectangle can be reported in $O(n^{1-1/d} + k)$ time.

PARTIAL-SUM QUERIES

Partial-sum queries require preprocessing a d -dimensional array A with n entries, in an additive semigroup, into a data structure, so that for a d -dimensional rectangle $\gamma = [a_1, b_1] \times \dots \times [a_d, b_d]$, the sum

$$\sigma(A, \gamma) = \sum_{(k_1, k_2, \dots, k_d) \in \gamma} A[k_1, k_2, \dots, k_d]$$

can be computed efficiently. In the off-line version, given A and m rectangles $\gamma_1, \gamma_2, \dots, \gamma_m$, we wish to compute $\sigma(A, \gamma_i)$ for each i . This is just a special case of orthogonal range searching, where the points lie on a regular d -dimensional lattice.

Partial-sum queries are widely used for on-line analytical processing (OLAP) of commercial databases. OLAP allows companies to analyze aggregate databases built from their data warehouses. A popular data model for OLAP applications is the multidimensional database, known as **data cube** [GBLP96], which represents the data as d -dimensional array. Thus, an aggregate query can be formulated as a partial-sum query. Driven by this application, several heuristics have been proposed to answer partial-sum queries on data cubes [HBA97, HAMS97] and the references therein.

Yao [Yao82] showed that, for $d = 1$, a partial-sum query can be answered in $O(\alpha(n))$ time using $O(n)$ space, where $\alpha(n)$ is the inverse Ackermann function. If the additive operator is *max* or *min*, then a partial-sum query can be answered in $O(1)$ time under the RAM model using a Cartesian tree, developed by Vuillemin [Vui80].

For $d > 1$, Chazelle and Rosenberg [CR89] developed a data structure of size $O(n \log^{d-1} n)$ that can answer a partial-sum query in time $O(\alpha(n) \log^{d-2} n)$. They also showed that the off-line version that answers m given partial-sum queries on n points takes $\Omega(n + m\alpha(m, n))$ time for any fixed $d \geq 1$. If points are allowed to insert into S , the query time is $\Omega(\log n / \log \log n)$ [Fre79, Yao85] for the one-dimensional case; the bounds were extended by Chazelle [Cha90b] to $\Omega((\log n / \log \log n)^d)$, for any fixed dimension d .

36.3 SIMPLEX RANGE SEARCHING

Unlike orthogonal range searching, no simplex range-searching data structure is known that can answer a query in polylogarithmic time using near-linear storage. In fact, the lower bounds stated below indicate that there is little hope of obtaining such a data structure, since the query time of a linear-size data structure, under the semigroup model, is roughly at least $n^{1-1/d}$ (thus only saving a factor of $n^{1/d}$ over the naive approach). Because the size and query time of any data structure have to be at least linear and logarithmic, respectively, we consider these two ends of the spectrum: (i) how fast a simplex range query can be answered using a linear-size data structure; and (ii) how large the size of a data structure should be in order to answer a query in logarithmic time. Combining these two extreme cases leads to a space/query-time tradeoff.

GLOSSARY

Arrangements: The arrangement of a set H of hyperplanes in $\mathbb{R}^d$ is the subdivision of $\mathbb{R}^d$ into cells of dimension k , for $0 \leq k \leq d$, each cell of dimension $k < d$ being a maximal connected set contained in the intersection of a fixed subset of H and not intersecting any other hyperplane of H . See [Chapter 24](#).

$1/r$ -cutting: Let H be a set of n hyperplanes in $\mathbb{R}^d$ and let $1 \leq r \leq n$ be a parameter. A $(1/r)$ -cutting of H is a set of (relatively open) disjoint simplices covering $\mathbb{R}^d$ so that each simplex intersects at most n/r hyperplanes of H .

Duality: The dual of a point $(a_1, \dots, a_d) \in \mathbb{R}^d$ is the hyperplane $x_d = -a_1x_1 - \dots - a_{d-1}x_{d-1} + a_d$, and the dual of a hyperplane $x_d = b_1x_1 + \dots + b_d$ is the point $(b_1, \dots, b_{d-1}, b_d)$.

LINEAR-SIZE DATA STRUCTURES

Most of the linear-size data structures for simplex range searching are based on **partition trees**, originally introduced by Willard [Wil82] for a set of points in the plane. Roughly speaking, a partition tree is a hierarchical decomposition scheme (in the sense described in Section 36.1) that recursively partitions the points into canonical subsets and encloses each canonical subset by a simple convex region (e.g. simplex), so that any hyperplane intersects only a fraction of the regions associated with the “children” of a canonical subset. A query is answered as described in Section 36.1. The query time depends on the maximum number of children regions of a node that a hyperplane can intersect. The partition tree proposed by Willard partitions each canonical subsets into four children, each contained in a wedge so that any line intersects at most three of them. As a result, the time spent in reporting all k points lying inside a triangle is $O(n^{0.792} + k)$. A number of partition trees with improved query time were introduced later, but a major breakthrough in simplex range searching was made by Haussler and Welzl [HW87]. They formulated range searching in an abstract setting and, using elegant probabilistic methods, gave a randomized algorithm to construct a linear-size partition tree with $O(n^\alpha)$ query time, where $\alpha = 1 - \frac{1}{d(d-1)+1} + \epsilon$ for any $\epsilon > 0$. The best linear-size data structure known for simplex range searching, which almost matches the lower bounds mentioned below, is by Matoušek [Mat93]. He showed that a simplex range-counting (resp. range-reporting) query in $\mathbb{R}^d$ can be answered in time $O(n^{1-1/d})$ (resp. $O(n^{1-1/d} + k)$). His algorithm is based on a stronger version of the following theorem.

THEOREM 36.3.1 *Matoušek* [Mat92]

Let S be a set of n points in $\mathbb{R}^d$, and let $1 < r \leq n/2$ be a given parameter. Then there exists a family of pairs $\Pi = \{(S_1, \Delta_1), \dots, (S_m, \Delta_m)\}$ such that $S_i \subseteq S$ lies inside simplex Δ_i , $n/r \leq |S_i| \leq 2n/r$, $S_i \cap S_j = \emptyset$ for $i \neq j$, and every hyperplane crosses at most $cr^{1-1/d}$ simplices of Π ; here c is a constant. If r is a constant, then Π can be constructed in $O(n)$ time.

Using this theorem, a partition tree T can be constructed as follows. Each interior node v of T is associated with a subset $S_v \subseteq S$ and a simplex Δ_v containing S_v ; the root of T is associated with S and $\mathbb{R}^d$. Choose r to be a sufficiently large

constant. If $|S| \leq 4r$, T consists of a single node, and it stores all points of S . Otherwise, we construct a family of pairs $\Pi = \{(S_1, \Delta_1), \dots, (S_m, \Delta_m)\}$ using Theorem 36.3.1. We recursively construct a partition tree T_i for each S_i and attach T_i as the i th subtree of u . The root of T_i also stores Δ_i . The total size of the data structure is linear, and it can be constructed in time $O(n \log n)$. Since any hyperplane intersects at most $cr^{1-1/d}$ simplices of Π , the query time of simplex range reporting is $O(n^{1-1/d} \cdot n^{\log_r c} + k)$; the $\log_r c$ factor can be reduced to any arbitrarily small positive constant ϵ by choosing r sufficiently large. Although the query time can be improved to $O(n^{1-1/d} \log^c n + k)$ by choosing r to be n^ϵ , a stronger version of Theorem 36.3.1, which was proved in [Mat93], and some other sophisticated techniques are needed to obtain $O(n^{1-1/d} + k)$ query time.

If the points in S lie on a b -dimensional algebraic surface of constant degree, a simplex range-counting query can be answered in time $O(n^{1-\gamma})$ using linear space, where $\gamma = 1/\lfloor (d+b)/2 \rfloor$. Better bounds can be obtained for halfspace range reporting, using *filtering search*; see Table 36.3.1. A halfspace range-reporting query in the I/O model can be answered in $O(\log_B \nu + \kappa)$ I/Os using $O(\nu)$ (resp. $O(\nu \log_B \nu)$) blocks of storage for $d = 2$ (resp. $d = 3$) [AAE⁺00].

TABLE 36.3.1 Near-linear-size data structures for halfspace range searching.

d	$S(n)$	$Q(n)$	NOTES
$d = 2$	n	$\log n + k$	reporting
	n	$\log n$	emptiness
$d = 3$	$n \log \log n$	$\log n + k$	reporting
	n	$\log^2 n + k$	reporting
	n	$\log n$	emptiness
$d > 3$	$n \log \log n$	$n^{1-1/\lfloor d/2 \rfloor} \log^c n + k$	reporting
	n	$n^{1-1/d} 2^{O(\log^* n)}$	emptiness
even d	n	$n^{1-1/\lfloor d/2 \rfloor} \log^c n + k$	reporting

DATA STRUCTURES WITH LOGARITHMIC QUERY TIME

For the sake of simplicity, we first consider the halfspace range-counting problem. Using a standard duality transform, this problem can be reduced to the following: *Given a set H of n hyperplanes, determine the number of hyperplanes of H lying above a query point.* Since the same subset of hyperplanes lies above all points in a single cell of $\mathcal{A}(\mathcal{H})$, the arrangement of H , we can answer a halfspace range-counting query by locating the cell of $\mathcal{A}(\mathcal{H})$ that contains the point dual to the hyperplane bounding the query halfspace. The following theorem of Chazelle [Cha93] yields an $O((n/\log n)^d)$ -size data structure, with $O(\log n)$ query time, for halfspace range counting.

THEOREM 36.3.2 *Chazelle* [Cha93]

Let H be a set of n hyperplanes and $r \leq n$ a parameter. Set $s = \lceil \log_2 r \rceil$. There exist k cuttings $\Xi_1, \dots, \Xi_s$ so that Ξ_i is a $(1/2^i)$ -cutting of size $O(2^{id})$, each simplex of Ξ_i is contained in a simplex of Ξ_{i-1} , and each simplex of Ξ_{i-1} contains a constant number of simplices of Ξ_i . Moreover, $\Xi_1, \dots, \Xi_s$ can be computed in time $O(nr^{d-1})$.

The above approach can be extended to the simplex range-counting problem as well. That is, store the solution of every combinatorially distinct simplex (two simplices are combinatorially distinct if they do not contain the same subset of S). Since there are $\Theta(n^{d(d+1)})$ combinatorially distinct simplices, such an approach will require $\Omega(n^{d(d+1)})$ storage. Chazelle et al. [CSW92] showed that the size can be reduced to $O(n^{d+\epsilon})$, for any $\epsilon > 0$, using a multilevel data structure, with each level composed of a halfspace range-counting data structure. The space bound can be reduced to $O(n^d)$ by increasing the query time to $O(\log^{d+1} n)$ [Mat93]. Halfspace range-reporting queries can be answered in $O(\log n + k)$ time, using $O(n^{\lfloor d/2 \rfloor} \text{polylog} n)$ space.

A space/query-time tradeoff for simplex range searching can be attained by combining the linear-size and logarithmic query-time data structures. The known results on this tradeoff are summarized in Table 36.3.2. $Q(m, n)$ is the query time on n points using m units of storage.

TABLE 36.3.2 Space/query-time tradeoff.

RANGE	MODE	$Q(m, n)$
Simplex	reporting	$\frac{n}{m^{1/d}} \log^{d+1} \frac{m}{n} + k$
Simplex	counting	$\frac{n}{m^{1/d}} \log^{d+1} \frac{m}{n}$
Halfspace	reporting	$\frac{n}{m^{1/\lfloor d/2 \rfloor}} \log^c n + k$
Halfspace	emptiness	$\frac{n}{m^{1/\lfloor d/2 \rfloor}} \log^c n$
Halfspace	counting	$\frac{n}{m^{1/d}} \log \frac{m}{n}$

LOWER BOUNDS

Fredman [Fre81b] showed that a sequence of n insertions, deletions, and halfplane queries on a set of points in the plane requires $\Omega(n^{4/3})$ time, in the semigroup model. His technique, however, does not extend to static data structures. In a series of papers, Chazelle has proved nontrivial lower bounds on the complexity of on-line simplex range searching, using various elegant mathematical techniques. The following theorem is perhaps the most interesting result on lower bounds.

THEOREM 36.3.3 *Chazelle* [Cha89]

Let $(S, \oplus)$ be a faithful semigroup, let n, m be positive integers such that $n \leq m \leq$

n^d , and let S be a random set of weighted points in $[0, 1]^d$ with weights from $\mathbf{S}$. If only m words of storage is available, then with high probability, the worst-case query time for a simplex range query in S is $\Omega(n/\sqrt{m})$ for $d = 2$, or $\Omega(n/(m^{1/d} \log n))$ for $d \geq 3$, in the semigroup model.

It should be pointed out that this theorem holds even if the query ranges are wedges or strips, but it does not hold if the ranges are hyperplanes. Chazelle and Rosenberg [CR96] proved a lower bound of $\Omega(n^{1-\epsilon}/m + k)$ for simplex range reporting under the pointer-machine model. These lower bounds do not hold for halfspace range searching. A somewhat weaker lower bound for halfspace queries was proved by Brönnimann et al. [BCP93].

As we saw earlier, faster data structures are known for halfspace emptiness queries. A series of papers by Erickson established the first nontrivial lower bounds for on-line and off-line emptiness query problems, in the partition-graph model of computation. He first considered this model for Hopcroft's problem—Given a set of n points and m lines, does any point lie on a line?—for which he obtained a lower bound of $\Omega(n \log m + n^{2/3} m^{2/3} + m \log n)$ [Eri96b], almost matching the best known upper bound $O(n \log m + n^{2/3} m^{2/3} 2^{O(\log^*(n+m))} + m \log n)$, due to Matoušek [Mat93]. He later established lower bounds on a tradeoff between space and query time, or preprocessing and query time, for on-line hyperplane emptiness queries [Eri00]. For d -dimensional hyperplane queries, $\Omega(n^d/\text{polylog } n)$ preprocessing time is required to achieve polylogarithmic query time, and the best possible query time is $\Omega(n^{1/d}/\text{polylog } n)$ if only $O(n \text{polylog } n)$ preprocessing time is allowed. More generally, in two dimensions, if the preprocessing time is p , the query time is $\Omega(n/\sqrt{p})$.

Table 36.3.3 summarizes the best lower bounds known for on-line simplex queries. Lower bounds for emptiness problems apply to counting and reporting problems as well.

TABLE 36.3.3 Lower bounds for on-line simplex range searching using $O(m)$ space.

Range	Problem	Model	Query Time
Simplex	Semigroup	Semigroup ($d = 2$)	$n/\sqrt{m}$
	Semigroup	Semigroup ($d > 2$)	$n/(m^{1/d} \log n)$
	Reporting	Pointer machine	$n^{1-\epsilon}/m^{1/d} + k$
Hyperplane	Semigroup	Semigroup	$(n/m^{1/d})^{2/(d+1)}$
	Emptiness	Partition graph	$(n/\log n)^{\frac{d^2+1}{d^2+d}} \cdot (1/m^{1/d})$
Halfspace	Semigroup	Semigroup	$(n/\log n)^{\frac{d^2+1}{d^2+d}} \cdot (1/m^{1/d})$
	Emptiness	Partition graph	$(n/\log n)^{\frac{\delta^2+1}{\delta^2+\delta}} \cdot (1/m^{1/\delta})$, where $d \geq \delta(\delta + 3)/2$

OPEN PROBLEMS

1. Bridge the gap between the known upper and lower bounds in the group model. Even in the semigroup model there is a small gap between the known bounds.

2. Can a halfspace range-reporting query be answered in $O(n^{1-1/\lfloor d/2 \rfloor} + k)$ time using linear space if d is odd?

36.4 VARIANTS AND EXTENSIONS

In this section we review a few extensions of range-searching data structures: multilevel structures, semialgebraic range searching, and kinetic range searching.

GLOSSARY

Semialgebraic set: A subset of $\mathbb{R}^d$ obtained as a finite Boolean combination of sets of the form $\{f \geq 0\}$, where f is a d -variate polynomial (see [Chapter 29](#)).

Tarski cells: A simply connected real semialgebraic set defined by a constant number of polynomials, each of constant degree.

MULTI-LEVEL STRUCTURES

A powerful property of data structures based on decomposition schemes (described in Section 36.1) is that they can be cascaded together to answer more complex queries, at the increase of a logarithmic factor per level in their performance. The real power of the cascading property was first observed by Dobkin and Edelsbrunner [DE87], who used this property to answer several complex geometric queries. Since their result, several papers have exploited and extended this property to solve numerous geometric-searching problems. We briefly sketch the general cascading scheme.

Let S be a set of weighted objects. Recall that a geometric-searching problem $\mathcal{P}$, with underlying relation $\diamond$, requires computing $\sum_{p \diamond \gamma} w(p)$ for a query range γ . Let $\mathcal{P}^1$ and $\mathcal{P}^2$ be two geometric-searching problems, and let $\diamond^1$ and $\diamond^2$ be the corresponding relations. Then we define $\mathcal{P}^1 \circ \mathcal{P}^2$ to be the conjunction of $\mathcal{P}^1$ and $\mathcal{P}^2$, whose relation is $\diamond^1 \cap \diamond^2$. That is, for a query range γ , we want to compute $\sum_{p \diamond^1 \gamma, p \diamond^2 \gamma} w(p)$. Suppose we have hierarchical decomposition schemes $\mathcal{D}^1$ and $\mathcal{D}^2$ for problems $\mathcal{P}^1$ and $\mathcal{P}^2$. Let $\mathcal{F}^1 = \mathcal{F}^1(S)$ be the set of canonical subsets constructed by $\mathcal{D}^1$, and for a range γ , let $\mathcal{C}_\gamma^1 = \mathcal{C}^1(S, \gamma)$ be the corresponding partition of $\{p \in S \mid p \diamond^1 \gamma\}$ into canonical subsets. For each canonical subset $C \in \mathcal{F}^1$, let $\mathcal{F}^2(C)$ be the collection of canonical subsets of C constructed by $\mathcal{D}^2$, and let $\mathcal{C}^2(C, \gamma)$ be the corresponding partition of $\{p \in C \mid p \diamond^2 \gamma\}$ into level-two canonical subsets. The decomposition scheme $\mathcal{D}^1 \circ \mathcal{D}^2$ for the problem $\mathcal{P}^1 \circ \mathcal{P}^2$ consists of the canonical subsets $\mathcal{F} = \bigcup_{C \in \mathcal{F}^1} \mathcal{F}^2(C)$. For a query range γ , the query output is $\mathcal{C}_\gamma = \bigcup_{C \in \mathcal{C}_\gamma^1} \mathcal{C}^2(C, \gamma)$. We can cascade any number of decomposition schemes in this manner.

If we view $\mathcal{D}^1$ and $\mathcal{D}^2$ as tree data structures, then cascading the two decomposition schemes can be regarded as constructing a two-level tree, as follows. We first construct the tree induced by $\mathcal{D}^1$ on S . Each node v of $\mathcal{D}^1$ is associated with a canonical subset C_v . We construct a second-level tree $\mathcal{D}_v^2$ on C_v and store $\mathcal{D}_v^2$ at v as its secondary structure. A query is answered by first identifying the nodes that

correspond to the canonical subsets $C_v \in \mathcal{C}_\gamma^1$ and then searching the corresponding secondary trees to compute the second-level canonical subsets $\mathcal{C}^2(C_v, \gamma)$.

Suppose the size and query time of each decomposition scheme are at most $S(n)$ and $Q(n)$, respectively, and $\mathcal{D}^1$ is efficient and r -convergent (cf. Section 36.1), for some constant $r > 1$. Then the size and query time of the decomposition scheme $\mathcal{D}$ are $O(S(n) \log_r n)$ and $O(Q(n) \log_r n)$, respectively. If $\mathcal{D}^2$ is also efficient and r -convergent, then $\mathcal{D}$ is efficient and r -convergent. In some cases, the logarithmic overhead in the query time or the space can be avoided.

The real power of multilevel data structures stems from the fact that there are no restrictions on the relations $\diamond^1$ and $\diamond^2$. Hence, any query that can be represented as a conjunction of a constant number of “primitive” queries, each of which admits an efficient, r -convergent decomposition scheme, can be answered by cascading individual decomposition schemes. We will describe a few multilevel data structures in this and the following sections.

SEMIALGEBRAIC RANGE SEARCHING

So far we have assumed that the ranges were bounded by hyperplanes, but in many applications one has to deal with ranges bounded by nonlinear functions. For example, a query of the form, “for a given point p and a real number r , find all points of S lying within distance r from p ,” is a range-searching problem in which the ranges are balls.

As shown below, ball range searching in $\mathbb{R}^d$ can be formulated as an instance of the halfspace range searching in $\mathbb{R}^{d+1}$. So a ball range-reporting (resp. range-counting) query in $\mathbb{R}^d$ can be answered in time $O(n/m^{1/\lceil d/2 \rceil} \log^c n + k)$ (resp. $O(n/m^{1/(d+1)} \log(m/n))$), using $O(m)$ space; somewhat better performance can be obtained using a more direct approach (Table 36.4.1). However, relatively little is known about range-searching data structures for more general ranges.

A natural class of nonlinear ranges is the family of Tarski cells. It suffices to consider the ranges bounded by a single polynomial because the ranges bounded by multiple polynomials can be handled using multilevel data structures. We assume that the ranges are of the form

$$\Gamma_f(a) = \{x \in \mathbb{R}^d \mid f(x, a) \geq 0\},$$

where f is a $(d+p)$ -variate polynomial specifying the type of ranges (disks, cylinders, cones, etc.), and a is a p -tuple specifying a specific range of the given type (e.g., a specific disk). We will refer to the range-searching problem in which the ranges are from the set Γ_f as **Γ_f -range searching**.

One approach to answering Γ_f -range queries is **linearization**. We represent the polynomial $f(x, a)$ in the form

$$f(x, a) = \psi_0(a) + \psi_1(a)\varphi_1(x) + \cdots + \psi_\lambda(a)\varphi_\lambda(x)$$

where $\varphi_1, \dots, \varphi_\lambda, \psi_0, \dots, \psi_\lambda$ are real functions. A point $x \in \mathbb{R}^d$ is mapped to the point

$$\varphi(x) = (\varphi_1(x), \varphi_2(x), \dots, \varphi_\lambda(x)) \in \mathbb{R}^\lambda.$$

Then a range $\gamma_f(a) = \{x \in \mathbb{R}^d \mid f(x, a) \geq 0\}$ is mapped to a halfspace

$$\varphi^\#(a) : \{y \in \mathbb{R}^\lambda \mid \psi_0(a) + \psi_1(a)y_1 + \cdots + \psi_\lambda(a)y_\lambda \geq 0\};$$

TABLE 36.4.1 Semialgebraic range counting; λ is the dimension of linearization.

d	RANGE	$S(n)$	$Q(n)$	NOTES
$d = 2$	disk	$n \log n$	$\sqrt{n \log n}$	
$d \leq 4$	Tarski cell	n	$n^{1-1/d+\epsilon}$	partition tree
$d \geq 4$	Tarski cell	n	$n^{1-\frac{1}{2d-4}+\epsilon}$	partition tree
	Tarski cell	n	$n^{1-\frac{1}{\lambda}+\epsilon}$	linearization
	disk	n	$n^{1-\frac{1}{d}+\epsilon}$	linearization

λ is called the **dimension** of linearization. For example, a set of spheres in $\mathbb{R}^d$ admit a linearization of dimension $d + 1$, using the well-known lifting transform. Agarwal and Matoušek [AM94] have described an algorithm for computing a linearization of the smallest dimension under certain assumptions on φ_i 's and ψ_i 's. If f admits a linearization of dimension λ , a Γ_f -range query can be answered using a λ -dimensional halfspace range-searching data structure. Agarwal and Matoušek [AM94] have also proposed another approach to answer Γ_f -range queries, by extending Theorem 36.3.1 to Tarski cells and by constructing partition trees using this extension. Table 36.4.1 summarizes the known results on Γ_f -range-counting queries. The bounds mentioned in the third row of the table rely on the result by Koltun [Kol01] on the vertical decomposition of arrangements of surfaces.

KINETIC RANGE SEARCHING

Let $S = \{p_1, \dots, p_n\}$ be a set of n points in $\mathbb{R}^2$, each moving continuously. Let $p_i(t)$ denote the position of p_i at time t , and let $S(t) = \{p_1(t), \dots, p_n(t)\}$. We assume that each point p_i is moving with fixed velocity, i.e., $p_i(t) = a_i + b_i t$ for $a_i, b_i \in \mathbb{R}^2$, and the trajectory of a point p_i is a line $\bar{p}_i$. Let L denote the set of lines corresponding to the trajectories of points in S .

We consider the following two range-reporting queries:

- Q1.** Given an axis-aligned rectangle R in the xy -plane and a time value t_q , report all points of S that lie inside R at time t_q , i.e., report $S(t_q) \cap R$; t_q is called the *time stamp* of the query.
- Q2.** Given a rectangle R and two time values $t_1 \leq t_2$, report all points of S that lie inside R at any time between t_1 and t_2 , i.e., report $\bigcup_{t=t_1}^{t_2} (S(t) \cap R)$.

Two general approaches have been proposed to preprocess moving points for range searching. The first approach, which is known as the *time-oblivious* approach, regards time as a new dimension and stores the trajectories $\bar{p}_i$ of input points p_i . One can either preprocess the trajectories themselves using various techniques, or one can work in a parametric space, map each trajectory to a point in this space, and build a data structure on these points. An advantage of the time-oblivious scheme is that the data structure is updated only if the trajectory of a point changes or if a point is inserted into or deleted from the index. Since this approach preprocesses either curves in $\mathbb{R}^2$ or points in higher dimensions, the query time tends to be large. For example, if S is a set of points moving in $\mathbb{R}^1$, then the trajectory of each point

is a line in $\mathbb{R}^2$ and a Q1 query corresponds to reporting all lines of L that intersect a query segment σ parallel to the x -axis. As we will see below, L can be preprocessed into a data structure of linear size so that all lines intersecting σ can be reported in $O(n^{1/2+\epsilon} + k)$ time. A similar structure can answer Q2 queries within the same asymptotic time bound. The lower bounds on simplex range searching suggest that one cannot hope to answer a query in $O(\log n + k)$ time using this approach. If S is a set of points moving in $\mathbb{R}^2$, then a Q1 query asks for reporting all lines of L that intersect a query rectangle R parallel to the xy -plane (in the xyt -space). A line ℓ in $\mathbb{R}^3$ (xyt -space) intersects R if and only if their projections onto the xt - and yt -planes both intersect. Using this observation one can construct a two-level partition tree of size $O(n)$ to report in $O(n^{1/2+\epsilon} + k)$ time all lines of L intersecting R [AAE03]. Again a Q2 query can be answered within the same time bound.

The second approach, based on the *kinetic-data-structure* framework [Gui98], builds a dynamic data structure on the moving points (see Chapter 50). Roughly speaking, at any time it maintains a data structure on the current configuration of the points. As the points move, the data structure evolves. The main observation is that although the points are moving continuously, the data structure is updated only at discrete time instances when certain *events* occur, e.g., when any of the coordinates of two points become equal. This approach leads to fast query time, but at the cost of updating the structure periodically even if the trajectory of no point changes. Another disadvantage of this approach is that it can answer a query only at the current configurations of points, though it can be extended to handle queries arriving in chronological order, i.e., the time stamps of queries are in nondecreasing order. In particular, if S is a set of points moving in $\mathbb{R}^1$, using a kinetic B -tree, a one-dimensional Q1 query can be answered in $O(\log n + k)$ time. The data structure processes $O(n^2)$ events, each of which requires $O(\log n)$ time. Similarly, by kinetizing range trees, a two-dimensional Q1 query can be answered in $O(\log n + k)$ time; the data structure processes $O(n^2)$ events, each of which requires $O(\log^2 n / \log \log n)$ time [AAE03].

Since range trees are too complicated, a more practical approach is to use the kinetic-data-structure framework on k -d-trees, as proposed by Agarwal et al. [AGG02]. They propose two variants of kinetic k -d-trees, each of which answers Q1 queries that arrive in chronological order in $O(n^{1/2+\epsilon})$ time, for any constant $\epsilon > 0$, process $O(n^2)$ kinetic events, and spend $O(\text{polylog } n)$ time at each event. Since kinetic k -d-trees process too many events because of the strong invariants they maintain, kinetic R-trees have also been proposed [JLL00, PAHP02], which typically require weaker invariants and thus are updated less frequently.

OPEN PROBLEMS

1. Can a ball range-counting query be answered in $O(\log n)$ time using $O(n^2)$ space?
2. If the hyperplanes bounding the query halfspaces satisfy some property—e.g., all of them are tangent to a given sphere—can a halfspace range-counting query be answered more efficiently?
3. Is there a simple, linear-size kinetic data structure that can answer Q1 queries

in $O(\sqrt{n} + k)$ time and processes near-linear events, each requiring $O(\log^c n)$ time?

36.5 INTERSECTION SEARCHING

A general intersection-searching problem can be formulated as follows: *Given a set S of objects in $\mathbb{R}^d$, a semigroup $(\mathbf{S}, +)$, and a weight function $w : S \rightarrow \mathbf{S}$; we wish to preprocess S into a data structure so that for a query object γ , we can compute the weighted sum $\sum w(p)$, where the sum is taken over all objects of S that intersect γ .* Range searching is a special case of intersection-searching in which S is a set of points.

An intersection-searching problem can be formulated as a semialgebraic range-searching problem by mapping each object $p \in S$ to a point $\varphi(p)$ in a parametric space $\mathbb{R}^\lambda$ and every query range γ to a semialgebraic set $\psi(\gamma)$ so that p intersects γ if and only if $\varphi(p) \in \psi(\gamma)$. For example, let both S and the query ranges be sets of segments in the plane. Each segment $e \in S$ with left and right endpoints (p_x, p_y) and (q_x, q_y) , respectively, can be mapped to a point $\varphi(e) = (p_x, p_y, q_x, q_y)$ in $\mathbb{R}^4$, and a query segment γ can be mapped to a semialgebraic region $\psi(\gamma)$ so that γ intersects e if and only if $\psi(\gamma) \in \varphi(e)$. A shortcoming of this approach is that λ , the dimension of the parametric space, is typically much larger than d , and thereby affecting the query time adversely. The efficiency can be significantly improved by expressing the intersection test as a conjunction of simple primitive tests (in low dimensions) and using a multilevel data structure to perform these tests. For example, a segment γ intersects another segment e if the endpoints of e lie on the opposite sides of the line containing γ and vice versa. We can construct a two-level data structure—the first level sifts the subset $S_1 \subseteq S$ of all the segments that intersect the line supporting the query segment, and the second level reports those segments of S_1 whose supporting lines separate the endpoints of γ . Each level of this structure can be implemented using a two-dimensional simplex range-searching structure, and hence a reporting query can be answered in $O(n/\sqrt{m} \log^c n + k)$ time using $O(m)$ space.

It is beyond the scope of this chapter to cover all intersection-searching problems. Instead, we discuss a selection of basic problems that have been studied extensively. All intersection-counting data structures described here can answer intersection-reporting queries at an additional cost proportional to the output size. In some cases an intersection-reporting query can be answered faster. Moreover, using intersection-reporting data structures, intersection-detection queries can be answered in time proportional to their query-search time. Finally, all the data structures described in this section can be dynamized at the expense of an $O(n^\epsilon)$ factor in the storage and query time.

POINT INTERSECTION SEARCHING

Preprocess a set S of objects (e.g., balls, halfspaces, simplices, Tarski cells) in $\mathbb{R}^d$ into a data structure so that the objects of S containing a query point can be reported (or counted) efficiently. This is the inverse of the range-searching problem, and it

can also be viewed as locating a point in the subdivision induced by the objects in S . Table 36.5.1 gives some of the known results.

TABLE 36.5.1 Point intersection searching.

d	OBJECTS	$S(n)$	$Q(n)$	NOTES
$d = 2$	disks	m	$(n/\sqrt{m})^{4/3}$	counting
	disks	$n \log n$	$\log n + k$	reporting
	triangles	m	$\frac{n}{\sqrt{m}} \log^3 n$	counting
	fat triangles	$n \log^2 n$	$\log^3 n + k$	reporting
	Tarski cells	$n^{2+\epsilon}$	$\log n$	counting
$d = 3$	functions	$n^{1+\epsilon}$	$\log n + k$	reporting
	Tarski cells	$n^{3+\epsilon}$	$\log n$	counting
$d \geq 3$	simplices	m	$\frac{n}{m^{1/d}} \log^{d+1} n$	counting
	balls	$n^{d+\epsilon}$	$\log n$	counting
	balls	m	$\frac{n}{m^{1/\lceil d/2 \rceil}} \log^c n + k$	reporting
$d \geq 4$	Tarski cells	$n^{2d-4+\epsilon}$	$\log n$	counting

SEGMENT INTERSECTION SEARCHING

Preprocess a set of objects in $\mathbb{R}^d$ into a data structure so that the objects of S intersected by a query segment can be reported (or counted) efficiently. See Table 36.5.2 for some of the known results on segment intersection searching. For the sake of clarity, we have omitted polylogarithmic factors from the query-search time whenever it is of the form n/m^α .

TABLE 36.5.2 Segment intersection searching.

d	OBJECTS	$S(n)$	$Q(n)$	NOTES
$d = 2$	simple polygon	n	$(k+1) \log n$	reporting
	segments	m	$n/\sqrt{m}$	counting
	circles	$n^{2+\epsilon}$	$\log n$	counting
	circular arcs	m	$n/m^{1/3}$	counting
$d = 3$	planes	m	$n/m^{1/3}$	counting
	spheres	m	$n/m^{1/3}$	counting
	triangles	m	$n/m^{1/4}$	counting

A special case of segment intersection searching, in which the objects are horizontal segments in the plane and query ranges are vertical segments, has been widely studied. In this case a query can be answered in time $O(\log n + k)$ using

$O(n \log \log n)$ space and $O(n \log n)$ preprocessing (in the RAM model), and a point can be inserted or deleted in $O(\log n)$ time [Mor03]. Slightly weaker bounds are known in the pointer-machine model.

COLORED INTERSECTION SEARCHING

Preprocess a given set S of colored objects in $\mathbb{R}^d$ (i.e., each object in S is assigned a color) so that we can report (or count) the colors of the objects that intersect the query range. This problem arises in many contexts in which one wants to answer intersection-searching queries for nonconstant-size input objects. For example, given a set $P = \{P_1, \dots, P_m\}$ of m simple polygons, one may wish to report all polygons of P that intersect a query segment; the goal is to return the indices, and not the description, of these polygons. If we color the edges of P_i with color i , the problem reduces to colored segment intersection searching in a set of segments.

A colored orthogonal range searching query for points on a two-dimensional grid $[0, U]^2$ can be answered in $O(\log \log U + k)$ time using $O(n \log^2 U)$ storage and $O(n \log n \log^2 U)$ preprocessing [AGM02]. On the other hand, a set S of n colored rectangles in the plane can be stored into a data structure of size $O(n \log n)$ so that the colors of all rectangles in S that contain a query point can be reported in time $O(\log n + k)$ [BKMT97]. If the vertices of the rectangles in S and all the query points lie on the grid $[0, U]^2$, the query time can be improved to $O(\log \log U + k)$ by increasing the storage to $O(n^{1+\epsilon})$.

Gupta et al. [GJS94] have shown that the colored halfplane-reporting queries in the plane can be answered in $O(\log^2 n + k)$ using $O(n \log n)$ space. Agarwal and van Kreveld [AvK96] presented a linear-size data structure with $O(n^{1/2+\epsilon} + k)$ query time for colored segment intersection-reporting queries amidst a set of segments in the plane, assuming that the segments of the same color form a connected planar graph or the boundary of a simple polygon; these data structures can also handle insertions of new segments.

36.6 OPTIMIZATION QUERIES

In optimization queries, we want to return an object that satisfies certain conditions with respect to a query range. The most common example of optimization queries is, perhaps, ray-shooting queries. Other examples include segment-dragging and linear-programming queries.

RAY-SHOOTING QUERIES

Preprocess a set S of objects in $\mathbb{R}^d$ into a data structure so that the first object (if one exists) intersected by a query ray can be reported efficiently. This problem arises in ray tracing, hidden-surface removal, radiosity, and other graphics problems. Efficient solutions to many geometric problems have also been developed using ray-shooting data structures.

A general approach to the ray-shooting problem, using segment intersection-detection structures and Megiddo's parametric-searching technique (Chapter 37),

was proposed by Agarwal and Matoušek [AM93]. The basic idea of their approach is as follows. Suppose we have a segment intersection-detection data structure for S , based on partition trees. Let ρ be a query ray. Their algorithm maintains a segment $\vec{ab} \subseteq \rho$ so that the first intersection point of $\vec{ab}$ with S is the same as that of ρ . If a lies on an object of S , it returns a . Otherwise, it picks a point $c \in ab$ and determines, using the segment intersection-detection data structure, whether the interior of the segment ac intersects any object of S . If the answer is YES, it recursively finds the first intersection point of $\vec{ac}$ with S ; otherwise, it recursively finds the first intersection point of $\vec{cb}$ with S . Using parametric searching, the point c at each stage can be chosen so that the algorithm terminates after $O(\log n)$ steps.

In some cases the query time can be improved by a polylogarithmic factor using a more direct approach.

TABLE 36.6.1 Ray shooting.

d	OBJECTS	$S(n)$	$Q(n)$
$d = 2$	simple polygon	n	$\log n$
	s disjoint polygons	n	$\sqrt{s} \log n$
	s disjoint polygons	$(s^2 + n) \log s$	$\log s \log n$
	s convex polygons	$sn \log s$	$\log s \log n$
	segments	m	$n/\sqrt{m}$
	circular arcs	m	$n/m^{1/3}$
	disjoint arcs	n	$\sqrt{n}$
$d = 3$	convex polytope	n	$\log n$
	c -oriented polytopes	n	$\log n$
	s convex polytopes	$s^2 n^{2+\epsilon}$	$\log^2 n$
	halfplanes	m	$n/\sqrt{m}$
	terrain	m	$n/\sqrt{m}$
	triangles	m	$n/m^{1/4}$
	spheres	m	$n/m^{1/3}$
$d > 3$	hyperplanes	m	$n/m^{1/d}$
	hyperplanes	$\frac{n^d}{\log^{d-\epsilon} n}$	$\log n$
	convex polytope	m	$n/m^{1/\lfloor d/2 \rfloor}$

Table 36.6.1 gives a summary of known ray-shooting results. For the sake of clarity, we have ignored the polylogarithmic factors in the query time whenever it is of the form n/m^α .

Like simplex range searching, many practical data structures have been proposed that, despite having poor worst-case performance, work well in practice. One common approach is to construct a subdivision of $\mathbb{R}^d$ into constant-size cells so that the interior of each cell does not intersect any object of S . A ray-shooting query can be answered by traversing the query ray through the subdivision until we find an object that intersects the ray. The worst-case query time is proportional to the maximum number of cells intersected by a segment that does not intersect any object in S . Hershberger and Suri [HS95] showed that a triangulation with $O(\log n)$

query time can be constructed when S is the boundary of a simple polygon in the plane. Agarwal et al. [AAS95] proved worst-case bounds for many cases on the number of cells in the subdivision that a line can intersect. Aronov and Fortune [AF99] have obtained a bound on the expected number of cells in the subdivision that a line can intersect.

LINEAR-PROGRAMMING QUERIES

Let S be a set of n halfspaces in $\mathbb{R}^d$. We wish to preprocess S into a data structure so that for a direction vector $\vec{v}$, we can determine the first point of $\bigcap_{h \in S} h$ in the direction $\vec{v}$. For $d \leq 3$, such a query can be answered in $O(\log n)$ time using $O(n)$ storage, by constructing the normal diagram of the convex polytope $\bigcap_{h \in S} h$ and preprocessing it for point-location queries. For higher dimensions, Ramos [Ram00] has proposed two data structures. His first structure can answer a query in time $(\log n)^{O(\log d)}$ using $n^{\lfloor d/2 \rfloor} \log^{O(1)} n$ space and preprocessing, and his second structure can answer a query in time $n^{1-1/\lfloor d/2 \rfloor} 2^{O(\log^* n)}$ using $O(n)$ space and $O(n^{1+\epsilon})$ preprocessing.

SEGMENT-DRAGGING QUERIES

Preprocess a set S of objects in the plane so that for a query segment e and a ray ρ , the first position at which e intersects any object of S as it is translated (dragged) along ρ can be determined quickly. This query can be answered in $O((n/\sqrt{m}) \log^c n)$ time, with $O(m)$ storage, using segment-intersection searching structures and the parametric-search technique. Chazelle [Cha88a] gave a linear-size, $O(\log n)$ query-time data structure for the special case in which S is a set of points, e is a horizontal segment, and ρ is the vertical direction. Instead of dragging a segment along a ray, one can ask the same question for dragging along a more complex trajectory (along a curve, and allowing both translation and rotation). These problems arise naturally in motion planning and manufacturing.

37 RAY SHOOTING AND LINES IN SPACE

Marco Pellegrini

INTRODUCTION

The geometry of lines in 3-space has been a part of the body of classical algebraic geometry since the pioneering work of Plücker. Interest in this branch of geometry has been revived in recent years by several converging trends in computer science. The discipline of computer graphics ([Chapter 49](#)) has pursued the task of rendering realistic images by simulating the flow of light within a scene according to the laws of elementary optical physics. In these models light moves along straight lines in 3-space and a computational challenge is to find efficiently the intersections of a very large number of rays with the objects comprising the scene. In robotics ([Chapters 47 and 48](#)) the chief problem is that of moving 3D objects without collisions. Effects due to the edges of objects have been studied as a special case of the more general problem of representing and manipulating lines in 3-space. Computational geometry (whose core is better termed “design and analysis of geometric algorithms”) has moved recently from the realm of planar problems to tackling directly problems that are specifically 3D. The new and sometimes unexpected computational phenomena generated by lines (and segments) in 3-space have emerged as a main focus of research.

In this chapter we will survey the present state of the art on lines and ray shooting in 3-space from the point of view of computational geometry. The emphasis is on provable nontrivial bounds for the time and storage used by algorithms for solving natural problems on lines, rays, and polyhedra in 3-space. We start by mentioning different possible choices of coordinates for lines ([Section 37.1](#)). This is an essential initial step because different coordinates highlight different properties of the lines in their interaction with other geometric objects. Here a special role is played by *Plücker coordinates* [[Plu65](#)] ([Section 37.1](#)), which represent the starting point for many of the most recent results. Then we consider how lines interact with each other ([Section 37.2](#)). We are given a finite set of lines L that act as obstacles and we will define other (infinite) sets of lines induced by L that capture some of the important properties of visibility and motion problems. We show bounds on the storage required for a complete description of such sets. Then we move a step forward by considering the same sets of lines when the obstacles are polyhedral sets, more commonly encountered in applications. We arrive in [Section 37.3](#) at the ray-shooting problem and its variants (on-line, off-line, arbitrary direction, fixed direction, and shooting with objects other than rays). Again, the obstacles are usually polyhedral objects, but in one case we are able to report a ray-shooting result on spheres.

[Section 37.4](#) is devoted to the problem of collision-free movements (arbitrary or translation only) of lines among obstacles. This problem arises, for example, when lines are used to model radiation or light beams (e.g., lasers). In [Section 37.5](#) we define a few notions of distance among lines, and as a consequence we have several

natural proximity problems for lines in 3-space. Finding the closest pair in a set of lines is the most basic of such problems.

In Section 37.6 we survey what is known about the “dominance” relation among lines. This relation is central for many visibility problems in graphics. It is used, for example, in the painter’s algorithm for hidden surface removal (Chapter 49). Another direction of research has explored the relation between lines in 3-space and their orthogonal projections. A central topic here is realizability: Given a set of planar lines together with a relation, does there exist a corresponding set of lines in 3-space whose dominance is consistent with the given relation?

37.1 COORDINATES OF LINES

GLOSSARY

Homogeneous coordinates: A point (x, y, z) in Cartesian coordinates has homogeneous coordinates (x_0, x_1, x_2, x_3) , where $x = x_1/x_0$, $y = x_2/x_0$, and $z = x_3/x_0$.

Oriented lines: A line may have two distinct orientations. A line and an orientation form an oriented line.

Unoriented line: A line for which an orientation is not distinguished.

(I) Canonical coordinates by pairs of planes. The intersection of two planes with equations $y = az + b$ and $x = cz + d$ is a nonhorizontal line in 3-space, uniquely defined by the four parameters (a, b, c, d) . Thus these parameters can be taken as coordinates of such lines. In fact, the space of nonhorizontal lines is homeomorphic to $\mathbb{R}^4$. Results on ray shooting among boxes and some lower bounds on stabbing are obtained using these coordinates.

(II) Canonical coordinates by pairs of points. Given two parallel horizontal planes, $z = 1$ and $z = 0$, the intersection points of a nonhorizontal line l with the two planes uniquely define that line. If $(x_0, y_0, 0)$ and $(x_1, y_1, 1)$ are two such points for l , then the quadruple (x_0, y_0, x_1, y_1) can be used as coordinates of l . Results on sets of horizontal polygons are obtained using these coordinates.

Although four is the minimum number of coordinates needed to represent an *unoriented* line, such parametrizations have proved useful only in special cases. Many interesting results have been derived using instead a five-dimensional parametrization for *oriented* lines, called **Plücker coordinates**.

(III) Plücker coordinates of lines. An oriented line in 3-space can be given by the homogeneous coordinates of two of its points. Let l be a line in 3-space and let $a = (a_0, a_1, a_2, a_3)$ and $b = (b_0, b_1, b_2, b_3)$ be two distinct points in homogeneous coordinates on l . We can represent the line l , oriented from a to b , by the matrix

$$l = \begin{pmatrix} a_0 & a_1 & a_2 & a_3 \\ b_0 & b_1 & b_2 & b_3 \end{pmatrix}, \quad \text{with } a_0, b_0 > 0.$$

By taking the determinants of the six 2×2 submatrices of the above 2×4 matrix

we obtain the *homogeneous Plücker coordinates* of the line:

$$p(l) = (\xi_{01}, \xi_{02}, \xi_{03}, \xi_{12}, \xi_{31}, \xi_{23}), \quad \text{with } \xi_{ij} = \det \begin{pmatrix} a_i & a_j \\ b_i & b_j \end{pmatrix}.$$

The six numbers ξ_{ij} are interpreted as homogeneous coordinates of a point in 5-space. For a given line l the six numbers are unique modulo a positive multiplicative factor, and they do not depend on the particular distinct points a and b that we have chosen on l . We call $p(l)$ the **Plücker point** of l in projective 5-dimensional space $\mathbb{P}^5$.

We also define the **Plücker hyperplane** of the line l to be the hyperplane in $\mathbb{P}^5$ with vector of coefficients $v(l) = (\xi_{23}, \xi_{31}, \xi_{12}, \xi_{03}, \xi_{02}, \xi_{01})$. So the Plücker hyperplane is:

$$h(l) = \{p \in \mathbb{P}^5 \mid v(l) \cdot p = 0\}.$$

For each Plücker hyperplane we have a positive and a negative halfspace given by $h^+(l) = \{p \in \mathbb{P}^5 \mid v(l) \cdot p \geq 0\}$ and $h^-(l) = \{p \in \mathbb{P}^5 \mid v(l) \cdot p \leq 0\}$. Not every tuple of 6 real numbers corresponds to a line in 3-space since the Plücker coordinates must satisfy the condition

$$\xi_{01}\xi_{23} + \xi_{02}\xi_{31} + \xi_{03}\xi_{12} = 0. \quad (37.1.1)$$

The set of points in $\mathbb{P}^5$ satisfying Equation 37.1.1 forms the so-called **Plücker hypersurface** Π ; it is also called the **Klein quadric** or the **Grassmannian** (manifold). The converse is also true: every tuple of six real numbers satisfying Equation 37.1.1 is the Plücker point of some line in 3-space. Given two lines l and l' , they intersect or are parallel (i.e., they intersect at infinity) when the four defining points are coplanar. In this case the determinant of the 4×4 matrix formed by the 16 homogeneous coordinates of the four points is zero. In terms of Plücker coordinates we have the following basic lemmas.

LEMMA 37.1.1

Lines l and l' intersect or are parallel (meet at infinity) if and only if $p(l) \in h(l')$.

Note that Equation 37.1.1 states in terms of Plücker coordinates the fact that any line always meets itself.

LEMMA 37.1.2

Let l be an oriented line and t a triangle in Cartesian 3-space with vertices (p_0, p_1, p_2) . Let l_i be the oriented line through (p_i, p_{i+1}) (indices mod 3). Then l intersects t if and only if either $p(l) \in h^+(l_0) \cap h^+(l_1) \cap h^+(l_2)$ or $p(l) \in h^-(l_0) \cap h^-(l_1) \cap h^-(l_2)$.

These two lemmas allow us to map combinatorial and algorithmic problems involving lines (and polyhedral sets) in 3-space into problems involving sets of hyperplanes and points in projective 5-space (Plücker space). The main advantage is that we can use the rich collection of results on the combinatorics of high dimensional arrangements of hyperplanes (see [Chapter 24](#)). The main drawback is that we are using five (nonhomogeneous) parameters, instead of four which is the minimum number necessary. This choice has a potential for increasing the time bounds of line algorithms. We are rescued by the following theorem:

THEOREM 37.1.3 [APS93]

*Given a set H of n hyperplanes in 5-dimensional space, the complexity of the cells of the arrangement $\mathcal{A}(H)$ intersected by the Plücker hypersurface Π (also called the **zone** of Π in $\mathcal{A}(H)$) is $O(n^4 \log n)$.*

Although the entire arrangement $\mathcal{A}(H)$ can be of complexity $\Theta(n^5)$, if we are working only with Plücker points we can limit our constructions to the zone of Π , the complexity of which is one order of magnitude smaller. Theorem 37.1.3 is especially useful for deriving ray-shooting results.

The list of coordinatizations discussed in this section is by no means exhaustive. Other parametrizations are used, for example, in [Ame92], [AAS97], and [AS96].

A TYPICAL EXAMPLE

A typical example of the use of Plücker coordinates in 3D problems is the result for fast ray shooting among polyhedra (see [Table 37.3.1](#)). We triangulate the faces of the polyhedra and extend each edge to a full line. Each such line is mapped to a Plücker hyperplane. Lemma 37.1.2 guarantees that each cell in the resulting arrangement of Plücker hyperplanes contains Plücker points that pass through the same set of triangles. Thus to answer a ray-shooting query, we first locate the query Plücker point in the arrangement, and then search the list of triangles associated with the retrieved cell. This final step is accomplished using a binary search strategy when the polyhedra are disjoint. Theorem 37.1.3 guarantees that we need to build a point location structure only for the zone of the Plücker hypersurface, thus saving an order of magnitude over general point location methods for arrangements (see [Sections 21.3](#) and 30.7).

37.2 SETS OF LINES IN 3-SPACE

With Plücker coordinates (III) to represent oriented lines, we can use the topology induced by the standard topology of 5-dimensional projective space $\mathbb{P}^5$ on Π as a natural topology on sets of oriented lines. Using the four-dimensional coordinatizations (I) or (II), we can impose the standard topology of $\mathbb{R}^4$ on the set of nonhorizontal unoriented lines. Thus we can define the concepts of “neighbourhood,” “continuous path,” “open set,” “closed set,” “boundary,” “path-connected component,” and so on, for the set $\mathcal{L}$ of lines in 3-space. The distinction between oriented lines and unoriented lines is mainly technical and the complexity bounds hold in either case.

GROUPS OF LINES INDUCED BY A FINITE SET OF LINES**GLOSSARY**

Semialgebraic set: The set of all points that satisfy a Boolean combination of a finite number of algebraic constraints (equalities and inequalities) in the Cartesian coordinates of $\mathbb{R}^d$. See [Chapter 33](#).

Path-connected component: A maximal set of lines that can be connected by a path of lines, a continuous function from the interval $[0, 1]$ to the space of lines.

Positively-oriented lines: Oriented lines l'_1 and l'_2 on the xy -plane are positively-oriented if the triple scalar product of vectors parallel to l'_1 , l'_2 , and the positive z -axis is positive.

Consistently-oriented lines: An oriented line l in 3-space is oriented consistently with a 3D set L of oriented lines if the projection l' of l onto a plane is positively-oriented with the projection of every line in L .

A finite set L of n lines in 3-space can be viewed as an obstacle to the free movement of other lines in 3-space. Many applications lead to defining groups of lines with some special properties with respect to the fixed lines L . The resources used by algorithms for these applications are often bounded by the “complexity” of such groups.

The boundary of a semialgebraic set in $\mathbb{R}^4$ is partitioned into a finite number of faces of dimension 0, 1, 2, and 3, each of which is also a semialgebraic set. The number of faces on the boundary of a semialgebraic set is the **complexity** of that set. The groups of lines that we consider are represented in $\mathbb{R}^4$ by semialgebraic sets, with the coefficients of the corresponding algebraic constraints a function of the given finite set of lines L .

The set $\text{Miss}(L)$ consists of lines that do not meet any line in L . The sets $\text{Vert}(L)$ and $\text{Free}(L)$ consists of lines that may be translated to infinity without collision with lines in L . The basic complexities displayed in Table 37.2.1 are derived from [CEGS96, Pel94b, Aga94].

TABLE 37.2.1 Complexity of groups of lines defined by lines.

SET OF LINES	DEFINITION	COMPLEXITY
$\text{Miss}(L)$	do not meet any line in L	$\Theta(n^4)$
1 component of $\text{Miss}(L)$	1 path-connected component	$\Theta(n^2)$
$\text{Vert}(L)$	can be translated vertically to ∞	$\Theta(n^3)$
$\text{Free}(L)$	can be translated to ∞ in some direction	$\Omega(n^3), O(n^3 \log n)$
$\text{VertCO}(L)$	above L and oriented consistently with L	$\Theta(n^2)$

MEMBERSHIP TESTS

Given L , we can build a data structure during a preprocessing phase so that when presented with a new (query) line l , we can decide efficiently whether l is in one of the sets defined in the previous section. Such an algorithm implements a membership test for a group of lines. Table 37.2.2 shows the main results.

GROUPS OF LINES INDUCED BY POLYHEDRA

GLOSSARY

ϵ : A positive real number, which we may choose arbitrarily close to zero for each

TABLE 37.2.2 Membership tests for groups of lines defined by lines.

SET OF LINES	QUERY TIME	PREPROC/STORAGE	SOURCE
Miss(L)	$O(\log n)$	$O(n^{4+\epsilon})$	[Pel93b, AM93]
1 component of Miss(L)	$O(\log n)$	$O(n^{2+\epsilon})$	[Pel91]
Vert(L), VertCO(L)	$O(\log n)$	$O(n^{2+\epsilon})$	[CEGS96]
Free(L)	$O(\log n)$	$O(n^{3+\epsilon})$	[Pel94b]

algorithm or data structure. A caveat is that the multiplicative constant implicit in the big- O notation depends on ϵ and its value increases when ϵ tends to zero.

$\alpha(\cdot)$: The inverse of Ackermann's function. $\alpha(n)$ grows very slowly and is at most 4 for any practical value of n . See [Section 47.4](#).

$\beta(\cdot)$: $\beta(n) = 2^{c\sqrt{\log n}}$ for a constant c . $\beta(\cdot)$ is a function that is smaller than any polynomial but larger than any polylogarithmic factor. Formally we have that for every $a, b > 0$, $\log^a n \leq \beta(n) \leq n^b$ for any $n \geq n_0(a, b)$.

Polyhedral set P : A region of 3-space bounded by a collection of interior-disjoint vertices, segments, and planar polygons. We denote with n the total number of vertices, edges, and faces.

Star-shaped polyhedron: A polyhedron P for which there exists a point $o \in P$ such that for every point $p \in P$, the open segment op is contained in P .

Terrain: When the star-shaped polyhedron is unbounded and o is at infinity we obtain a terrain, a monotone surface (cf. [Section 26.1](#)).

A collection of polyhedra in 3-space may act as obstacles limiting the collision-free movements of lines. Following the blueprint of the previous section, the complexity of some interesting groups of lines induced by polyhedra are displayed in [Table 37.2.3](#) (see [HS94, Pel94b, Aga94]).

TABLE 37.2.3 Complexity of groups of lines defined by polyhedra.

SET OF LINES	DEFINITION	COMPLEXITY
Miss(P)	do not meet polyhedron P	$\Theta(n^4)$
Vert(P)	can be translated vertically to ∞	$\Omega(n^3)$, $O(n^3\beta(n))$
Free(P)	can be translated to ∞ in some direction	$\Omega(n^3)$
Miss(Q), Free(Q)	Q star-shaped polyhedron or a terrain	$\Omega(n^2\alpha(n))$, $O(n^3 \log n)$

Similarly, we can define groups of *3D segments* defined by polyhedra in 3D. The set of relatively open segments that miss P is also a semialgebraic set, known as the **3D Visibility skeleton** (see [DDP97, Dur99]). Its combinatorial complexity is $\Theta(n^4)$.

OPEN PROBLEMS

1. Find an almost cubic upper bound on the complexity of the group of lines $\text{Free}(P)$ for a polyhedron P .
2. Close the gap between the quadratic lower and the cubic upper bound for the group $\text{Free}(T)$ induced by a terrain T (Table 37.2.3).

SETS OF STABBING LINES

GLOSSARY

Stabber: A line l that intersects every member of a collection $\mathcal{P} = \{P_1, \dots, P_k\}$ of polyhedral sets. The sum of the sizes of the polyhedral sets in $\mathcal{P}$ is n . The set of lines stabbing $\mathcal{P}$ is denoted $S(\mathcal{P})$.

Box: A parallelepiped each of whose faces is orthogonal to one of the three Cartesian axes.

***c*-oriented:** Polyhedra whose face normals come from a set of c fixed directions.

Table 37.2.4 lists the worst-case complexity of the set $S(\mathcal{P})$ and the time to find a witness stabbing line.

TABLE 37.2.4 Complexity of the set of stabbing lines and detection time.

OBJECTS	COMPLEXITY OF $S(\mathcal{P})$	FIND TIME	SOURCES
Convex polyhedra	$\Omega(n^3), O(n^3 \log n)$	$O(n^3 \beta(n))$	[PS92, Pel93a, Aga94]
Boxes	$O(n^2)$	$O(n)$	[Ame92, Meg91]
<i>c</i> -oriented polyhedra	$O(n^2)$	$O(n^2)$	[Pel91]
Horiz polygons	$\Theta(n^2)$	$O(n)$	[Pel91]

Note that in some cases (boxes, parallel polygons) a stabbing line can be found in linear time, even though the best bound known for the complexity of the stabbing set is quadratic. These results are obtained using linear programming techniques (Chapter 45).

We can determine whether a given line l is a stabber for a preprocessed set $\mathcal{P}$ of convex polyhedra in time $O(\log n)$, using data structures of size $O(n^{2+\epsilon})$ that can be constructed in time $O(n^{2+\epsilon})$ [PS92].

For an *oriented* stabber l and a set $\mathcal{O}$ of k *disjoint* convex bodies in R^d , the order of the intersection of the objects along l is called a **geometric permutation** (cf. Chapter 4). A recent advance of Zhou and Suri [ZS01] shows that for balls of unit radius and k large enough there are at most 4 geometric permutations. For k rectangular boxes there are at most 2^{d-1} geometric permutations, which is tight (see also [OR01]).

OPEN PROBLEMS

1. Can linear programming techniques yield a linear-time algorithm for c -oriented polyhedra?
 2. The lower bound for $S(\mathcal{P})$ for a set of pairwise *disjoint* convex polyhedra is only $\Omega(n^2)$ [PS92]. Close the gap between this and the cubic upper bound.
-

37.3 RAY SHOOTING

Ray shooting is an important operation in computer graphics and a primitive operation useful in several geometric computations (e.g., hidden surface removal, and detecting and computing intersections of polyhedra). The problem is defined as follows. Given a large collection $\mathcal{P}$ of simple polyhedral objects, we want to know, for a given point p and direction $\vec{d}$, the first object in $\mathcal{P}$ intersected by the ray defined by the pair $p, \vec{d}$. A single polyhedron with many faces can be represented without loss of generality by the collection of its faces, each treated as a separate polygon.

ON-LINE RAY SHOOTING IN AN ARBITRARY DIRECTION

Here we consider the on-line model in which the set $\mathcal{P}$ is given in advance and a data structure is produced and stored. Afterward we are given the query rays one-by-one and the answer to one query must be produced before the next query is asked.

Table 37.3.1 summarizes the known complexity bounds on this problem. For a given class of objects we report the query time, the storage, and the preprocessing time of the method with the best bound. In this table and in the following ones we omit the big- O symbols. Again, n denotes the sum of the sizes of all the polyhedra in $\mathcal{P}$. The main references on ray shooting (Table 37.3.1) are in [Pel93b, dBH⁺94] (boxes), [AM93, AM94, Pel93b, dBH⁺94, AS93b] (polyhedra), [Pel96] (horizontal polygons), [AAS97, MS97] (spheres), and [DK85, AS96a] (convex polyhedra).

GLOSSARY

Fat horizontal polygons: Convex polygons contained in planes parallel to the xy -plane, with a lower bound on the size of their minimum interior angle.

Curtains: Polygons in 3-space bounded by one segment and by two vertical rays from the endpoints of the segment.

Axis-oriented curtains: Curtains hanging from a segment parallel to the x - or y -axis.

When we drop the fatness assumption for horizontal polygons we obtain bounds that depend on K , the complexity of the set of lines missing the *edges* of the polygons. K is in the range $[n^2, \dots, n^4]$ and reaches the upper end of the range only when the polygons are very long and thin.

TABLE 37.3.1 On-line ray shooting in an arbitrary direction.

OBJECTS	QUERY	STORAGE	PREPROCESSING
Boxes, terrains, curtains	$\log n$	$n^{2+\epsilon}$	$n^{2+\epsilon}$
Boxes	$n^{1+\epsilon}/m^{1/2}$	$n \leq m \leq n^2$	$m^{1+\epsilon}$
Polyhedra	$\log n$	$n^{4+\epsilon}$	$n^{4+\epsilon}$
Polyhedra	$n^{1+\epsilon}/m^{1/4}$	$n \leq m \leq n^4$	$m^{1+\epsilon}$
Fat horiz polygons	$\log n$	$n^{2+\epsilon}$	$n^{2+\epsilon}$
Horiz polygons	$\log^3 n$	$n^{3+\epsilon} + K$	$n^{3+\epsilon} + K \log n$
Spheres	$\log^4 n$	$n^{3+\epsilon}$	$n^{3+\epsilon}$
1 convex polyhedron	$\log n$	n	$n \log n$
s convex polyhedra	$\log^2 n$	$n^{2+\epsilon} s^2$	$n^{2+\epsilon} s^2$

Most of the data structures for ray shooting mentioned in Table 37.3.1 can be made dynamic (under insertion and deletion of objects in the scene) by using general dynamization techniques (see [Meh84]) and other more recent results [AEM92].

ON-LINE RAY SHOOTING IN A FIXED DIRECTION

We can usually improve on the general case if the direction of the rays is fixed a priori, while the source of the ray can lie anywhere in $\mathbb{R}^3$. See Table 37.3.2; here k is the number of vertices, edges, faces, and cells of the arrangement of the (possibly intersecting) polyhedra. References for ray shooting in a fixed direction (Table 37.3.2) are [dB93, dBGH94].

TABLE 37.3.2 On-line ray shooting in a fixed direction.

OBJECTS	QUERY TIME	STORAGE	PREPROCESSING
Boxes	$\log n$	$n^{1+\epsilon}$	$n^{1+\epsilon}$
Boxes	$\log n (\log \log n)^2$	$n \log n$	$n \log^2 n$
Axis-oriented curtains	$\log n$	$n \log n$	$n \log n$
Polyhedra	$\log^2 n$	$n^{2+\epsilon} + k$	$n^{2+\epsilon} + k \log n$
Polyhedra	$n^{1+\epsilon}/m^{1/3}$	$n \leq m \leq n^3$	$m^{1+\epsilon}$

OFF-LINE RAY SHOOTING IN AN ARBITRARY DIRECTION

In the previous section we considered the on-line situation when the answer to the query must be generated before the next question is asked. In many situations we do not need such strict requirements. For example, we might know all the queries from the start and are interested in minimizing the total time needed to answer all of the queries (the *off-line* situation). In this case there are simpler algorithms that improve on the storage bounds of on-line algorithms:

THEOREM 37.3.1

Given a polyhedral set $\mathcal{P}$ with n vertices, edges, and faces, and given m rays off-

line, we can answer the m ray-shooting queries in time $O(m^{0.8}n^{0.8+\epsilon} + m \log^2 n + \log n \log m)$ using $O(n + m)$ storage.

One of the most interesting applications of this result is the current asymptotically fastest algorithm for detecting whether two nonconvex polyhedra in 3-space intersect, and to compute their intersection. See Table 37.3.3; here k is the size of the intersection.

TABLE 37.3.3 Detection and computation of intersection among polyhedra.

OBJECTS	DETECTION	COMPUTATION	SOURCES
Polyhedra	$n^{1.6+\epsilon}$	$n^{1.6+\epsilon} + k \log^2 n$	[Pel93b]
Terrains	$n^{4/3+\epsilon}$	$n^{4/3+\epsilon} + k^{1/3}n^{1+\epsilon} + k \log^2 n$	[CEGS94, Pel94b]

Lower bounds on off-line ray-shooting and intersection problems in 3D are difficult to prove. It has been shown in [Eri95] that many such problems are at least as hard as Hopcroft’s incidence problem (in the appropriate ambient space).

RAY-SHOOTING IN SIMPLICIAL COMPLEXES

If we have a subdivision of the free space $\mathbb{R}^3 \setminus \mathcal{P}$ into a simplicial complex we can answer ray-shooting queries by locating the tetrahedron containing the source of the ray and tracing the ray in the complex at cost $O(1)$ for each visited face of the complex. There are scenes $\mathcal{P}$ for which any simplicial complex has some line meeting $\Omega(n)$ faces of the complex. The average time for tracing a ray in a simplicial complex is proportional to the sum of the areas of all faces in the complex. It is possible to find a complex of total surface within a constant multiplicative factor of the minimum, with $O(n^3 \log n)$ simplices in time $O(n^3 \log n)$ for general $\mathcal{P}$. For $\mathcal{P}$ a point set or a single polyhedron $O(n^2 \log n)$ time suffices (see [AAS95, AF99, CD99]). These results are obtained via a generalization of Eppstein’s method for two-dimensional Minimum Weighted Steiner Triangulation (2D-MWST) of a point set [Epp94]. In the 3D context the weight is the surface of the 2D faces of the complex. Starting from the set $\mathcal{P}$ of polyhedral obstacles in R^3 , an oct-tree-based decomposition of R^3 is produced which is “balanced” and “smooth.” It is then proved, via a charging argument, that the sum of the surfaces of all the boxes in the decomposition is within a constant factor of the surface of any Minimum Surface Steiner Simplicial Complex compatible with $\mathcal{P}$. From the oct-tree the final complex is derived within just a constant factor increase in the total surface.

EXTENSIONS AND ALTERNATIVE METHODS

Some ray-shooting results of Agarwal and Matoušek are obtained from the observation that a ray is traced by a family of segments $\rho(t)$, where one endpoint is the ray source and the second endpoint lies on the ray at distance t from the source. Using *parametric search* techniques (Chapter 43), Agarwal and Matoušek compute the first value of t for which $\rho(t)$ intersects $\mathcal{P}$, and thus answer the ray-shooting query.

An interesting extension of the concept of shooting rays against obstacles is obtained by shooting triangles and more generally simplices. We consider a family of simplices $s(t)$, indexed by real parameter $t \in \mathbb{R}^+$, where t is the volume of the simplex $s(t)$, such that the simplices form a chain of inclusions: $t_1 \leq t_2 \Rightarrow s(t_1) \subset s(t_2)$. Intuitively we grow a simplex until it first meets one of the obstacles. Surprisingly, when the obstacles are general polyhedra, shooting simplices is not harder than shooting rays.

THEOREM 37.3.2 [Pel94a]

Given a set of polyhedra $\mathcal{P}$ with n edges we can preprocess it in time $O(m^{1+\epsilon})$ into a data structure of size m , such that the following queries can be answered in time $O(n^{1+\epsilon}/m^{1/4})$: Given a simplex s , does s avoid $\mathcal{P}$? Given a family of simplices $s(t)$ as above, which is the first value of t for which $s(t)$ intersects $\mathcal{P}$?

Computing the interaction between beams and polyhedral objects is a central problem in radio-therapy and radio-surgery (see e.g. [SAL93] [For99] [CHX00]).

Other popular methods for solving ray-shooting problems are based binary space partitions, kD-trees, solid modeling schemes, etc. These methods, although important in practice, are usually not fully analyzable a priori using algorithmic analysis. In [AB⁺02] Aronov et al. propose techniques that give a posteriori estimates of the cost of ray shooting.

OPEN PROBLEMS

1. Find time and storage bounds for ray-shooting general polyhedra that are sensitive to the actual complexity of a group of lines (as opposed to the worst case bound on such a complexity).
2. For a collection of s convex polyhedra there is a wide gap in storage and preprocessing between the special case $s = 1$ and the case for general s . It would be interesting to obtain a bound that depends smoothly on s .
3. No lower bound on time or storage required for ray shooting is known.

37.4 MOVING LINES AMONG OBSTACLES

ARBITRARY MOTIONS

So far we have treated lines as static objects. In this section we consider moving lines. A laser beam in manufacturing or a radiation beam in radiation therapy can be modeled as lines in 3-space moving among obstacles. The main computational problem is to decide whether a source line l_1 can be moved continuously until it coincides with a target line l_2 so that it avoids a set of obstacles $\mathcal{P}$. We consider the following situation where the set of obstacles $\mathcal{P}$ is given in advance and preprocessed to obtain a data structure. When the query lines l_1 and l_2 are given the answer is produced before a new query is accepted. We have the results shown in [Table 37.4.1](#), where K is the complexity of the set of lines missing the edges of the polygons (cf. Section 37.2).

TABLE 37.4.1 On-line collision-free movement of lines among obstacles.

OBJECTS	QUERY TIME	STORAGE	PREPROC	SOURCES
Polyhedra	$\log n$	$n^{4+\epsilon}$	$n^{4+\epsilon}$	[Pel93b]
Horiz polygons	$\log^3 n$	$n^{3+\epsilon} + K$	$n^{3+\epsilon} + K \log n$	[Pel96]

OPEN PROBLEMS

It is not known how to trade off storage and query time, or whether better bounds can be obtained in an off-line situation.

TRANSLATIONS

We now restrict the type of motion and consider only translations of lines. The first result is negative: there are sets of lines which cannot be split by any collision-free translation. There exists a set L of 9 lines such that, for all directions v and all subsets $L_1 \subset L$, L_1 cannot be translated continuously in direction v without collisions with $L \setminus L_1$ [SS93]. Positive results are displayed in Table 37.4.2.

GLOSSARY

Towering property: Two sets of lines L_1 and L_2 are said to satisfy the towering property if we can translate simultaneously all lines in L_1 in the vertical direction without any collision with any lines in L_2 .

Separation property: Two sets of lines satisfy the separation property if they satisfy the towering property in some direction (not necessarily vertical).

TABLE 37.4.2 Separating lines by translations.

PROPERTY	TIME TO CHECK PROPERTY	SOURCES
Towering	$O(n^{4/3+\epsilon})$	[CEGS96]
Separation	$O(n^{3/2+\epsilon})$	[Pel94b]

37.5 CLOSEST PAIR OF LINES

GLOSSARY

Distance between lines: The Euclidean distance between two lines l_1 and l_2 in 3-space is the length of the shortest segment with one endpoint on l_1 and the other on l_2 .

Vertical distance between lines: The length of the vertical segment with one endpoint on l_1 and one endpoint of l_2 (provided a unique such segment exists).

Vertical distance between segments: The length of the vertical segment with one endpoint in s_1 and one in s_2 . If a unique such vertical segment does not exist the vertical distance is undefined.

TABLE 37.5.1 Closest and farthest pair of lines and segments.

PROBLEM	OBJECTS	TIME	SOURCES
Smallest distance	lines	$O(n^{8/5+\epsilon})$	[CEGS93]
Smallest vertical distance	lines, segments	$O(n^{8/5+\epsilon})$	[Pel94a]
Largest vertical distance	lines, segments	$O(n^{4/3+\epsilon})$	[Pel94a]

Any centrally symmetric convex polyhedron C in 3D defines a metric L_C . If C has constant combinatorial complexity, then the complexity of the Voronoi diagram of n lines in 3-space is $O(n^2 \alpha(n) \log n)$ [CKS⁺98]. For Euclidean distance the best bound is $O(n^{3+\epsilon})$.

OPEN PROBLEM

1. Finding an algorithm with subquadratic time complexity for the smallest distance among segments (and more generally, among polyhedra) is a notable open question.
2. Close the gap between the complexity of Voronoi diagrams of lines induced by polyhedral metrics and the Euclidean metric.

37.6 DOMINANCE RELATION AND WEAVINGS

GLOSSARY

Dominance relation: Given a finite set L of nonvertical disjoint lines in $\mathbb{R}^3$, define a dominance relation $\prec$ among lines in L as follows: $l_1 \prec l_2$ if l_2 lies above l_1 , i.e., if, on the vertical line intersecting l_1 and l_2 , the intersection with l_1 has a smaller z -coordinate than does the intersection with l_2 .

Weaving: A weaving is a pair $(L', \prec')$ where L' is a set of lines on the plane and $\prec'$ is an anti-symmetric nonreflexive binary relation $\prec' \subset L' \times L'$ among the lines in L' .

Realizable: A weaving is realizable if there exists a set of lines L in 3-space such that L' is the projection of L and $\prec'$ is the image of the dominance relation $\prec$ for L .

Elementary cycle: A cycle in the dominance relation such that the projections of the lines in such a cycle bound a cell of the arrangement of projected lines.

Perfect: A weaving $(L', \prec')$ is perfect if each line l alternates below and above the other lines in the order they cross l (see Figure 37.6.1a).

Bipartite weaving: Two families of segments in 3-space such that, when projecting on the xy -plane, each segment does not meet segments from its own family and meets all the segments from the other family. (A bipartite weaving of size 4×4 is shown in Figure 37.6.1b.)

Perfect bipartite weaving: Every segment alternates above and below the segments of the other family (see Figure 37.6.1b).

FIGURE 37.6.1

- (a) A perfect weaving;
(b) a perfect bipartite weaving.

The dominance relation is possibly cyclic, that is, there may be three lines such that $l_1 \prec l_2 \prec l_3 \prec l_1$. Some results in [CEG⁺92, PPW93, dBOS94, Sol98] related to dominance are the following:

1. *How fast can we generate a consistent linear extension if the relation $\prec$ is acyclic?* $O(n^{4/3+\epsilon})$ time is sufficient for the case of lines. This result has been extended to the case of segments and polyhedra. If an ordering is given as input, it is possible to *verify* that it is a linear extension of $\prec$ in time $O(n^{4/3+\epsilon})$.
2. *How many elementary cycles in the dominance relation can n lines define?* In the case of bipartite weavings, the dominance relation can have $O(n^{3/2})$ elementary cycles and there is a family of bipartite weavings attaining the lower bound $\Omega(n^{4/3})$. For general weavings there is a construction attaining $\Omega(n^{3/2})$.
3. *If we cut the segments to eliminate cycles, how many “cuts” are necessary to eliminate all cycles?* From the previous result we have that sometimes $\Omega(n^{4/3})$ cuts are necessary since a single cut can eliminate only one elementary cycle. In order to eliminate all cycles (including the nonelementary ones) in a bipartite weaving, $O(n^{9/5})$ cuts are always sufficient.
4. *How fast can we find those cuts?* There is an algorithm to find cuts in bipartite weavings in time $O(n^{9/5} \log n)$. In a general weaving, calling μ is the minimum number of cuts, there is an algorithm to cut all cycles in time $O(n^{4/3+\epsilon} \mu^{1/3})$ that produces $O(n^{1+\epsilon} \mu^{1/3})$ cuts.

5. The fraction of realizable weavings over all possible weavings of n lines tends to 0 exponentially as n tends to ∞ .
6. A perfect weaving of $n \geq 4$ lines is not realizable.
7. Perfect bipartite weavings are realizable only if one of the families has fewer than four segments.

38 GEOMETRIC INTERSECTION

David M. Mount

INTRODUCTION

Detecting whether two geometric objects intersect and computing the region of intersection are fundamental problems in computational geometry. Geometric intersection problems arise naturally in a number of applications. Examples include geometric packing and covering, wire and component layout in VLSI, map overlay in geographic information systems, motion planning, and collision detection. In solid modeling, computing the volume of intersection of two shapes is an important step in defining complex solids. In computer graphics, detecting the objects that overlap a viewing window is an example of an intersection problem, as is computing the first intersection of a ray and a collection of geometric solids.

Intersection problems are fundamental to many aspects of geometric computing. It is beyond the scope of this chapter to completely survey this area. Instead we illustrate a number of the principal techniques used in efficient intersection algorithms. This chapter is organized as follows. Section 38.1 discusses intersection primitives, the low-level issues of computing intersections that are common to high-level algorithms. Section 38.2 discusses detecting the existence of intersections. Section 38.3 focuses on issues related to counting the number of intersections and reporting intersections. Section 38.4 deals with problems related to constructing the actual region of intersection. Section 38.5 considers methods for geometric intersections based on spatial subdivisions.

38.1 INTERSECTION PREDICATES

GLOSSARY

Geometric predicate: A function that computes a discrete relationship between basic geometric objects.

Boundary elements: The vertices, edges, and faces of various dimensions that make up the boundary of an object.

Complex geometric objects are typically constructed from a number of primitive objects. Intersection algorithms that operate on complex objects often work by breaking the problem into a series of primitive geometric predicates acting on basic elements, such as points, lines and curves, that form the boundary of the objects involved. Examples of geometric predicates include determining whether two line segments intersect each other or whether a point lies above, below, or on a given line.

Computing these predicates can be reduced to computing the sign of a polynomial, ideally of low degree. In many instances the polynomial arises as the determinant of a symbolic matrix.

Computing geometric predicates in a manner that is efficient, accurate, and robust can be quite challenging. Floating-point computations are fast but suffer from round-off errors, which can result in erroneous decisions. These errors in turn can lead to topological inconsistencies in object representations, and these inconsistencies can cause the run-time failures. Some of the approaches used to address robustness in geometric predicates include approximation algorithm that are robust to floating-point errors [SI94], computing geometric predicates exactly using adaptive floating-point arithmetic [Cla92, ABD⁺97], exact arithmetic combined with fast floating-point filters [BKM⁺95, FV96], and designing algorithms that are based on a restricted set of geometric predicates [BS00].

We will concentrate on geometric intersections involving flat objects (line segments, polygons, polyhedra), but there is considerable interest in computing intersections of curves and surfaces. Predicates for curve and surface intersections are particularly challenging, because the intersection of surfaces of a given algebraic degree generally results in a curve of a significantly higher degree. Computing intersection primitives typically involves solving an algebraic system equations, which can be performed either exactly by algebraic and symbolic methods [Yap93] or approximately by numerical methods [Hof89, MC91]. See [Chapter 41](#).

38.2 INTERSECTION DETECTION

GLOSSARY

Polygonal chain: A sequence of line segments joined end-to-end.

Self-intersecting: Said of a polygonal chain if any pair of nonadjacent edges intersects one another.

Bounding box: A rectangular box surrounding an object, usually axis-aligned (*isothetic*).

Intersection detection, the easiest of all intersection tasks, requires merely determining the existence of an intersection. Nonetheless, detecting intersections efficiently in the absence of simplifying geometric structure can be challenging. As an example, consider the following fundamental intersection problem, posed by John Hopcroft in the early 1980's. Given a set of n points and n lines in the plane, does any point lie on any line? See [Figure 38.2.1](#). A series of efforts to solve *Hopcroft's problem* culminated in the best algorithm known for this problem to date, due to Matoušek [Mat93], which runs in $O(n^{4/3})2^{O(\log^* n)}$. There is reason to believe that this may be close to optimal; Erickson [Eri96] has shown that, in certain models of computation, $\Omega(n^{4/3})$ is a lower bound. Agarwal and Sharir [AS90] have shown that, given two sets of line segments denoted red and blue, it is possible to determine whether there is any red-blue intersection in $O(n^{4/3+\epsilon})$ time, for any positive constant ϵ .

FIGURE 38.2.1
Hopcroft's Problem.

The types of objects considered in this section are polygons, polyhedra, and line segments. Let P and Q denote the two objects to be tested for intersection. Throughout, n_p and n_q denote the combinatorial complexity of P and Q , respectively, that is, the number of vertices, edges, and faces (for polyhedra). Let $n = n_p + n_q$ denote the total complexity.

Table 38.2.1 summarizes a number of results on intersection detection, which will be discussed further in this section. In the table, the terms *convex* and *simple* refer to convex and simple polygons, respectively. The notation $(s(n), q(n))$ in the “Time” column means that the solution involves preprocessing, where a data structure of size $O(s(n))$ is constructed so that intersection detection queries can be answered in $O(q(n))$ time.

TABLE 38.2.1 Intersection detection.

DIM	OBJECTS	TIME	SOURCE
2	convex-convex	$\log n$	[DK83]

	simple-simple	$(n, s \log^2 n)$	[Mou92]
	line segments	$n \log n$	[SH76]
	Hopcroft's problem	$n^{4/3} 2^{O(\log^* n)}$	[Mat93]
3	convex-convex	n	[DK85]
	convex-convex	$(n, \log n_p \log n_q)$	[DK90]

INTERSECTION DETECTION OF CONVEX POLYGONS

Perhaps the most easily understood example of how the structure of geometric objects can be exploited to yield an efficient intersection test is that of detecting the intersection of two convex polygons. There are a number of solutions to this problem that run in $O(\log n)$ time. We present one due to Dobkin and Kirkpatrick [DK83].

Assume that each polygon is given by an array of vertex coordinates, sorted in counterclockwise order. The first step of the algorithm is to find the vertices of each of P and Q with the highest and lowest y -coordinates. This can be done in $O(\log n)$ time by an appropriate modification of binary search and consideration of the direction of the edges incident to each vertex [O'R98, Section 7.6]. After these vertices are located, the boundary of each polygon is split into two semi-infinite convex chains, denoted P_L, P_R and Q_L, Q_R (see Figure 38.2.2(a)). P and Q intersect if and only if P_L and Q_R intersect, and P_R and Q_L intersect.

FIGURE 38.2.2

Intersection detection for two convex polygons.

Consider the case of P_L and Q_R . The algorithm applies a variant of binary search. Consider the median edge e_p of P_L and the median edge e_q of Q_R (shown as heavy lines in the figure). By a simple analysis of the relative positions of these edges and the intersection point of the two lines on which they lie, it is possible to determine in constant time either that the polygons intersect, or that half of at least one of the two boundary chains can be eliminated from further consideration. The cases that arise are illustrated in Figure 38.2.2(b)–(d). The shaded regions indicate the portion of the boundary that can be eliminated from consideration.

SIMPLE POLYGONS

Without convexity, it is generally not possible to detect intersections in sublinear time without preprocessing; but efficient tests do exist.

One of the important intersection questions is whether a closed polygonal chain defines the edges of a simple polygon. The problem reduces to detecting whether the chain is self-intersecting. This problem can be solved efficiently by supposing that the polygonal chain is a simple polygon, attempting to triangulate the polygon, and seeing whether anything goes wrong in the process. Some triangulation algorithms can be modified to detect self intersections. In particular, the problem can be solved in $O(n)$ time by modifying Chazelle's linear-time triangulation algorithm [Cha91]. See [Section 25.2](#).

Another variation is that of determining the intersection of two simple polygons. Chazelle observed that this can also be reduced to testing self intersections in $O(n)$ time by joining the polygons into a single closed chain by a narrow channel as shown in Figure 38.2.3.

FIGURE 38.2.3

Intersection detection for two simple polygons.

DETECTING INTERSECTIONS OF MULTIPLE OBJECTS

In many applications it is important to know whether any pair of a set of objects intersects one another. Shamos and Hoey showed that the problem of detecting whether a set of n line segments in the plane have an intersecting pair can be solved in $O(n \log n)$ time [SH76]. This is done by plane sweep, which will be discussed below. They also showed that the same can be done for a set of circles. Reichling showed that this can be generalized to detecting whether any pair of m convex n -gons intersects in $O(m \log m \log n)$ time, and whether they all share a common intersection point in $O(m \log^2 n)$ time [Rei88]. Hopcroft, Schwartz, and Sharir [HSS83] showed how to detect the intersection of any pair of n spheres in 3-space in $O(n \log^2 n)$ time and $O(n \log n)$ space by applying a 3D plane sweep.

INTERSECTION DETECTION WITH PREPROCESSING

If preprocessing is allowed, then significant improvements in intersection detection time may be possible. One of the best-known techniques is to filter complex intersection tests is to compute an axis-aligned bounding box for each object. Two objects need to be tested for intersection only if their bounding boxes intersect. It is very easy to test whether two such boxes intersect by comparing their projections on each coordinate axis. For example, in Figure 38.2.4, of the 15 possible pairs of object intersections, all but 3 may be eliminated by the bounding box filter.

FIGURE 38.2.4

Using bounding boxes as an intersection filter.

It is hard to prove good worst-case bounds for the bounding-box filter since it is possible to create instances of n disjoint objects in which all $O(n^2)$ pairs of bounding boxes intersect. Nonetheless, this popular heuristic tends to perform well in practice. Suri and others [SHH99, ZS99] provided an explanation for this. They proved that if the boxes have bounded aspect ratio and the relative object sizes are within a constant factor each other, then (up to an additive linear term) the number of intersecting boxes is proportional to the number of intersecting object pairs. Combining this with Dobkin and Kirkpatrick's results leads to an algorithm, which given n convex polytopes in dimension d , reports all k intersecting pairs in time $O(n \log^{d-1} n + k \log^{d-1} m)$, where m is the maximum number of vertices in any polytope.

Another example is that of ray shooting in a simple polygon. This is a planar version of a well-known 3D problem in computer graphics. The problem is to preprocess a simple polygon so that given a query ray, the first intersection of the ray with the boundary of the polygon can be determined. After $O(n)$ preprocessing it is possible to answer ray-shooting queries in $O(\log n)$ time. A particularly elegant

solution was given by Hershberger and Suri [HS95]. The polygon is triangulated in a special way, called a *geodesic triangulation*, so that any line segment that does not intersect the boundary of the polygon crosses at most $O(\log n)$ triangles. Ray-shooting queries are answered by locating the triangle that contains the origin of the ray, and “walking” the ray through the triangulation. See also [Section 25.4](#).

Mount showed how the geodesic triangulation can be used to generalize the bounding box test for the intersection of simple polygons. Each polygon is preprocessed by computing a geodesic triangulation of its exterior. From this it is possible to determine whether they intersect in $O(s \log^2 n)$ time, where s is the minimum number of edges in a polygonal chain that separates the two polygons [Mou92]. Separation sensitive intersections of polygons has been studied in the context of kinetic algorithms for collision detection. See [Chapter 50](#).

CONVEX POLYHEDRA IN 3-SPACE

Extending a problem from the plane to 3-space often involves in a significant increase in difficulty. Nonetheless, Dobkin and Kirkpatrick showed that this detection can be performed efficiently by adapting Kirkpatrick’s hierarchical decomposition of planar triangulations. Given two polyhedra P and Q having boundary complexity n_p and n_q , respectively, their algorithm runs in $O(\log n_p \log n_q)$ time, assuming that each polyhedron has been preprocessed in linear time and space [DK90].

DOBKIN-KIRKPATRICK DECOMPOSITION

Before describing the intersection algorithm, it is important to understand how the hierarchical representation works. Let $P = P_0$ be the initial polyhedron. Assume that P ’s faces have been triangulated. The vertices, edges, and faces of P ’s boundary define a planar graph with triangular faces. Let n denote the number of vertices in this graph. An important fact is that every planar graph has an independent set (a subset of pairwise nonadjacent vertices) that contains a constant fraction of the vertices formed entirely from vertices of bounded degree. Such an independent set is computed and is removed along with any incident edges and faces from P . Then any resulting “holes” in the boundary of P are filled in with triangles, resulting in a convex polyhedron with fewer vertices (cf. [Section 34.6](#)).

These holes can be triangulated independently of one another, each in constant time. The resulting convex polyhedron is denoted P_1 . The process is repeated until reaching a polyhedron having a constant number of vertices. The result is a sequence of polyhedra, $\langle P_0, P_1, \dots, P_k \rangle$, called the *Dobkin-Kirkpatrick hierarchy*. Because a constant fraction of vertices are eliminated at each stage, the depth k of the hierarchy is $O(\log n)$. The hierarchical decomposition is illustrated in [Figure 38.2.5](#). The vertices that are eliminated at each stage, which form an independent set, are highlighted in the figure.

INTERSECTION DETECTION ALGORITHM

Suppose that the hierarchical representations of P and Q have already been computed. The intersection detection algorithm actually computes the *separation*, that is, the minimum distance between the two polyhedra. First consider the task of determining the separation between P and a triangle T in 3-space. We start with

FIGURE 38.2.5

Dobkin-Kirkpatrick decomposition of a convex polyhedron.

the top of the hierarchy, P_k . Because P_k and T are both of constant complexity, the separation between P_k and T can be computed in constant time. Given the separation between P_i and T , it is possible to determine the separation between P_{i-1} and T in constant time. This is done by a consideration of the newly added boundary elements of P_{i-1} that lie in the neighborhood of the two closest points.

Given the hierarchical decompositions of two polyhedra P and Q , the Dobkin-Kirkpatrick intersection algorithm begins by computing the separation at the highest common level of the two hierarchies (so that at least one of the decomposed polyhedra is of bounded complexity). They show that in $O(\log n_p + \log n_q)$ time it is possible to determine the separation of the polyhedra at the next lower level of the hierarchies. This leads to a total running time of $O(\log n_p \log n_q)$.

OPEN PROBLEM

Is it possible to detect the intersection of two preprocessed convex polyhedra in $O(\log(n_p + n_q))$ time using linear space?

38.3 INTERSECTION COUNTING AND REPORTING

GLOSSARY

Plane sweep: An algorithm paradigm based on simulating the left-to-right sweep of the plane with a vertical *sweepline*. See [Figure 38.3.1](#).

Red-blue intersection: Segment intersection between segments of two colors, where only intersections between segments of different colors are to be reported.

In many applications geometric intersections can be viewed as a discrete set of entities to be counted or reported. The problems of intersection counting and reporting have been heavily studied in computational geometry from the perspective of *intersection searching*, employing preprocessing and subsequent queries (Chapter 36). We limit our discussion here to batch problems, where the geometric objects are all given at once. In many instances, the best algorithms known for batch counting and reporting reduce the problem to intersection searching.

Table 38.3.1 summarizes a number of results on intersection counting and reporting. The quantity n denotes the combinatorial complexity of the objects, d denotes the dimension of the space, and k denotes the number of intersections. Because every pair of elements might intersect, the number of intersections k may generally be as large as $O(n^2)$, but it is frequently much smaller.

TABLE 38.3.1 Intersection counting and reporting.

PROBLEM	DIM	OBJECTS	TIME	SOURCE
Reporting	2	line segments	$n \log n + k$	[CE92][Bal95]
	2	red-blue segments (general)	$n^{4/3} \log^{O(1)} n + k$	[Aga90][Cha93]
	2	red-blue segments (disjoint)	$n + k$	[FH95]
	d	orthogonal segments	$n \log^{d-1} n + k$	[EM81]
Counting	2	line segments	$n^{4/3} \log^{O(1)} n$	[Aga90][Cha93]
	2	red-blue segments (general)	$n^{4/3} \log^{O(1)} n$	[Aga90][Cha93]
	2	red-blue segments (disjoint)	$n \log n$	[CEGS94]
	d	orthogonal segments	$n \log^{d-1} n$	[EM81, Cha88]

REPORTING LINE SEGMENT INTERSECTIONS

Consider the problem of reporting the intersections of n line segments in the plane. This problem is an excellent vehicle for introducing the powerful technique of plane sweep (Figure 38.3.1). The plane-sweep algorithm maintains an active list of segments that intersect the current sweepline, sorted from bottom to top by intersection point. If two line segments intersect, then at some point prior to this intersection they must be consecutive in the sweep list. Thus, we need only test consecutive pairs in this list for intersection, rather than testing all $O(n^2)$ pairs.

At each step the algorithm advances the sweepline to the next event: a line segment endpoint or an intersection point between two segments. Events are stored in a *priority queue* by their x -coordinates. After advancing the sweepline to the next event point, the algorithm updates the contents of the active list, tests new consecutive pairs for intersection, and inserts any newly-discovered events in the priority queue. For example, in Figure 38.3.1 the locations of the sweepline are shown with dashed lines.

Bentley and Ottmann showed that by using plane sweep it is possible to report all k intersecting pairs of n line segments in $O((n + k) \log n)$ time [BO79]. If the number of intersections k is much less than the $O(n^2)$ worst-case bound, then this is great savings over a brute-force test of all pairs.

For many years the question of whether this could be improved to $O(n \log n + k)$

FIGURE 38.3.1
Plane sweep for line segment intersection.

was open, until Edelsbrunner and Chazelle presented such an algorithm [CE92]. This algorithm is optimal with respect to running time because at least $\Omega(k)$ time is needed to report the result, and it can be shown that $\Omega(n \log n)$ time is needed to detect whether there is any intersection at all. However, their algorithm uses $O(n + k)$ space. Balaban [Bal95] how to achieve the same running time using only $O(n)$ space. Clarkson and Shor [CS89] and later Mulmuley [Mul91] presented simpler, randomized algorithms with the same expected running time but using only $O(n)$ space.

Mulmuley's algorithm is particularly elegant. It involves maintaining a **trapezoidal decomposition**, a subdivision which results by shooting a vertical ray up and down from each segment endpoint and intersection point until it hits another segment. The algorithm inserts the segments one by one in random order by “walking” each segment through the subdivision and updating the decomposition as it goes. (This is shown in Figure 38.3.2, where the broken horizontal line on the left is being inserted and the shaded regions on the right are the newly created trapezoids.)

FIGURE 38.3.2
Incremental construction of a trapezoidal decomposition.

RED-BLUE INTERSECTION PROBLEMS

Among the numerous variations of the segment intersection problem, the most widely studied is the problem of computing intersections that arise between two sets of segments, say red and blue, whose total size is n . The goal is to compute all **bichromatic intersections**, that is, intersections that arise when a red segment intersects a blue segments. Let k denote the number of such intersections.

The case where there are no monochromatic (blue-blue or red-red) intersections is particularly important. It arises, for example, when two planar subdivisions are

overlaid, called the *map overlay* problem in GIS applications, as well as in many intersection algorithms based on divide-and-conquer. (See Figure 38.3.3.) In this case the problem can be solved by in $O(n \log n + k)$ time by any optimal monochromatic line-segment intersection algorithm. This problem seems to be somewhat simpler than the monochromatic case, because Mairson and Stolfi [MS88] showed the existence of an $O(n \log n + k)$ algorithm prior to the discovery of these optimal monochromatic algorithms. Chazelle et al. [CEGS94] presented an algorithm based on a simple but powerful data structure, called the *hereditary segment tree*. Chan [Cha94] presented a practical approach based on a plane sweep of the trapezoidal decomposition of the two sets. Guibas and Seidel [GS87] showed that, if the segments form a simple connected convex subdivision of the plane, the problem can be solved more efficiently in $O(n + k)$ time. This was extended to simply connected subdivisions that are not necessarily convex by Finke and Hinrichs [FH95].

FIGURE 38.3.3
Overlaying planar subdivisions.

The problem is considerably more difficult if monochromatic intersections exist. This is because there may be quadratically many monochromatic intersections, even if there are no bichromatic intersections. Agarwal [Aga90] and Chazelle [Cha93] showed that the k bichromatic intersections can be reported in $O(n^{4/3} \log^{O(1)} n + k)$ time through the use of a partitioning technique called *cuttings*. Basch et al. [BGR96] showed that if the set of red-segments forms a connected set and the blue set does as well, then it is possible to report all bichromatic intersections in $O((n + k) \log^{O(1)} n)$ time. Agarwal et al. [AdBH⁺02] and Gupta et al. [GJS99] considered a multi-chromatic variant in which the input consists of m convex polygons and the objective is to report all intersections between pairs of polygons. They show that many of the same techniques can be applied to this problem and present algorithms with similar running times.

COUNTING LINE SEGMENT INTERSECTIONS

Efficient intersection counting often requires quite different techniques from reporting because it is not possible to rely on the lower bound of k needed to report the results. Nonetheless, a number of the efficient intersection reporting algorithms can be modified to count intersections efficiently. For example, methods based on cuttings [Aga90, Cha93] can be used to count the number of intersections among n planar line segments and bichromatic intersections between n red and blue segments in $O(n^{4/3} \log^{O(1)} n)$ time. If there are no monochromatic intersections then the hereditary segment tree [CEGS94] can be used to count the number bichromatic intersections in $O(n \log n)$ time.

Many of the algorithms for performing segment intersection exploit the observation that if the line segments span a closed region, it is possible to infer the number

of segment intersections within the region simply by knowing the order in which the lines intersect the boundary of the region. Consider, for example, the problem of counting the number of line intersections that occur within a vertical strip in the plane. This problem can be solved in $O(n \log n)$ time by sorting the points according to their intersections on the left side of the strip, computing the associated permutation of indices on the right side, and then counting the number *inversions* in the resulting sequence [DMN92, Mat91]. An inversion is any pair of values that are not in sorted order. See Figure. 38.3.4. Inversion counting can be performed by a simple modification of the Mergesort algorithm. It is possible to generalize this idea to regions whose boundary is not simply connected [Asa94, MN01].

FIGURE 38.3.4

Intersections and inversion counting.

INTERSECTION SEARCHING AND RANGE SEARCHING

Range and intersection searching are powerful tools that can be applied to more complex intersection counting and reporting problems. This fact was first observed by Dobkin and Edelsbrunner [DE87], and has been applied to many other intersection searching problems since.

As an illustration, consider the problem of counting all intersecting pairs from a set of n rectangles. Edelsbrunner and Maurer [EM81] observed that intersections among orthogonal objects can be broken down to a set of orthogonal search queries (see Figure 38.3.5). For each rectangle x we can count all the intersecting rectangles of the set satisfying each of these conditions and sum them. Each of these counting queries can be answered in $O(\log n)$ time after $O(n \log n)$ preprocessing time [Cha88], leading to an overall $O(n \log n)$ time algorithm. This counts every intersection twice and counts self intersections, but these are easy to factor out from the final result. Generalizations to hyperrectangle intersection counting in higher dimensions are straightforward, with an additional factor of $\log n$ in time and space for each increase in dimension. We refer the reader to [Chapter 36](#) for more information on intersection searching and its relationship to range searching.

FIGURE 38.3.5

Types of intersections between rectangles x and y .

38.4 INTERSECTION CONSTRUCTION

GLOSSARY

Regularization: Discarding measure-zero parts of the result of an operation by taking the closure of the interior.

Clipping: Computing the intersection of each of many polygons with an axis-aligned rectangular viewing *window*.

Kernel of a polygon: The set of points that can see every point of the polygon. (See [Section 26.1](#).)

Intersection construction involves determining the region of intersection between geometric objects. Many of the same techniques that are used for computing geometric intersections are used for computing Boolean operations in general (e.g., union and difference). Many of the results presented here can be applied to these other problems as well. Typically intersection construction reduces to the following tasks: (1) compute the intersection between the boundaries of the objects; (2) if the boundaries do not intersect then determine whether one object is nested within the other; and (3) if the boundaries do intersect then classify the resulting boundary fragments and piece together the final intersection region.

When Boolean operations are computed on solid geometric objects, it is possible that lower-dimensional “dangling” components may result. It is common to eliminate these lower-dimensional components by a process called *regularization* (see [Section 56.1.1](#)). The *regularized* intersection of P and Q , denoted $P \cap^* Q$, is defined formally to be the closure of the interior of the standard intersection $P \cap Q$ (see Figure 38.4.1).

FIGURE 38.4.1

Regularized intersection: (a) Polygons P and Q ; (b) $P \cap Q$; (c) $P \cap^* Q$.

Some results on intersection construction are summarized in [Table 38.4.1](#), where n is the total complexity of the objects being intersected, and k is the number of pairs of intersecting edges.

CONVEX POLYGONS

Determining the intersection of two convex polygons is illustrative of many intersection construction algorithms. Observe that the intersection of two convex polygons having a total of n edges is either empty or a convex polygon with at most n edges.

TABLE 38.4.1 Intersection construction.

DIM	OBJECTS	TIME	SOURCE
2	convex-convex	n	[SH76, OCON82]
2	simple-simple	$n \log n + k$	[CE92]
2	kernel	n	[LP79]
3	convex-convex	n	[Cha92]

O'Rourke et al. present an $O(n)$ time algorithm, which given two convex polygons P and Q determines their intersection [OCON82].

The algorithm can be viewed as a geometric generalization of merging two sorted lists. It performs a counterclockwise traversal of the boundaries of the two polygons. The algorithm maintains a pair of edges, one from each polygon. From a consideration of the relative positions of these edges the algorithm advances one of them to the next edge in counterclockwise order around its polygon. Intuitively, this is done in such a way that these two edges effectively “chase” each other around the boundary of the intersection polygon (see Figure 38.4.2(a)-(i)).

FIGURE 38.4.2

Convex polygon intersection construction.

OPEN PROBLEM

Reichling has shown that it is possible to detect whether m convex n -gons share a common point in $O(m \log^2 n)$ time [Rei88]. Is there an output-sensitive algorithm of similar complexity for constructing the intersection region?

SIMPLE POLYGONS AND CLIPPING

As with convex polygons, computing the intersection of two simple polygons reduces to first computing the points at which the two boundaries intersect and then classifying the resulting edge fragments. Computing the edge intersections and edge fragments can be performed by any algorithm for reporting line segment intersec-

tions. Classifying the edge fragments is a simple task. Margalit and Knott describe a method for edge classification that works not only for intersection, but for any Boolean operation on the polygons [MK89].

Clipping a set of polygons to a rectangular window is a special case of simple polygon intersection that is particularly important in computer graphics (see Section 49.3). One popular algorithm for this problem is the Sutherland-Hodgman algorithm [FvD⁺90]. It works by intersecting each polygon with each of the four halfplanes that bound the clipping window. The algorithm traverses the boundary of the polygon, and classifies each edge as lying either entirely inside, entirely outside, or crossing each such halfplane.

An elegant feature of the algorithm is that it effectively “pipelines” the clipping process by clipping each edge against one of the window’s four sides and then passing the clipped edge, if it is nonempty, to the next side to be clipped. This makes the algorithm easy to implement in hardware. An unusual consequence, however, is that if a polygon’s intersection with the window has multiple connected components (as can happen with a nonconvex polygon), then the resulting clipped polygon consists of a single component connected by one or more “invisible” channels that run along the boundary of the window (see Figure 38.4.3).

FIGURE 38.4.3

Clipping using the Sutherland-Hodgman algorithm.

INTERSECTION CONSTRUCTION IN HIGHER DIMENSIONS

Intersection construction in higher dimensions, and particularly in dimension 3, is important to many applications such as solid modeling. The basic paradigm of computing boundary intersections and classifying boundary fragments applies here as well. Muller and Preparata gave an $O(n \log n)$ algorithm that computes the intersection of two convex polyhedra in 3-space (see [PS85]). The existence of a linear-time algorithm remained open for years until Chazelle discovered such an algorithm [Cha92]. He showed that the Dobkin-Kirkpatrick hierarchical representation of polyhedra can be applied to the problem. A particularly interesting element of his algorithm is the use of the hierarchy for representing the interior of each polyhedron, and a dual hierarchy for representing the exterior of each polyhedron. Dobrindt, Mehlhorn, and Yvinec [DMY93] presented an output-sensitive algorithm for intersecting two polyhedra, one of which is convex.

Another class of problems can be solved efficiently are those involving *polyhedral terrains*, that is, a polyhedral surface that intersects every vertical line in at most one point. Chazelle et al. [CEGS94] show that the hereditary segment tree can be applied to compute the smallest vertical distance between two polyhedral terrains in roughly $O(n^{4/3})$ time. They also show the the upper envelope of two polyhedral terrains can be computed in $O(n^{3/2+\epsilon} + k \log^2 n)$ time, where ϵ is an arbitrary constant and k is the number of edges in the upper envelope.

KERNELS AND THE INTERSECTION OF HALFSPACES

Because of the highly structured nature of convex polygons, algorithms for convex polygons can often avoid additional $O(\log n)$ factors that seem to be necessary when dealing with less structured objects. An example of this structure arises in computing the kernel of a simple polygon: the (possibly empty) locus of points that can see every point in the polygon (the shaded region of Figure 38.4.4). Put another way, the kernel is the intersection of inner halfplanes defined by all the sides of P . The kernel of P is a convex polygon having at most n sides. Lee and Preparata gave an $O(n)$ time algorithm for constructing it [LP79] (see also Table 26.3.1). Their algorithm operates by traversing the boundary of the polygon, and incrementally updating the boundary of the kernel as each new edge is encountered.

FIGURE 38.4.4

The kernel of a simple polygon.

The general problem of computing the intersection of halfplanes, when the halfplanes do not necessarily arise from the sides of a simple polygon, requires $\Omega(n \log n)$ time. See Chapter 22 for more information on this problem.

38.5 METHODS BASED ON SPATIAL SUBDIVISIONS

So far we have considered methods with proven worst-case asymptotic efficiency. However, there are numerous approaches to intersection problems for which worst-case efficiency is hard to establish, but that practical experience has shown to be quite efficient on the types of inputs that often arise in practice. Most of these methods are based on subdividing space into disjoint regions, or *cells*. Intersections can be computed by determining which objects overlap each cell, and then performing primitive intersection tests between objects that overlap the same cell.

GRIDS

Perhaps the simplest spatial subdivision is based on “bucketing” with square grids. Space is subdivided into a regular grid of squares (or generally hypercubes) of equal side length. The side length is typically chosen so that either the total number of cells is bounded, or the expected number of objects overlapping each cell is bounded. Edahiro et al. [ETHA89] showed that this method is competitive with and often performs much better than more sophisticated data structures for reporting intersections between randomly generated line segments in the plane. Conventional wisdom is that grids perform well as long as the objects are small on average and their distribution is roughly uniform.

HIERARCHICAL SUBDIVISIONS

The principle shortcoming of grids is their inability to deal with nonuniformly distributed objects. Hierarchical subdivisions of space are designed to overcome this weakness. There is quite a variety of different data structures based on hierarchical subdivisions, but almost all are based on the principal of recursively subdividing space into successively smaller regions, until each region is sufficiently simple in the sense that it overlaps only a small number of objects. When a region is subdivided, the resulting subregions are its *children* in the hierarchy. Well-known examples of hierarchical subdivisions for storing geometric objects include quadtrees and k -d trees, R-trees, and binary space partition (BSP) trees. See [Sam90b] for a discussion of all of these.

Intersection construction with hierarchical subdivisions can be performed by a process of *merging* the two hierarchical spatial subdivisions. This method is described by Samet for quadtrees [Sam90a] and Naylor et al. [NAT90] for BSP trees. To illustrate the idea on a simple example, consider a quadtree representation of two black-and-white images. The problem is to compute the intersection of the two black regions. For example, in Figure 38.5.1 the two images on the left are intersected, resulting in the image on the right.

FIGURE 38.5.1

Intersection of images using quadtrees.

The algorithm recursively considers two overlapping square regions from each quadtree. A region of the quadtree is *black* if the entire region is black, *white* if the entire region is white, and *gray* otherwise. If either region is white, then the result is white. If either region is black, then the result is the other region. Otherwise both regions are gray, and we apply the procedure recursively to each of the four pairs of overlapping children.

38.6 SOURCES

Geometric intersections and related topics are covered in general sources on computational geometry [dBvK⁺00, O'R98, Mul93, Ede87, PS85, Meh84]. A good source of information on the complexity of the lower envelopes and faces in arrangements is the book by Sharir and Agarwal [SA95]. Intersections of convex objects are

discussed in the paper by Chazelle and Dobkin [CD87]. For information on data structures useful for geometric intersections see Samet's books [Sam90a, Sam90b]. Sources on computing intersection primitives include O'Rourke's book on computational geometry [O'R98], Yap's book [Yap93] on algebraic algorithms, and most texts on computer graphics, for example [FvD⁺90]. For 3D surface intersections consult books on solid modeling, including those by Hoffmann [Hof89] and Mäntylä [Män88]. The *Graphics Gems* series (e.g., [Pae95]) contains a number of excellent tips and techniques for computing geometric operations including intersection primitives.

39 NEAREST NEIGHBORS IN HIGH-DIMENSIONAL SPACES

Piotr Indyk

INTRODUCTION

In this chapter we consider the following problem: given a set P of points in a high-dimensional space, construct a data structure which given any *query* point q finds the point in P closest to q . This problem, called *nearest neighbor search*¹, is of significant importance to several areas of computer science, including pattern recognition, searching in multimedia data, vector compression [GG91], computational statistics [DW82], and data mining. Many of these applications involve data sets which are very large (e.g., a database containing Web documents could contain over one billion documents). Moreover, the dimensionality of the points is usually large as well (e.g., in the order of a few hundred). Therefore, it is crucial to design algorithms which scale well with the database size as well as with the dimension.

The nearest-neighbor problem is an example of a large class of *proximity problems*, which, roughly speaking, are problems whose definitions involve the notion of distance between the input points. Apart from nearest-neighbor search, the class contains problems like closest pair, diameter, minimum spanning tree and variants of clustering problems.

Many of these problems were among the first investigated in the field of computational geometry. As a result of this research effort, many efficient solutions have been discovered for the case when the points lie in a space of *constant* dimension. For example, if the points lie in the plane, the nearest-neighbor problem can be solved with $O(\log n)$ time per query, using only $O(n)$ storage [SH75, LT80]. Similar results can be obtained for other problems as well. Unfortunately, as the dimension grows, the algorithms become less and less efficient. More specifically, their space or time requirements grow *exponentially* in the dimension. In particular, the nearest-neighbor problem has a solution with $O(d^{O(1)} \log n)$ query time, but using roughly $n^{O(d)}$ space [Cla88, Mei93]. Alternatively, if one insists on linear or near-linear storage, the best known running time bound for *random* input is of the form $\min(2^{O(d)}, dn)$, which is essentially linear in n even for moderate d . Worse still, the exponential dependence of space and/or time on the dimension (called the “curse of dimensionality”) has been observed in applied settings as well. Specifically, it is known that many popular data structures (using linear or near-linear storage), exhibit query time linear in n when the dimension exceeds a certain threshold (usually 10–20, depending on the number of points), e.g., see [W⁺98] for more information.

The lack of success in removing the exponential dependence on the dimension led many researchers to conjecture that no efficient solutions exists for these problems when the dimension is sufficiently large (e.g., see [MP69]). At the same time,

¹Many other names occur in literature, including *best match*, *post office problem* and *nearest neighbor*.

it raised the question: Is it possible to remove the exponential dependence on d , if we allow the answers to be *approximate*. The notion of approximation is best explained for nearest-neighbor search: instead of reporting a point p closest to q , the algorithm is allowed to report *any* point within distance $(1 + \epsilon)$ times the distance from q to p . Similar definitions can be naturally applied to other problems. Note that this approach is similar to designing efficient approximation algorithms for NP-hard problems.

During recent years, several researchers have shown that indeed in many cases approximation enables reduction of the dependence on dimension from exponential to polynomial. In this chapter we will survey these results. In addition, we will discuss the issue of *proving* that the curse of dimensionality is inevitable if one insists on exact answers, and survey the known results in this direction.

Although this chapter is devoted almost entirely to approximation algorithms with running times polynomial in the dimension, the notion of approximate nearest neighbor was first formulated in the context of algorithms with exponential query times. [Chapter 51.7](#) of this Handbook covers those results in more detail.

Before proceeding further, we mention that our treatment of the topic is primarily theoretical. For experimental evaluations and applications of the algorithms described in this chapter, see e.g., [GIM99, CD⁺00, HGI00, Shi00, Buh01, BT01, Ya01, Buh02, O⁺02, GS⁺03]. In addition, we focus on algorithms operating in main memory. For external memory algorithms, see e.g., recent proceedings of *SIGMOD* and *VLDB* conferences.

39.1 APPROXIMATE NEAR NEIGHBOR

Almost all algorithms for proximity problems in high-dimensional spaces proceed by reducing the problem to the problem of finding an *approximate near neighbor*, which is the decision version of the approximate nearest-neighbor problem. Thus, we start from describing the results for the former problem.

For the definitions of metric spaces and normed spaces, see [Chapter 8](#).

GLOSSARY

Approximate Near Neighbor, or (r, c) -NN: Given a set P on n points in a metric space $M = (X, D)$, design a data structure that supports the following operation: For any query $q \in X$, if there exists $p \in P$ such that $D(p, q) \leq r$, find a point $p' \in P$ such that $D(q, p') \leq cr$

Dynamic problems: Problems which involve designing a data structure for a set of points (e.g., approximate near neighbor) and support insertions and deletions of points. We distinguish dynamic problems from their *static* versions by adding the word “Dynamic” (or letter “D”) in front of their names (or acronyms). E.g., the dynamic version of the approximate near-neighbor problem is denoted by (r, c) -DNN.

Hamming metric: A metric (Σ^d, D) where Σ is a set of *symbols*, and for any $p, q \in \Sigma^d$, $D(p, q)$ is equal to the number of $i \in \{1 \dots d\}$ such that $p_i \neq q_i$.

RANDOM PROJECTION APPROACH

The first algorithms for (r, c) -NN in high dimensions were obtained by using the technique of random projections. This technique is applicable if the underlying metric D is induced by an l_p norm, for $p \in [0, 2]$. We first focus on the case where all input and query points are binary vectors from $\{0, 1\}^d$, and D is the Hamming distance (or equivalently, the metric is induced by the l_1 norm). The parameters of the algorithms discovered for this case are presented in Table 39.1.1.

We mention that the idea of using random projections for high-dimensional approximate nearest neighbor first appeared in the paper by Kleinberg [Kle97]. Although his algorithms still suffered from the curse of dimensionality (i.e., used exponential storage or had $\Omega(n)$ query time), his ideas provided inspiration for designing improved algorithms.

Dimensionality reduction. The key technique used to obtain results (1a), (1b), (3), and (4) is **dimensionality reduction**, i.e., a randomized procedure which reduces the dimension of Hamming space from d to $k = O(\log n / \epsilon^2)$, while preserving a certain range of distances between the input points and the query up to a factor of $1 + \epsilon$. This notion has been introduced earlier in Chapter 8 in the context of Euclidean space. In case of Hamming space, [KOR00] showed the following.

THEOREM 39.1.1

For any given $r \in \{1 \dots d\}$, $\epsilon \in (0, 1]$ and $P \in (0, 1)$, one can construct a distribution over mappings $A : \{0, 1\}^d \rightarrow \{0, 1\}^k$, $k = O(\log(1/P)/\epsilon^2)$, and a “scaling factor” S , so that for any $p, q \in \{0, 1\}^d$, if $D(p, q) \in [r, 10r]$, then $D(A(p), A(q)) = S \cdot D(p, q)(1 \pm \epsilon)$ with probability at least $1 - P$.

The factor 10 can be replaced by any constant. As in the case of Euclidean norm, the mapping A is linear. However, unlike in the Euclidean case where the mapping was defined over the set of reals $\mathbb{R}$, the mapping A is defined over $GF(2)$

(i.e., over the set $\{0, 1\}$ with addition and multiplication taken modulo 2). The $k \times n$ matrix A is obtained by choosing each entry of A independently at random from the set $\{0, 1\}$. The probability that an entry is equal to 1 is roughly r/d .

A different method of generating mapping A was proposed in [Ind00]. The mapping is nonlinear, but somewhat easier to analyze (and derandomize). It is based on “Locality-Sensitive Hashing,” described later in this section.

Algorithm (1a) is an immediate application of Theorem 39.1.1. Specifically, it allows us to reduce the $(r, c + \epsilon)$ -NN problem in d -dimensional space to (r, c) -NN problem in k -dimensional space. Since the *exact* nearest-neighbor problem in k -dimensional space can be solved by storing the answers to all 2^k queries q , the bound follows. Algorithm (1b) follows by using a variation of this approach. Algorithms (3) and (4) are obtained by using a deterministic version of Theorem 39.1.1 [Ind00].

We note that one can apply the same approach to solve the near-neighbor problem in the Euclidean space. In particular, it is fairly easy to solve the $(r, 1 + \epsilon)$ -NN problem in l_2^d using $n(1/\epsilon)^{O(d)}$ space [HIM03]. Applying the Johnson-Lindenstrauss lemma leads to an algorithm with storage bound similar (although slightly worse) to the bound of algorithm (1a) [HIM03].

Locality-Sensitive Hashing. As may have been noticed, the storage bounds for algorithms (1a), (3) and (4) are quite high. On the other hand, the query time of algorithm (1b) is low only for fairly large values of ϵ [Ind01a]. In this context, algorithm (2) provides an attractive tradeoff, since even for small values of ϵ (e.g., $\epsilon = 1.0$) its running time is fairly low (e.g., $d\sqrt{n}$). The algorithm is based on the concept of **Locality-Sensitive Hashing**, or *LSH* [HIM03] (see also [K⁺95, Bro00]). A family of hash functions $h : \{0, 1\}^d \rightarrow U$ is called (r_1, r_2, P_1, P_2) -sensitive (for $r_1 < r_2$ and $P_1 > P_2$) if for any $q, p \in \{0, 1\}^d$

- If $D(p, q) \leq r_1$ then $\Pr[h(q) = h(p)] \geq P_1$,
- If $D(p, q) > r_2$ then $\Pr[h(q) = h(p)] \leq P_2$

where $\Pr[\cdot]$ is defined over the random choice of h . We note that the notion of locality-sensitive hashing can be defined for any metric space D in a natural way (see [Cha02] for sufficient and necessary conditions for existence of LSH for D). However, for Hamming space, LSH families are particularly easy: it is sufficient to take all functions h_i , $i = 1 \dots d$, such that $h_i(p) = p_i$, $p \in \{0, 1\}^d$. Because $\Pr[h(p) = h(q)] = 1 - D(p, q)/d$, it is immediate that this family is sensitive.

If we are provided with an LSH family with a “large” gap between P_1 and P_2 , the $(r_2/r_1, r_1)$ -NN problem can be solved in the following way. During preprocessing, all input points p are hashed to the bucket $h(p)$. In order to answer the query q , the algorithm retrieves the points in the bucket $h(q)$ and checks if any one of them is close to q . If the gap between P_1 and P_2 is sufficiently large, this approach can be shown to result in sublinear query time. Unfortunately, the P_1/P_2 gap guaranteed by the above LSH family is not large enough. However, the gap can be amplified by concatenating several independently chosen hash functions $h_1 \dots h_l$ (i.e., hashing the points using functions h' such that $h'(p) = (h_1(p), \dots, h_l(p))$). Details can be found in [HIM03].

A somewhat similar hashing-based algorithm (for the closest-pair problem) was earlier proposed in [K⁺95], and also in [Bro00]. Due to different problem formulation and analysis, comparing their performance with the guarantees of the

LSH approach seems difficult.

We also mention that the above algorithm can be modified to solve the approximate *nearest-neighbor* problem, within the same time bounds (i.e., without incurring any additional overhead, as is the case for the reductions presented in the next section). Details can be found in [Cha02].

Extensions to l_p norms. The approximate near-neighbor problem under l_p norms, for $p \in [1, 2]$, can be reduced to the same problem in Hamming space. The reduction is particularly easy for the l_1^d norm. If we assume that all points of interest p have coordinates in the range $\{1 \dots M\}$, then if we define $U(p) = (U(p_1), \dots, U(p_d))$ where $U(x)$ is a string of x ones followed by $M - x$ zeros, we get $\|p - q\|_1 = D(U(p), U(q))$. In general, M could be quite large, but can be reduced to $d^{O(1)}$ in the context of approximate near neighbor [HIM03]. Thus we can reduce (r, c) -NN under l_1 to (r, c) -NN in Hamming space.

In order to obtain algorithms for l_p norm where $p \in (1, 2]$, we use the fact that l_p^d can be embedded into $l_1^{O(d)}$ with bounded distortion (see Chapter 8). Alternatively, for $p = 2$, one can solve the problem directly in Euclidean space [HIM03], as described earlier.

DIVIDE-AND-CONQUER APPROACH

The dimensionality reduction and locality-sensitive hashing techniques have natural limitations. In particular, they cannot be used for solving the near-neighbor problem under the l_∞ norm. Fortunately, this norm has other nice properties which makes designing approximate nearest-neighbor data structures possible.

The only algorithm known for solving (r, c) -NN under the l_∞^d norm [Ind01b] has the following parameters, for any $\rho > 0$:

- Approximation factor: $c = O(4 \lceil \log_{1+\rho} \log 4d \rceil)$; if $\rho = \log d$ then $c = 3$
- Space: $dn^{1+\rho}$
- Query time: $O(d \log n)$ for the static, or $(d + \log n)^{O(1)}$ for the dynamic case
- Update time: $d^{O(1)} n^\rho$ (described in [Ind01a])

The basic idea of the algorithm is to use a divide and conquer approach. In particular, consider hyperplanes H consisting of all points with one (say the i th) coordinate equal to the same value. The algorithm tries to find a hyperplane H having the property that the set of points $P_L \subset P$ which are on the left side of H and within distance $\geq r$ from H , is not “much smaller” than the set P_M of points within distance r from H . Moreover, a similar condition has to be satisfied for an analogously defined set P_R of points on the right side of H . If such H exists, we divide P into $P_1 = P_L \cup P_M$ and set $P_2 = P \setminus P_L$ and build the data structure recursively on P_1 and P_2 . It is easy to see that while processing a query q , it suffices to recurse on either P_1 or P_2 , depending on the side of H the query q lies on. Also, one can prove that the increase in storage caused by duplicating P_M is moderate. On the other hand, if H does not exist, one can prove that a large subset C of P has $O(r)$ diameter. In such a case we can pick any point from C as its representative, and apply the algorithm recursively on $P \setminus C$.

GLOSSARY

Product metrics: An f -product of metrics $M_1, \dots, M_k$ with distance functions $D_1, \dots, D_k$ is a metric over $M_1 \times \dots \times M_k$ with distance function D such that $D((p_1, \dots, p_k), (q_1, \dots, q_k)) = f(D_1(p_1, q_1), \dots, D_k(p_k, q_k))$.

Although the l_∞ data structure seems to rely on the geometry of the l_∞ norm, it turns out that it can be used in a much more general setting. In particular, assume that we are given k metrics $M_1 \dots M_k$ such that for each metric M_i we have a data structure for (a variant of) (r, c) -NN in metric M_i , with $Q(n)$ query time and $S(n)$ space. In this setting, it is possible to construct a data structure solving $(r, O(c \log \log n))$ -NN in the max-product metric M of $M_1, \dots, M_k$ (i.e., an f -product with f computing the maximum of its arguments) [Ind02]. The data structure for M achieves query time roughly $O(Q(n) \log n + k \log n)$ and space $O(kS(n)n^{1+\delta})$, for any constant $\delta > 0$. The data structure could be viewed as an abstract version of the data structure for the l_∞ norm (note that the l_∞^d norm is a max-product of l_p^1 norms). For the particular case of the l_∞^d norm, it is easy to verify that the result of [Ind02] provides a $O(\log \log n)$ -approximate algorithm using space polynomial in n . At the same time, the algorithm of [Ind01b] has $O(\log \log d)$ -approximation guarantee when using the same amount of space. Interestingly, the former data structure gives an approximation bound comparable to the latter one, while being applicable in a much more general setting.

EXTENSIONS VIA EMBEDDINGS

Most of the algorithms described so far work only for l_p norms. However, they can be used for other metric spaces M , by using low-distortion embeddings of M into l_p norms. See [Chapter 8](#) for more information.

AVERAGE-CASE ALGORITHMS

The approximate algorithms described so far are designed to work for any (i.e., worst-case) input. However, researchers have also investigated *exact* algorithms for the NN problem, which achieve fast query times for *average* input. Below we describe three such results.

Near-neighbor in Hamming space. Consider the point set P where each point is chosen independently and uniformly at random from the set $\{0, 1\}^d$. In addition, assume that the nearest neighbor p of the query point q is located within distance r from q . In this setting, it was shown in [GP⁺94] that q can be retrieved in $O(dn^{r/d})$ time, using a data structure which requires $O(dn^{1+r/d})$ space. The basic idea of their approach is similar to the locality-sensitive hashing approach of [HIM03]; however, the set of projected coordinates is chosen in a deterministic fashion, to optimize certain parameters.

Nearest neighbor in the l_2^d norm. Consider the “continuous” version of the Hamming distance scenario, such that each point in P is chosen independently and uniformly at random from the set $[-1, 1]^d$. In addition, assume that the nearest

neighbor p of the query point q is located within distance $r = 2b\sqrt{d}$ for some (small) constant b . The value of b is always small enough so that r does not exceed the average distance between two random points.

Under these assumptions, it was shown in [Yia00] that the k - d -tree data structure (augmented in a proper way) enjoys $O(dn^\rho)$ query time, where ρ is a function of b . The analysis in the paper is idealized (i.e., uses approximations not shown to be rigorous).

We note that if d is large enough, then the distance between the query point and any data point is sharply concentrated around its mean (say $2t\sqrt{d}$). In this case, if $r = 2bt\sqrt{d}$, $b \in (0, 1)$, then by using locality-sensitive hashing with approximation factor $1/b$, one obtains an algorithm with query time dn^b . It appears that this bound outperforms the computational bound given in [Yia00]. However, the k - d -tree data structure used in [Yia00] uses only linear space, unlike the LSH-based approach.

Nearest neighbor in the l_∞^d norm. Consider a point set generated as before, but with the query point generated from the same distribution as the input points (and independently from the latter). In this setting, it was shown [AHL01, HL02] that there is a nearest-neighbor data structure using $O(dn)$ space, with query time $O(n \log d)$. Note that a naive algorithm would suffer from query time of $O(nd)$. The algorithm uses a clever pruning approach to quickly eliminate points that *cannot* be nearest neighbors of the query point.

39.2 REDUCTIONS TO APPROXIMATE NEAR NEIGHBOR

GLOSSARY

We define the following problems, for a given set of points P in a metric space $M = (X, D)$:

Approximate Closest Pair, or c -CP: Find a pair of points $p', q' \in P$ such that $D(p', q') \leq c \min_{p, q \in P, p \neq q} D(p, q)$

Approximate Close Pair, or (r, c) -CP: If there exists $p, q \in P, p \neq q$, such that $D(p, q) \leq r$, find a pair $p', q' \in P, p' \neq q'$, such that $D(q', p') \leq cr$.

Approximate Chromatic Closest Pair, or c -CCP: Assume that each point $p \in P$ is labeled with a color $c(p)$. The goal is to find a pair of points p, q such that $c(p) \neq c(q)$ and $D(p, q)$ is approximately minimal (as in the definition of c -CP).

Approximate Bichromatic Closest Pair, or c -BCP: As above, but $c(p)$ assumes only two values.

Approximate Chromatic/Bichromatic Close Pair, or (r, c) -CCP/ (r, c) -BCP: Decision versions of c -CCP or c -BCP (as in the definition of (r, c) -CP).

Approximate Furthest Pair, or Diameter, or c -FP: Find $p, q \in P$ such that $D(p, q) \geq \max_{p', q' \in P} D(p', q')/c$. The decision problem, called **Approximate Far Pair**, or (r, c) -FP, is defined in the natural way.

approximate Furthest Neighbor, or c -FN: A maximization version of the Approximate Near Neighbor. The decision problem, called Approximate Far Neigh-

bor or (r, c) -FN, is defined in a natural way.

Approximate Minimum Spanning Tree, or c -MST: Find a tree T spanning all points in P whose weight $w(T) = \sum_{(p,q) \in T} D(p, q)$ is at most c times larger than the weight of any tree spanning P .

approximate Bottleneck Matching, or c -BM: Assuming $|P|$ is even, find a set of $|P|/2$ non-incident edges E joining points in P (i.e., a matching), such that the following function is minimized (up to factor of c)

$$\max_{\{p,q\} \in E} D(p, q)$$

Approximate Facility Location, or c -FL: Find a set $F \subset P$ such that the following function is minimized (up to factor of c), given the cost function $c : P \rightarrow \mathbb{R}^+$

$$\sum_{p \in F} c(p) + \sum_{p \in P} \min_{f \in F} D(p, f)$$

In general, we could have two sets: P_c of *cities* and P_f of *facilities*; in this case we require that $F \subset P_f$ and we are only interested in the cost of P_c .

Spread (of a point set): The ratio between the diameter of the set to the distance between its closest pair of points.

In this section we show that the problems defined above can be efficiently reduced to the approximate near-neighbor problem discussed in the previous section.

First, we observe that any problem from the above list, say $c(1 + \delta)$ -P for some $\delta > 0$, can be easily reduced to its decision version (say (r, c) -P), if we assume that the spread of $P \cup \{q\}$ is always bounded by some value, say Δ . For simplicity, assume that the minimum distance between the points in P is 1. The reduction proceeds by building (or maintaining) $O(\log_{1+\delta} \Delta)$ data structures for (r, c) -P, where r takes values $(1 + \delta)^i/2$ for $i = 0, 1, \dots$. It is not difficult to see that a query to $c(1 + \delta)$ -P can be answered by $O(\log \log_{1+\delta} \Delta)$ calls to these structures for (r, c) -P, via binary search.

In general, the spread of P could be unbounded. However, in many cases it is easy to ensure that $\Delta \leq n^{O(1)}$. This can be accomplished, for example, by “discretizing” the input to c -MST or c -FL. In those cases, the above reduction is very efficient.

Reductions from other problems are specified in the following table. The bounds for the time and space used by the algorithm in the “To” column are denoted by $T(n)$ and $S(n)$, respectively.

We mention that a few other reductions have been given in [KOR00, B⁺99b]. For the problems discussed in this section, they are less efficient than the reductions in the above table. Additionally, [B⁺99b] reduces the problems of computing *approximate agglomerative clustering* and *sparse partitions* to $O(n \log^{O(1)} n)$ calls to a dynamic approximate nearest-neighbor data structure. See [B⁺99b] for the definitions and algorithms.

Also, we mention that a reduction from $(1 + \epsilon)$ -approximate furthest neighbor to $(1 + \epsilon)$ -approximate nearest neighbor (for the static case and under the l_2 norm) has been given in [GIV01]. However, a direct (and dynamic) algorithm for the approximate furthest neighbor in l_2^d , achieving a better query and update times of $dn^{1/(1+\epsilon)^2}$, has been recently given in [Ind03]. The former paper also presents an

algorithm for computing a $\sqrt{2} + \epsilon$ -approximate diameter (for any $\epsilon > 0$) of a given pointset in $dn \log^{O(1)} n$ time.

We now describe briefly the main techniques used to achieve the above results.

Nearest neighbor. We start from the reduction of c -NN to (r, c) -NN. As we have seen already, the reduction is easy if the spread of P is small. Otherwise, it is shown that the data set can be clustered into $n/2$ clusters, in such a way that:

- If the query point q is “close” to one of the clusters, it must be far away from a constant fraction of points in P ; thus, we can ignore these points in the search for an approximate nearest neighbor.
- If the query point q is “far” from a cluster, then all points in the clusters are equally good candidates for the *approximate* nearest neighbor; thus we can replace the cluster by its representative point.

These ideas were originally introduced in [IM98], but their data structure was quite complex and inefficient. In [HP01] Har-Peled presented a considerably simpler data structure, achieving better time and space bounds.

Bichromatic closest pair. A very powerful reduction from various variants of c -DBCP to c -DNN was given in [Epp95]. His algorithm was originally designed for the case $c = 1$, but it can be verified to work also for general $c \geq 1$ [Epp99]. Moreover, as mentioned in the original paper, the reduction does not require the distance function $D()$ be a metric.

The basic idea of the algorithm is to try to maintain a graph that contains an edge connecting the two closest bichromatic points. A natural candidate for such a graph is the graph formed by connecting each point to its nearest neighbor. This, however, does not work, because a vertex in such a graph can have very high degree, leading to high update cost. Another option would be to maintain a single path, such that the i th vertex points to its nearest neighbor of the opposite color, chosen from points not yet included in the path. This graph has low degree, but its rigid

structure makes it difficult to update it at each step. So the actual data structure is based on the path idea but allows its structure to degrade in a controlled way, and only rebuilds it when it gets too far degraded, so that the rebuilding work is spread over many updates. Then, however, one needs to keep track of the information from the degraded parts of the path, which can be done using a second shorter path, and so on. The constant factor reduction in the lengths of each successive path means the total number of paths is only logarithmic.

Minimum spanning tree. Many existing algorithms for computing MST (e.g., Kruskal’s algorithm) can be expressed as a sequence of operations on a CCP data structure. For example, Kruskal’s algorithm repetitively seeks the lightest edge whose endpoints belong to different components, and then merges the components. These operations can be easily expressed as operations on a CCP data structure, where each component has a different color. The contribution of [HIM03] was to show that in case of Kruskal’s algorithm, using an *approximate c*-CCP data structure enables one to compute an *approximate c*-MST. Also, note that *c*-CCP can be implemented by $\log n$ *c*-BCP data structures [HIM03]. Other reductions from *c*-MST to *c*-BCP are given in [B⁺99b, IST99].

Minimum bottleneck matching. The main observation behind this algorithm is that a matching is also a spanning forest with the property that any connected component has even cardinality (call it an *even* forest). At the same time, it is possible to convert *any* even forest to a matching, in a way that increases the length of the longest edge by at most a factor of 2. Thus, it suffices to find an even forest with minimum edge length. This can be done by including longer and longer edges to the graph, and stopping at the moment when all components have even cardinality. It is not difficult to implement this procedure as a sequence of *c*-CCP (or *c*-BCP) calls.

Other algorithms. The algorithm for the remaining problem (*c*-FL) is obtained by implementing the primal-dual approximation algorithm [JV99]. Intuitively, the algorithm proceeds by maintaining a set of balls of increasing radii. The latter process can be implemented by resorting to *c*-CCP. The approximation factor follows from the analysis of the original algorithm.

39.3 LOWER BOUNDS

In the previous sections we presented many algorithms solving approximate versions of proximity problems. The main motivation for designing approximation algorithms was the “curse of dimensionality” conjecture, i.e., the conjecture that finding exact solutions to those problems requires either superpolynomial (in d) query time, or superpolynomial (in n) space. In this section we state the conjecture more rigorously, and describe the progress toward proving it.

We start from the exact near-neighbor problem. For this problem, the curse of dimensionality can be formalized as follows. Assume that $d = n^{o(1)}$, but $d = \omega(\log n)$.

Conjecture 1 *Any data structure for $(r, 1)$ -NN in Hamming space over $\{0, 1\}^d$, with $d^{O(1)}$ query time, must use $n^{\omega(1)}$ space.*

The conjecture as stated above is probably the weakest version of the “curse of dimensionality” phenomenon for the near-neighbor problem. It is plausible that other (stronger) versions of the conjecture could hold. In particular, at present, we do not know any data structure which simultaneously achieves $o(dn)$ query time and $2^{o(d)}$ space for the above range of d . At the same time, achieving $O(dn)$ query time with space dn , or $O(d)$ query time with space 2^d is quite simple (via linear scan or using exhaustive storage).

Also note that if $d = O(\log n)$, achieving $2^{o(d)} = o(n)$ space is impossible via a simple incompressibility argument.

Below we describe the work toward proving the conjecture. The first result addresses the complexity of a simpler problem, namely the *partial match* problem. This problem is of importance in databases and other areas and has been long investigated (e.g., see [Riv74]). Thus, the lower bounds for this problem are interesting in their own right.

GLOSSARY

Partial match: Given a set P of n vectors from $\{0, 1\}^d$, design a data structure that supports the following operation: For any query $q \in \{0, 1, *\}^d$, check if there exists $p \in P$ such that for all $i = 1 \dots d$, if $q_i \neq *$ then $p_i = q_i$.

It is not difficult to see that any data structure solving $(r, 1)$ -NN in the Hamming metric $\{0, 1\}^d$, can be used to solve the partial match problem using essentially the same space and query time. Thus, any lower bound for partial match problem implies a corresponding lower bound for the near-neighbor problem. The best currently known lower bound for the partial match has been established in [B⁺99a], following earlier work of [M⁺94]. Their lower bound holds in the *cell-probe* model, a very general model of computation, capturing e.g., the standard Random Access Machine model. Specifically, they show that any (possibly randomized) cell-probe algorithm for the partial match problem, in which the algorithm is allowed to retrieve at most $O(n^{1-\epsilon})$ bits from any memory cell in one step for $\epsilon > 0$, must either have $\Omega(\log d)$ query time or use $n^{\Omega(\log d)}$ memory cells.

For the exact near-neighbor problem, an exponentially larger bound was given in [BR00]. They showed that any (possibly randomized) cell-probe algorithm for $(r, 1)$ -NN in d -dimensional Hamming space, with cell size restriction as above, must either have query time $> t$, or use $2^{\Omega(d/t)}$ space. Thus, if $t = o(d/\log n)$, the space used must be superpolynomial in n .

The two aforementioned lower bounds are proved in a very general model, using the tools of *communication complexity*. As a result, they cannot yield lower bounds of $\omega(d/\log n)$ for the required query time, assuming $n^{\Theta(1)}$ space, as we now explain.

The communication complexity approach interprets the data structure as a communication channel between Alice (holding the query point q) and Bob (holding the database P). The goal of the communication (for Alice) is to learn the nearest neighbor of q . Since the data structure has polynomial size, each access to one of its memory cell is equivalent to Alice sending $O(\log n)$ bits of information to Bob. If we show that Alice needs to send at least b bits to Bob to solve the problem, we obtain $\Omega(b/\log n)$ lower bound for the query time. However, $b \leq d$, since Alice can always choose to transmit the whole input vector q . Thus, $\Omega(d/\log n)$ lower bound is the best result one can achieve using the communication complexity approach. A partial step toward removing this obstacle was made in [BV02], em-

playing the *branching programs* model of computation. In particular, they focused on randomized algorithms that have very small (inversely polynomial in n) probability of error. They showed that any algorithm for the $(r, 1)$ -NN problem in the Hamming metric over $\{1 \dots d^6\}^d$, has either $\Omega(d \log(d \log d/S))$ query time or uses $\Omega(S)$ space. This holds for $n = \Omega(d^6)$. Thus, if the query time is $o(d \log d)$, then the data structure must use $2^{d^{\Omega(1)}}$ space.

This completes the survey of lower bounds for the *exact* near-neighbor search. For the approximate version of this problem a cell-probe-based lower bound was shown in [CC⁺99]. Specifically, the authors show that any deterministic data structure for the c -approximate *nearest neighbor* $\{0, 1\}^d$ requires either $\Omega(\log \log d / \log \log \log d)$ query time, or use $n^{\omega(1)}$ space. They assume that a memory cell can contain up to $d^{O(1)}$ bits accessible in one step. Moreover, the approximation factor c can be as high as $2^{(\log d)^{1-\epsilon}}$ for any $\epsilon > 0$.

For comparison, if randomization is allowed, then by using Theorem 39.1.1 combined with binary search one can get a data structure for the same problem (for any fixed $c > 1$), with polynomial size and query time $O(\log \log_c d)$. Note that the assumption $c > 1$ is crucial for those algorithms to achieve polynomial space bound.

REDUCTIONS

Despite the recent progress toward resolving the “curse of dimensionality” conjecture and the widespread belief in its validity, proving it seems currently beyond reach. Nevertheless, it is natural to assume the validity of the conjecture (or its variants), and see what conclusions can be derived from this assumption. Below we survey a few results of this type.

In order to describe the results, we need to state another conjecture.

Conjecture 2 *Let $d = n^{o(1)}$ but $d = \log^{\omega(1)} n$. Any data structure for the partial match problem with parameters d and n which provides $d^{O(1)}$ query time must use $2^{d^{\Omega(1)}}$ space.*

Note that, for the same ranges² of d , Conjecture 2 is analogous to Conjecture 1, but much stronger: it considers an easier problem, and states stronger bounds. However, since the partial match problem was extensively investigated on its own, and no algorithm with bounds remotely resembling the above have been discovered (cf. [CIP02] for a survey), Conjecture 2 is believed to be true.

Assuming Conjecture 2, it is possible to show lower bounds for some of the approximate nearest-neighbor problems discussed in Section 39.1. In particular, it was shown [Ind01b] that any data structure for (r, c) -NN under l_∞^d for $c < 3$ can be used to solve the partial match problem with parameter d , using essentially the same query time and storage (the number of points in the database is the same in both cases). Thus, unless Conjecture 2 is false, the 3-approximation algorithm from Section 39.1 is optimal, in the sense that it provides the smallest approximation factor possible while preserving polynomial (in d) query time and subexponential (in d) storage. Note that this result resembles the non-approximability results based on the $P \neq NP$ conjecture.

On the other hand, it was shown [CIP02] that the exact near-neighbor problem

²For $d = \log^{O(1)} n$, Conjecture 2 is true by a simple incompressibility argument. At the same time, the status of Conjecture 1 for $d \in [\omega(\log n), \log^{O(1)} n]$ is still unresolved.

under the l_∞^k norm can be reduced to solving the partial match problem with the parameter $d = (k + \log n)^{O(1)}$; the number of points n is the same for both problems. In fact, the same holds for a more general problem of *orthogonal range queries*. Thus, Conjecture 2, and its variant for the $(r, 1)$ -NN under l_∞^d (or for orthogonal range queries), are equivalent. This strengthens the belief in the validity of Conjecture 2, since the exact nearest neighbor under l_∞ norm and the orthogonal range query problem received additional attention in the Computational Geometry community.

39.4 LOW VS. HIGH DIMENSIONS IN COMPUTATIONAL GEOMETRY

It is apparent that nearest neighbors and related problems in high dimensions enjoy properties quite different from their low-dimensional counterparts (see [Chapter 51](#)). Among the main differences are:

- Exact computation seems (and is conjectured to be) intractable in high dimensions; on the other hand, very efficient algorithms exist in low-dimensional cases.
- The core problem that seems to capture the computational difficulty is the near-neighbor problem in Hamming space $\{0, 1\}^d$, a problem trivial for constant dimension.
- Unlike the low-dimensional case, the tools of *combinatorial geometry* are rarely used to design or analyze algorithms in high dimensions. This phenomenon seems to reflect the fact that the typical tools (such as complexity of arrangements, or packing bounds) lead to exponential algorithmic complexity. Instead, tools from functional analysis (most notably embeddings) are used.

Nevertheless, there seem to be interesting connections between low and high dimensional scenarios. For example, the key component of several reductions given in Section 39.2 is the result of Eppstein [Epp95]. His algorithm was originally developed with low-dimensional applications in mind; however, its framework was sufficiently general to be useful in the high-dimensional case as well.

As an example of impact in the other direction, one could mention the nearest-to-near neighbor reduction of [IM98]. When applied in the low-dimensional case, their result gave the first algorithm for $(1 + \epsilon)$ -approximate nearest neighbor, with polynomial space and polylogarithmic query time, for dimension d up to $O(\log n)$ (earlier results could provide that bound only for $d = O(\log \log n)$, due to exponential dependence of the query time on the dimension). These results were further refined in the low-dimensional context in [HP01, AM02], yielding an efficient approximate nearest-neighbor data structure for low dimensions.

Finally, we mention an example of a fruitful marriage between low- and high-dimensional techniques. Consider the following problem. For a constant d , assume we are given n $(d-1)$ -dimensional flats $H_1 \dots H_n$ living in $\mathbb{R}^d$, as well as a set P of n points P in $\mathbb{R}^d$. The goal is to compute a tree spanning the points in P , such that the total number of times a tree edge crosses a flat is as small as possible.

In [HPI00], the authors provided a c -approximate algorithm for this problem, with running time $O(n^{2d/(d+1)+\delta} + n^{1+1/c} \log^{O(1)} n)$, for any $\delta > 0$ (the factors

polynomial in $1/(c-1)$ are omitted). Note that this time is subquadratic for any constant d and $c > 1$. The main idea of the algorithm is to observe that the number of flats crossed on the way from point p to p' is a metric, and moreover, this metric can be isometrically embedded into n -dimensional Hamming space. This allows one to use the high-dimensional approximate MST algorithms from Section 39.2. To make that algorithm run fast, one needs to perform the dimensionality reduction before computing MST (essentially as in Theorem 39.1.1). However, just computing the n -dimensional representation of each of n points in P requires $\Omega(n^2)$ time. To avoid this bottleneck, the dimensionality reduction is performed on “implicit” n -dimensional representations of the points in P , by using the partition trees of Matoušek.

COMPUTATIONAL TECHNIQUES

40 RANDOMIZATION AND DERANDOMIZATION

Otfried Cheong, Ketan Mulmuley, and Edgar Ramos

INTRODUCTION

Randomized (or probabilistic) algorithms and constructions were applied successfully in many areas of theoretical computer science before they were used widely in computational geometry. Following influential work in the mid-1980s, randomized algorithms became popular in geometry, and now a significant proportion of published research in computational geometry employs randomized algorithms or proof techniques. For many problems the best algorithms known are randomized, and even if both randomized and deterministic algorithms of comparable asymptotic complexity are available, the randomized algorithms are often much simpler and more efficient in an actual implementation. In some cases, the best deterministic algorithm known for a problem has been obtained by “derandomizing” a randomized algorithm.

This chapter focuses on the randomized algorithmic *techniques* being used in computational geometry, and not so much on particular results obtained using these techniques. Efficient randomized algorithms for specific problems are discussed in the relevant chapters throughout this Handbook.

GLOSSARY

Probabilistic or “Monte Carlo” algorithm: Traditionally, any algorithm that uses random bits. Now often used in contrast to *randomized algorithm* to denote an algorithm that is allowed to return an incorrect or inaccurate result, or fail completely, but with small probability. Monte Carlo methods for numerical integration provide an example. Algorithms of this kind are not used frequently in computational geometry.

Randomized or “Las Vegas” algorithm: An algorithm that uses random bits and is guaranteed to produce a correct answer; its running time and space requirements may depend on random choices. Typically, one tries to bound the expected running time (or other resource requirements) of the algorithm. In this chapter, we will only consider randomized algorithms in this sense.

Expected running time: The expected value of the running time of the algorithm, that is, the average running time over all possible choices of the random bits used by the algorithm. No assumptions are made about the distribution of input objects in space. When expressing bounds as a function of the input size, the worst case over all inputs of that size is given. Normally the random choices made by the algorithm are hidden from the outside, in contrast with average running time.

Average running time: The average of the running time, over all possible inputs. Some suitable distribution of inputs is assumed.

To illustrate the difference between expected running time and average running

time, consider the *Quicksort* algorithm. If it is implemented so that the pivot element is the first element of the list (and the assumed input distribution is the set of all possible permutations of the input set), then it has $O(n \log n)$ *average* running time. By providing a suitable input (here, a sorted list), an adversary can force the algorithm to perform worse than the average. If, however, Quicksort is implemented so that the pivot element is chosen at random, then it has $O(n \log n)$ *expected* running time, for any possible input. Since the random choices are hidden, an adversary cannot force the algorithm to behave badly, although it may perform poorly with some positive probability.

Randomized divide-and-conquer: A divide-and-conquer algorithm that uses a random sample to partition the original problem into subproblems (Section 40.1).

Randomized incremental algorithm: An incremental algorithm where the order in which the objects are examined is a random permutation (Section 40.2).

Tail estimate: A bound on the probability that a random variable deviates from its expected value. Tail estimates for the running time of randomized algorithms are useful but seldom available (Section 40.10).

High-probability bound: A strong tail estimate, where the probability of deviating from the expected value decreases as a fast-growing function of the input size n . The exact definition varies between authors, but a typical example would be to ask that for any $\alpha > 0$, there exists a $\beta > 0$ such that the probability that the random variable $X(n)$ exceeds $\alpha E[X(n)]$ be at most $n^{-\beta}$.

Derandomization: Obtaining a deterministic algorithm by “simulating” a randomized one (Section 40.6).

Trapezoidal map: A planar subdivision $\mathcal{T}(S)$ induced by a set S of line segments with disjoint interiors in the plane (cf. Section 34.3). $\mathcal{T}(S)$ can be obtained by passing vertical attachments through every endpoint of the given segments, extending upward and downward until each hits another segment, or extending to infinity; see Figure 40.0.1. Every face of the subdivision is a trapezoid (possibly degenerated to a triangle, or with a missing top or bottom side), hence the name.

FIGURE 40.0.1

The trapezoidal map of a set of 6 line segments.

We will use the problem of computing the trapezoidal map of a set of line segments with disjoint interiors as a running example throughout this chapter. We assume for presentation simplicity that no two distinct endpoints have the same x -coordinate, so that every trapezoid is adjacent to at most four segments. (This can be achieved by slight rotation of the vertical direction.)

The trapezoidal map can also be defined for intersecting line segments. In that situation, vertical attachments must be added to intersection points as well,

and the map may consist of a quadratic number of trapezoids. The trapezoidal map is also called the *vertical decomposition* of the set of line segments. Decompositions similar to this play an important role in randomized algorithms, because most algorithms assume that the structure to be computed has been subdivided into elementary objects. (Section 40.5 explains why this assumption is necessary.)

40.1 RANDOMIZED DIVIDE-AND-CONQUER

GLOSSARY

Top-down sampling: Sampling with small, usually constant-size random samples, and recursing on the subproblems.

Cutting: A subdivision Ξ of space into simple cells Δ (of constant description complexity, most often simplices). The *size* of a cutting is the number of cells.

ϵ -cutting Ξ : For a set X of n geometric objects, a cutting such that every cell $\Delta \in \Xi$ intersects at most n/r of the objects in X (also called a $1/r$ -cutting with $\epsilon = 1/r$ when convenient). See also [Section 36.3](#).

Bottom-up sampling: Sampling with random samples large enough that the subproblems may be solved directly (without recursion).

Bernoulli sampling: The “standard” way of obtaining a random sample of size r from a given n -element set uses a random number generator to choose among all the possible subsets of size r , with equal probability for each subset (also obtained as the first r elements in a random permutation of n elements). In Bernoulli sampling, we instead toss a coin for each element of the set independently, and accept it as part of the sample with probability r/n . While the size of the sample may vary, its expected size is r , and essentially all the bounds and results of this chapter hold for both sampling models.

Gradation: A hierarchy of samples for a set X of objects obtained by bottom-up sampling:

$$X = X_1 \supset X_2 \supset X_3 \supset \cdots \supset X_{r-1} \supset X_r = \emptyset.$$

With Bernoulli sampling, a new element can be inserted into the gradation by flipping a coin at most r times, leading to efficient dynamic data structures (Section 40.1).

Geometric problems lend themselves to solution by divide-and-conquer algorithms. It is natural to solve a geometric problem by dividing space into regions (perhaps with a grid), and solving the problem in every region separately. When the geometric objects under consideration are distributed uniformly over the space, then gridding or “slice-and-dice” techniques seem to work well. However, when object density varies widely throughout the environment, then the decomposition has to be fine in the areas where objects are abundant, while it may be coarse in places with low object density. Random sampling can help achieve this: the density of a random sample R of the set of objects will approach that of the original set. Therefore dividing space according to the sample R will create small regions where the geometric objects are dense, and larger regions that are sparsely populated.

We can distinguish two main types of randomized divide-and-conquer algorithm, depending on whether the size of the sample is rather small or quite large.

TOP-DOWN SAMPLING

Top-down sampling is the most common form of random sampling in computational geometry. It uses a random sample of small, usually constant, size to partition the problem into subproblems. We sketch the technique by giving an algorithm for the computation of the trapezoidal map of a set of segments in the plane.

Given a set S of n line segments with disjoint (relative) interiors, we take a sample $R \subset S$ consisting of r segments, where r is a constant. We compute the trapezoidal map $\mathcal{T}(R)$ of R . It consists of $O(r)$ trapezoids. For every trapezoid $\Delta \in \mathcal{T}(R)$, we determine the **conflict list** S_Δ , the list of segments in S intersecting Δ . We construct the trapezoidal map of every set S_Δ recursively, clip it to the trapezoid Δ , and finally glue all these maps together to obtain $\mathcal{T}(S)$.

The running time of this algorithm can be analyzed as follows. Because r is a constant, we can afford to compute $\mathcal{T}(R)$ and the lists S_Δ naively, in time $O(r^2)$ and $O(nr)$ respectively. Gluing together the small maps can be done in time $O(n)$. But what about the recursive calls? If we denote the size of S_Δ by n_Δ , then bounding the n_Δ becomes the key issue here. It turns out that the right intuition is to assume that the n_Δ are about n/r . Assuming this, we get the recursion

$$T(n) \leq O(r^2 + nr) + O(r)T(n/r),$$

which solves to $T(n) = O(n^{1+\epsilon})$, where $\epsilon > 0$ is a constant depending on r . By increasing the value of r , ϵ can be made arbitrarily small, but at the same time the constant of proportionality hidden in the O -notation increases.

The truth is that one cannot really assume that $n_\Delta = O(n/r)$ holds for every trapezoid Δ at the same time. Valid bounds are as follows. For randomly chosen R of size r , we have:

- The **pointwise bound**: With probability increasing with r ,

$$n_\Delta \leq C \frac{n}{r} \log r, \quad (40.1.1)$$

for all $\Delta \in \mathcal{T}(R)$, where the constant C does not depend on r and n .

- The **higher-moments bound**: For any constant $c \geq 1$, there is a constant $C(c)$ (independent of r and n) such that

$$\sum_{\Delta \in \mathcal{T}(R)} (n_\Delta)^c = C(c) \left(\frac{n}{r}\right)^c |\mathcal{T}(R)|. \quad (40.1.2)$$

In other words, while the maximum n_Δ can be as much as $O((n/r) \log r)$, on the average the n_Δ behave as if they indeed were $O(n/r)$.

Both bounds can be used to prove that $T(n) = O(n^{1+\epsilon})$, with the dependence on ϵ being somewhat better using the latter bound. The difference between the two bounds becomes more marked for larger values of r , as will be detailed below. (For a more general result that subsumes these two bounds, see [Theorem 40.5.2](#).)

The same scheme used to compute $\mathcal{T}(S)$ will also give a data structure for point location in the trapezoidal map. This data structure is a tree, constructed as follows. If the set S is small enough, simply store $\mathcal{T}(S)$ explicitly. Otherwise,

take a random sample R , and store $\mathcal{T}(R)$ in the root node. Subtrees are created for every $\Delta \in \mathcal{T}(R)$. These subtrees are constructed recursively, using the sets S_Δ .

By the pointwise bound, the depth of the tree is $O(\log n)$ with high probability, and therefore the query time is also $O(\log n)$. The storage requirement is easily seen to be $O(n^{1+\epsilon})$ as above.

The algorithmic technique described in this section is surprisingly robust. It works for a large number of problems in computational geometry, and for many problems it is the only known approach to solve the problem. It does have two major drawbacks, however. First, it seems to be difficult to remove the ϵ -term in the exponent, and truly optimal random-sampling algorithms are scarce. Second, the practicality of this method remains to be established. If the size of the random sample is chosen too small, then the problem size may not decrease fast enough to guarantee a fast-running algorithm, or even termination. Few papers in the literature calculate this size constant, and so for most applications it remains unclear whether the size of the random sample can be chosen considerably smaller than the problem size in practice.

CUTTINGS

The only use of randomization in the above algorithm was to subdivide the plane into a number of simply-shaped regions Δ , such that every region is intersected by only a few line segments. Such a subdivision is called a *cutting* Ξ for the set X of n segments; if every $\Delta \in \Xi$ intersects at most n/r of the objects in X , it is a $1/r$ -*cutting*. Cuttings are interesting in their own right, and have been studied intensively. This research has led to a number of results on the deterministic construction of efficient cuttings, with useful properties that go beyond those of the simple cutting based on a random sample discussed above (Section 40.7). Cuttings form the basis for many algorithms and search structures in computational geometry; see Section 36.2. As a result, most recent geometric divide-and-conquer algorithms no longer explicitly use randomization, and randomized divide-and-conquer is currently in the process of being replaced by divide-and-conquer based on cuttings.

In practice, however, cuttings may still be constructed most efficiently using random sampling. There are two basic techniques, which we illustrate again using a set X of n line segments with disjoint interiors in the plane.

- **ϵ -net based cuttings:** The easiest way to obtain a $1/r$ -cutting is to take a random sample $N \subset X$ of size $O(r \log r)$. If N is a $1/r$ -net for the range space (X, Γ) (defined in Section 40.4 and Section 36.2), then the trapezoidal map of N is a $1/r$ -cutting of size $O(r \log r)$. If not, we try a different sample.
- **Splitting the excess:** The construction based on ϵ -nets can be improved as follows. First take a random sample N of X of size $O(r)$, and compute its trapezoidal map. Every trapezoid Δ may be intersected by $O((n/r) \log r)$ segments. If we take a random sample of these segments, and form their trapezoidal map again (restricted to Δ), the pieces obtained are intersected by at most n/r segments. The size of this cutting is only $O(r)$, which is optimal.

Har-Peled [HP00] investigates the constants achievable for cuttings of lines in the plane.

BOTTOM-UP SAMPLING

In bottom-up sampling, the random sample is so large that the resulting subproblems are small enough to be solved directly. However, it is no longer trivial to compute the auxiliary structures needed to subdivide the problem. We again illustrate with the trapezoidal map.

Given a set S of n line segments, we take a sample R of size $n/2$, and compute the trapezoidal map of R recursively. For every $\Delta \in \mathcal{T}(R)$, we compute the list S_Δ of segments in $S \setminus R$ intersecting Δ . This can be done by locating an endpoint of every segment in $S \setminus R$ in $\mathcal{T}(R)$ and traversing $\mathcal{T}(R)$ from there. If we use a planar point location structure (Section 34.3), this takes time $O(n \log n + \sum_{\Delta \in \mathcal{T}(R)} n_\Delta)$. For every Δ , we then compute the trapezoidal map $\mathcal{T}(S_\Delta)$, and clip it to Δ . This can be done naively in time $O(n_\Delta^2)$. Finally, we glue together all the little maps.

The running time of the algorithm is bounded by the recursion

$$T(n) \leq T(n/2) + O(n \log n) + \sum_{\Delta \in \mathcal{T}(R)} O(n_\Delta^2).$$

The pointwise bound shows that with high probability, $n_\Delta = O(\log n)$ for all Δ . That would imply that the last term in the recursion is $O(n \log^2 n)$. Here, the higher-moments bound turns out to give a strictly better result, as it shows that the expected value of that term is only $O(n)$. The recursion therefore solves to $O(n \log^2 n)$.

Bottom-up sampling has the potential to lead to more efficient algorithms than top-down sampling, because it avoids the blow-up in problem size that manifests itself in the n^ϵ -term in top-down sampling. However, it needs more refined ingredients—as the constructions of $\mathcal{T}(R)$ and the lists S_Δ demonstrate—and therefore seems to apply to fewer problems.

As with top-down sampling, bottom-up sampling can be used for point location. These search structures have the advantage that they can often easily be made dynamic (Section 40.3).

40.2 RANDOMIZED INCREMENTAL ALGORITHMS

GLOSSARY

Backwards analysis: Analyzing the time complexity of an algorithm by viewing it running backwards in time [Sei93].

Conflict graph: A bipartite graph whose arcs represent conflicts (usually intersections) between objects to be added and objects already constructed.

History graph: A directed, acyclic graph that records the history of changes in the geometric structure being maintained. Also known as an *influence graph* or *I-DAG* (influence-directed acyclic graph).

Many problems in computational geometry permit a natural computation by an incremental algorithm. Incremental algorithms need only process one new object at a time, which often implies that changes in the geometric data structure remain localized in the neighborhood of the new object.

As an example, consider the computation of the trapezoidal map of a set of line segments (cf. Fig. 34.3.2; for another example, see [Section 22.3](#)). To add a new line segment s to the map, one would first identify the trapezoids of the map intersected by s . Those trapezoids must be split, creating new trapezoids, some of which then must be merged along the segment s . All these update operations can be accomplished in time linear in the sum of the number of old trapezoids that are destroyed and the number of new trapezoids that are created during the insertion of s . This quantity is called the **structural change**.

This results in a rather simple algorithm to compute the trapezoidal map of a set of line segments. Starting with the empty set, we treat the line segments one-by-one, maintaining the trapezoidal map of the set of line segments inserted so far.

However, a general disadvantage of incremental algorithms is that the total structural change during the insertions of n objects, and hence the running time of the algorithm, depends strongly on the order in which the objects are processed. In our case, it is not difficult to devise a sequence of n line segments leading to a total structural change of $\Theta(n^2)$. Even if we know that a good order of insertion exists (one that implies a small structural change), it seems difficult to determine this order beforehand. And this is exactly where randomization can help: we simply treat the n objects in random order. In the case of the trapezoidal map, we will show below that if the n segments are processed in random order, the *expected* structural change in every step of the algorithm is only constant.

BACKWARDS ANALYSIS

An easy way to see this is via **backwards analysis**. We first observe that it suffices to bound the number of trapezoids created in each stage of the algorithm. All these trapezoids are incident to the segment inserted in that stage. We imagine the algorithm removing the line segments from the final map one-by-one. In each step, we must bound the number of trapezoids incident to the segment s removed. Now we make two observations:

- The trapezoidal map is a planar graph, with every trapezoid incident to at most 4 segments. Hence, if there are m segments in the current set, the total number of trapezoid-segment incidences is $O(m)$.
- Since the order of the segments is a random permutation of the set of segments, each of the m segments is equally likely to be removed.

These two facts suffice to show that the expected number of trapezoids incident to s is constant. In fact, this number is bounded by the average degree of a segment in a trapezoidal map.

It follows that the expected total structural change during the course of the algorithm is $O(n)$. To obtain an efficient algorithm, however, we need a second ingredient: whenever a new segment s is inserted, we need to identify the trapezoids of the old map intersected by s . Two basic approaches are known to solve this problem: the conflict graph and the history graph.

CONFLICT GRAPH

A conflict graph is a bipartite graph whose nodes are the not-yet-added segments on one side and the trapezoids of the current map on the other side. There is an arc between a segment s and a trapezoid Δ if and only if s intersects Δ , in which case we say that s is *in conflict with* Δ .

It is possible to maintain the conflict graph during the course of the incremental algorithm. Whenever a new segment is inserted, all the conflicts of the newly-created trapezoids are found. This is not difficult, because a segment can only conflict with a newly-created trapezoid if it was previously in conflict with the old trapezoids at the same place. Thus the trapezoids intersected by the new segment s are just the neighbors of s in the conflict graph.

The time necessary to maintain the conflict graph can be bounded by summing the number of conflicts of all trapezoids created during the course of the algorithm. It follows from the higher-moments bound (Eq. 40.1.2) that the average number of conflicts of the trapezoids present after inserting the first r segments—note that these segments form a random sample of size r of S —is $O(n/r)$. Intuitively, we can assume that this is also correct if we look only at the trapezoids that are *created* by the insertion of the r th segment. Since the expected number of trapezoids created in every step of the algorithm is constant, the expected total time is $\sum_{i=1}^n O(n/r) = O(n \log n)$.

Note that an algorithm using a conflict graph needs to know the entire set of objects (segments in our example) in advance.

HISTORY GRAPH

A different approach uses a history graph, which records the history of changes in the maintained structure.

In our example, we can maintain a directed acyclic graph whose nodes correspond to trapezoids constructed during the course of the algorithm. The leaves are the trapezoids of the current map; all inner nodes correspond to trapezoids that have already been destroyed (with the root corresponding to the entire plane). When we insert a segment s , we create new nodes for the newly-created trapezoids, and create a pointer from an old trapezoid to every new one that overlaps it. Hence, there are at most four outgoing pointers for every inner node of the history graph.

We can now find the trapezoids intersected by a new segment s by performing a graph search from the root, using say, depth-first search on the connected subgraph consisting of all trapezoids intersecting s . Note that this search performs precisely the same computations that would have been necessary to maintain the conflict graph during the sequence of updates, but at a different time. We can therefore consider a history graph as a lazy implementation of a conflict graph: it postpones each computation to the moment it is actually needed. Consequently, the analysis is exactly the same as for conflict graphs.

Algorithms using a history graph are *on-line* or *semidynamic* in the sense that they do not need to know about a point until the moment it is inserted.

ABSTRACT FRAMEWORK AND ANALYSIS

Most randomized incremental algorithms in the literature follow the framework sketched here for the computation of the trapezoidal map: the structure to be

computed is maintained while the objects defining it are inserted in random order. To insert a new object, one first has to find a “conflict” of that object (the *location step*), then local updates in the structure are sufficient to bring it up to date (the *update step*). The cost of the update is usually linear in the size of the change in the combinatorial structure being maintained, and can often be bounded using backwards analysis. The location step can be implemented using either a conflict graph or a history graph. In both cases, the analysis is the same (since the actual computations performed are also often identical). To avoid having to prove the same bounds repeatedly for different problems, researchers have defined an axiomatic framework that captures the combinatorial essence of most randomized incremental algorithms. This framework, which uses *configuration spaces*, provides ready-to-use bounds for the expected running time of most randomized incremental algorithms. See [Section 40.5](#).

POINT LOCATION THROUGH HISTORY GRAPH

In our trapezoidal map example, the history graph may be used as a point location structure for the trapezoidal map: given a query point q , find the trapezoid containing q by following a path from the root to a leaf node of the history graph. At each step, we continue to the child node corresponding to the trapezoid containing q .

The search time is clearly proportional to the length of the path. Backwards analysis shows that the expected length of this path is $O(\log n)$ for any fixed query point. Even stronger, one can show that the maximum length of any search path in the history graph is $O(\log n)$ with high probability.

If point location is the goal, the history graph can be simplified: instead of storing trapezoids, the inner nodes of the graph can denote two different kinds of elementary tests (“Does a point lie to the left or right of another point?” and “Does a point lie above or below a line?”). The final result is then an efficient and practical planar point location structure [Sei91].

This observation can also lead to a somewhat different location step inside the randomized incremental algorithm. Instead of performing a graph search with the whole segment s , point location can be used to find the trapezoid containing one endpoint of s . From there, a traversal of the trapezoidal map allows locating all trapezoids intersected by s .

APPLICATIONS

The randomized incremental framework has been successfully applied to a large variety of problems. We list a number of important such applications. Details on the results can be found in the chapters dealing with the respective area, or in one of the surveys cited in [Section 40.12](#).

- Trapezoidal decomposition formed by segments in the plane, and point location structures for this decomposition ([Section 34.3](#)).
- Triangulation of simple polygons: an optimal randomized algorithm with linear running time, and a simple algorithm with running time $O(n \log^* n)$ ([Section 26.2](#)).
- Convex hulls of points in d -dimensional space, output-sensitive convex hulls

in $\mathbb{R}^3$ (Section 22.3).

- Voronoi diagrams in different metrics, including higher order and abstract Voronoi diagrams (Section 23.3).
- Linear programming in finite-dimensional space ([Chapter 45](#)).
- Generalized linear programming: optimization problems that are combinatorially similar to linear programming (Section 45.4).
- Hidden surface removal (Section 28.8 and [Chapter 49](#)).
- Constructing a single face in an arrangement of (curved) segments in the plane, or in an arrangement of triangles or surface patches in $\mathbb{R}^3$ (Sections 24.5 and 47.2); computing zones in an arrangement of hyperplanes in $\mathbb{R}^d$ (Section 24.4).

40.3 DYNAMIC ALGORITHMS

DYNAMIC RANDOMIZED INCREMENTAL

Any on-line randomized incremental algorithm can be used as a semidynamic algorithm, a dynamic algorithm that can only perform insertions of objects. The bound on the expected running time of the randomized incremental algorithm then turns into a bound on the *average* running time, under the assumption that every permutation of the input is equally likely. (The relation between the two uses of the algorithms is similar to that between randomized and ordinary Quicksort as mentioned in the Introduction.)

This observation has motivated researchers to extend randomized incremental algorithms so that they can also manage deletions of objects. Then bounds on the average running time of the algorithm are given, under the assumption that the input sequence is a *random update sequence*. In essence, one assumes that for an addition, every object currently not in the structure is equally likely to be inserted, while for a deletion every object currently present is equally likely to be removed (the precise definition varies between authors).

Two approaches have been suggested to handle deletions in history-graph based incremental algorithms. The first adds new nodes at the leaf level of the history graph for every deletion. This works for a wide variety of problems and is relatively easy to implement, but after a number of updates the history graph will become “dirty”: it will contain elements that are no longer part of the current structure but which still must be traversed by the point-location steps. Therefore, the history graph needs periodic “cleaning.” This can be accomplished by discarding the current graph, and reconstructing it from scratch using the elements currently present.

In the second approach, for every deletion the history graph is transformed to the state it would have been had the object never been inserted. The history graph is therefore always “clean.” However, in this model deletions are more complicated, and it therefore seems to apply to fewer problems.

DYNAMIC SAMPLING AND GRADATIONS

A rather different approach permits a number of search structures based on bottom-up sampling to be dynamized surprisingly easily. Such a search structure consists of a *gradation* using Bernoulli sampling (Section 40.1): The gradation is a hierarchy of $O(\log n)$ levels. Every object is included in the first level, and is chosen independently to be in the second level with probability $\frac{1}{2}$. Every object in the second level is propagated to level 3 with probability $\frac{1}{2}$, and so forth. Whenever an object is added to or removed from the current set, the search structure is updated to the proper state. When adding an object, it suffices to flip a coin at most $\log n$ times to determine where to place the object. Using this technique, it is possible to give high-probability bounds on the search time and sometimes also on the update time [Mul93].

40.4 RANGE SPACES

“Pointwise bounds” of the form in Equation 40.1.1 can be proved in the axiomatic framework of range spaces, which then leads to immediate application to a wide variety of geometric settings.

GLOSSARY

Range space: A pair (X, Γ) , with X a universe (possibly infinite), and Γ a family of subsets of X . The elements of Γ are called **ranges**. Typical examples of range spaces are of the form $(\mathbb{R}^d, \Gamma)$, where Γ is a set of geometric figures, such as all line segments, halfspaces, simplices, balls, etc. (cf. Section 36.2).

Shattered: A set $A \subseteq X$ is shattered if every subset A' of A can be expressed as $A' = A \cap \gamma$, for some range $\gamma \in \Gamma$.

In the range space $(\mathbb{R}^2, \mathcal{H})$, where $\mathcal{H}$ is the set of all closed halfplanes, a set of three points in convex position is shattered. However, no set of four points is shattered. See Figure 40.4.1: whether the point set is in convex position or not, there always is a subset (encircled) that cannot be expressed as $A \cap h$ for any halfplane h .

FIGURE 40.4.1

No set of four points can be shattered by halfplanes.

In the range space $(\mathbb{R}^2, \mathcal{C})$, where $\mathcal{C}$ is the set of all convex polygons, any set of points lying on a circle is shattered.

Vapnik-Chervonenkis dimension (VC-dimension): The VC-dimension of a range space (X, Γ) is the smallest integer d such that there is no shattered subset $A \subseteq X$ of size $d + 1$. If no such d exists, the VC-dimension is said to be infinite.

Range spaces $(\mathbb{R}^d, \Gamma)$, where Γ is the set of line segments, of simplices, of balls, or of halfspaces, have finite VC-dimension. For example, the range space $(\mathbb{R}^2, \mathcal{H})$ has VC-dimension 3. The range space $(\mathbb{R}^2, \mathcal{C})$, however, has infinite VC-dimension.

Shatter function: For a range space (X, Γ) , the shatter function $\pi_\Gamma(m)$ is defined as

$$\pi_\Gamma(m) = \max_{A \subseteq X, |A|=m} |\{A \cap \gamma \mid \gamma \in \Gamma\}|.$$

If the VC-dimension of the range space is infinite, then $\pi_\Gamma(m) = 2^m$. Otherwise the shatter function is bounded by $O(m^d)$, where d is the VC-dimension. (So the shatter function of any range space is either exponential or polynomially bounded.) If the shatter function is polynomial, the VC-dimension is finite. The order of magnitude of the shatter function is not necessarily the same as the VC-dimension; for instance, the range space $(\mathbb{R}^2, \mathcal{H})$ has VC-dimension 3 and shatter function $O(m^2)$. Since the VC-dimension is often difficult to compute, some authors have defined the *VC-exponent* as the order of magnitude of the shatter-function.

ϵ -net: A subset $N \subseteq X$ is called an ϵ -net for the range space (X, Γ) if $N \cap \gamma \neq \emptyset$ for every $\gamma \in \Gamma$ with $|\gamma|/|X| > \epsilon$ (here, $\epsilon \in [0, 1]$ and X is finite). It is often more convenient to write $1/r$ for ϵ , with $r > 1$.

ϵ -approximation: A subset $A \subseteq X$ is called an ϵ -approximation for the range space (X, Γ) if, for every $\gamma \in \Gamma$, we have

$$\left| \frac{|A \cap \gamma|}{|A|} - \frac{|\gamma|}{|X|} \right| \leq \epsilon.$$

An ϵ -approximation is also an ϵ -net, but not necessarily vice versa.

Linear range space: The range space $(\mathbb{R}^d, \mathcal{L}_k^d)$, where $\mathcal{L}_k^d$ consists of unions of polytopes of total complexity at most k in $\mathbb{R}^d$.

Linearizable range space: A typical range space $(\mathcal{X}, \mathcal{X}_\mathcal{C})$ is defined by a set of geometric “objects” $\mathcal{X}$ and a set of geometric “cells” $\mathcal{C}$: A cell $\Delta \in \mathcal{C}$ defines a range $\mathcal{X}_\Delta$ that consists of all the objects $x \in \mathcal{X}$ that intersect Δ . $(\mathcal{X}, \mathcal{X}_\mathcal{C})$ is linearizable if it can be embedded into a linear range space, that is, if there are constants d, k and maps $\varphi: \mathcal{X} \rightarrow \mathbb{R}^d$ and $\psi: \mathcal{C} \rightarrow \mathcal{L}_k^d$, such that for $x \in \mathcal{X}$ and $\Delta \in \mathcal{C}$, $x \cap \Delta \neq \emptyset$ iff $\varphi(x) \in \psi(\Delta)$ [YY85, AM94].

ϵ -NETS AND ϵ -APPROXIMATIONS

The pointwise bound translates into the abstract framework of range spaces as follows:

THEOREM 40.4.1

Let (X, Γ) be a range space with X finite and of finite VC-dimension d . Then a random sample $R \subset X$ of size $C(d)r \log r$ is a $1/r$ -net for (X, Γ) with probability whose complement to 1 is polynomially small in r . The constant $C(d)$ depends only on d .

This theorem forms the basis for “traditional” randomized divide-and-conquer algorithms, such as the one for the trapezoidal map of line segments sketched in

Section 40.1. The pointwise bound used there follows from the theorem. Consider the range space (S, Γ) , where $\Gamma := \{\gamma(\Delta) \mid \Delta \text{ an open trapezoid}\}$, and $\gamma(\Delta)$ is the set of all segments in S intersecting Δ . The VC-dimension of this range space is finite. The easiest way to see this is by looking at the shatter function. Consider a set of m line segments. Extend them to full lines, pass $2m$ vertical lines through all endpoints, and look at the arrangement of these $3m$ lines. Clearly, for any two trapezoids Δ and Δ' whose corners lie in the same faces of this arrangement we have $\gamma(\Delta) = \gamma(\Delta')$. Consequently, there are at most $O(m^8)$ different ranges, and that crudely bounds the shatter function as $O(m^8)$. Thus the VC-dimension is finite and Theorem 40.4.1 applies: with probability increasing rapidly with r , the sample R of size r is an ϵ -net for S with $\epsilon = \Omega((1/r) \log r)$. Assume this is the case, and consider some trapezoid $\Delta \in \mathcal{T}(R)$. The interior of Δ does not intersect any segment in R , so by the property of ϵ -nets, the range $\gamma(\Delta)$ can intersect at most ϵn segments of S . And so we have $n_\Delta = O((n/r) \log r)$.

The construction of ϵ -nets has been so successfully derandomized that ϵ -nets now are used routinely in deterministic algorithms (Section 40.7). At least in theory, the top-down sampling algorithm of Section 40.1 need no longer be considered a randomized algorithm.

ϵ -approximations are used in the deterministic computation of ϵ -nets (Section 40.7). They are also interesting in their own right, since some geometric problems—for instance, the computation of centerpoints or ham-sandwich cuts (see Section 14.2)—can be solved approximately by solving them exactly for an ϵ -approximation. A $1/r$ -approximation can be found by taking a random sample of size $O(r^2 \log r)$. This bound is not tight.

VC-dimension and ϵ -nets are also frequently used in statistics [VC71] (from which they derive) and in learning theory.

LINEARIZING RANGE SPACES

Most range spaces that appear in geometric problems can be linearized. A general procedure to obtain φ and ψ is the following [MS96]: Start with a first-order predicate Π in the theory of closed fields—one formed from polynomial inequalities using Boolean connectives and quantifiers, where the parameters defining x are regarded as variables, and the parameters defining Δ are regarded as constants—that describes when $x \cap \Delta \neq \emptyset$; then, using a quantifier elimination method, rewrite Π as a disjunction of several conjunctions of polynomial inequalities; finally, by introducing a variable for each monomial that appears in the polynomial inequalities, obtain linear inequalities that correspond to a linear cell.

For example, consider a set S of line segments and let $R \subseteq S$; we are interested in the conflict sets S_Δ for $\Delta \in \mathcal{T}(R)$. Whether a segment $s = uv \in S$ intersects $\Delta \in \mathcal{T}(R)$ can be written as a predicate in which the parameters defining s are regarded as variables, and the parameters defining Δ are regarded as constants: either $u \in \Delta$, or $v \in \Delta$, or uv intersects one of the edges of Δ .

In specific cases, a more efficient embedding (with smaller values of d and k) is possible. An important example is the range space defined on points in $\mathbb{R}^d$ by balls. It can be linearized by lifting the points to the paraboloid $x_{d+1} = x_1^2 + \cdots + x_d^2$ in $\mathbb{R}^{d+1}$.

One application of linearization is the computation of conflict lists. Consider the computation of the conflict lists S_Δ for $\Delta \in \mathcal{T}(R)$, $R \subseteq S$. By linearization, S_Δ

is equal to the set $\varphi(S) \cap \psi(\Delta)$. We have now the problem of locating the points $\varphi(S)$ in the arrangement of the hyperplanes H in $\mathbb{R}^d$ that bound the linear cells $\psi(\Delta)$. We construct a point location data structure for the arrangement of H , and use it to locate each of the points $\varphi(s)$, $s \in S$. If $r = |\mathcal{T}(R)|$ and $n = |S|$, then the cost of this procedure is $O(r^{d+1} + n \log r + k)$, where k is the number of conflicts reported. This approach is very general and easily parallelizable; on the other hand, it can be relatively inefficient in comparison with other problem-specific methods that make more use of the particular geometry of the problem.

Linearization is also used in the deterministic construction of cuttings (Section 40.7).

OPEN PROBLEM

For general range spaces, the bound $O(r \log r)$ in Theorem 40.4.1 is the best possible. However, for many geometrically-defined spaces the best lower bound is $\Omega(r)$. Can the upper bound be improved for some geometric range spaces? This is perhaps a difficult problem [MSW90].

40.5 CONFIGURATION SPACES

The framework of configuration spaces is somewhat more complicated than range spaces, but facilitates proving higher-moment bounds as in Equation 40.1.2. Terminology, axiomatics, and notation vary widely between authors. Note that the term “configuration space” is used in robotics with a different meaning (see [Chapters 47](#) and [48](#)).

GLOSSARY

Configuration space: A four-tuple $(X, \mathcal{T}, D, K)$. X is a finite set of geometric objects (the universe of size n). $\mathcal{T}$ is a mapping that assigns to every subset $S \subseteq X$ a set $\mathcal{T}(S)$; the elements of $\mathcal{T}(S)$ are called **configurations**. $\Pi(X) := \bigcup_{S \subseteq X} \mathcal{T}(S)$ is the set of all configurations occurring over some subset of X . D and K assign to every configuration $\Delta \in \Pi(X)$ subsets $D(\Delta)$ and $K(\Delta)$ of X . Elements of the set $D(\Delta)$ are said to **define** the configuration (they are also called **triggers**) and the elements of the set $K(\Delta)$ are said to **kill** the configuration (they are also said to be in **conflict** with the configuration and are sometimes called **stoppers**).

Conflict size of Δ : The number of elements of $K(\Delta)$.

We will require the following axioms:

- (i) The number $d = \max\{|D(\Delta)| \mid \Delta \in \Pi(X)\}$ is a constant (called the **maximum degree** or the **dimension** of the configuration space). Moreover, the number of configurations sharing the same defining set is bounded by a constant.
- (ii) For any $\Delta \in \mathcal{T}(S)$, $D(\Delta) \subseteq S$ and $S \cap K(\Delta) = \emptyset$.
- (iii) If $\Delta \in \mathcal{T}(S)$ and $D(\Delta) \subseteq S' \subseteq S$, then $\Delta \in \mathcal{T}(S')$.

(iii') If $D(\Delta) \subseteq S$ and $K(\Delta) \cap S = \emptyset$, then $\Delta \in \mathcal{T}(S)$.

Note that axiom (iii) follows from (iii'); see below.

EXAMPLES

1. *Trapezoidal map.* The universe X is a set of segments in the plane, and $\mathcal{T}(S)$ is the set of trapezoids in the trapezoidal map of S . The defining set $D(\Delta)$ is the set of segments that are necessary to define Δ (at most four segments suffice, so $d = 4$), and the killing set $K(\Delta)$ is the set of segments that intersect the trapezoid. It is easy to verify that conditions (i), (ii), (iii), (iii') all hold.
2. *Delaunay triangulation.* X is a set of points in the plane (assume that no four points lie on a circle), and $\mathcal{T}(S)$ is the set of triangles of the Delaunay triangulation of S . $D(\Delta)$ consists of the vertices of triangle Δ (so $d = 3$), while $K(\Delta)$ is the set of points lying inside the circumcircle of the triangle. Again, axioms (i), (ii), (iii), (iii') all hold.
3. *Convex hulls in 3D.* The universe X is a set of points in 3D (assume that no four points are coplanar), and $\mathcal{T}(S)$ is the set of facets of the convex hull of S . The defining set of a facet Δ is the set of its vertices ($d = 3$), and the killing set is the set of points lying in the outer open halfspace defined by Δ . Note that there can be two configurations sharing the same defining set. Again, axioms (i)–(iii') all hold.
4. *Single cell.* The universe X is a set of possibly intersecting segments in the plane, and $\mathcal{T}(S)$ is the set of trapezoids in the trapezoidal map of S that belongs to the cell of the line segment arrangement containing the origin (Figure 40.5.1). The defining and killing sets are defined as in the case of the trapezoidal map of the whole arrangement above. In this situation, axiom (iii') does not hold. Whether or not a given trapezoid appears in $\mathcal{T}(S)$ depends on segments other than the ones in $D(\Delta) \cup K(\Delta)$. Axioms (i), (ii), (iii) are nevertheless valid.

FIGURE 40.5.1

A single cell in an arrangement of line segments.

5. *Counterexample.* Let X be a set of line segments, and let $\mathcal{T}(S)$ be a decomposition of the arrangement that is obtained by drawing vertical extensions for faces with an even number of edges, and horizontal extensions for faces

with an odd number of edges. Axioms (i) and (ii) hold, but neither (iii) nor (iii') is satisfied.

Note that when (ii) and (iii') both hold, then $\Delta \in \mathcal{T}(S)$ if and only if $D(\Delta) \subseteq S$ and $K(\Delta) \cap S = \emptyset$. In other words, the mapping $\mathcal{T}$ is then completely defined by the functions D and K . In fact, in the first three examples we can decide from local information alone whether or not a configuration appears in $\mathcal{T}(S)$. For instance, a triangle Δ is in the Delaunay triangulation of S if and only if the vertices of Δ are in S , and no point of S lies in the circumcircle of Δ .

As mentioned above, axiom (iii) follows from (iii'), but not conversely. Axiom (iii) requires a kind of monotonicity: if Δ occurs in $\mathcal{T}(S)$ for some S , then we cannot destroy it by removing elements from S unless we remove some element in $D(\Delta)$.

We may say that the configuration spaces of the first three examples are defined *locally* and *canonically*. The fourth example is *canonical*, but *nonlocal*. The last example is not canonical and cannot be treated with the methods described here. (Fortunately, this is an artificial example with no practical use—but see the open problems below.)

HIGHER-MOMENTS AND EXPONENTIAL DECAY LEMMA

The higher-moments bound for configuration spaces generalizes the bound for trapezoidal maps, Equation 40.1.2:

THEOREM 40.5.1 *Higher-moments bound*

Let $(X, \mathcal{T}, D, K)$ be a configuration space satisfying axioms (i), (ii), (iii), and let R be a random sample of X of size r . For any constant c , we have

$$E \left[\sum_{\Delta \in \mathcal{T}(R)} |K(\Delta)|^c \right] = O((n/r)^c E[|\mathcal{T}(R)|]).$$

(Technically, rather than R , a sample R' of size $\lfloor r/2 \rfloor$ should appear on the right, but $E[|\mathcal{T}(R')|] = O(E[|\mathcal{T}(R)|])$ in all cases of interest). In other words, as far as the c th-degree average is concerned, the conflict size behaves as if it were $O(n/r)$, instead of $O((n/r) \log r)$ from the pointwise bound.

Let $(X, \mathcal{T}, D, K)$ and R be as in Theorem 40.5.1. For any natural number t , we define $\mathcal{T}_t(R)$ to be the subset of configurations of $\mathcal{T}(R)$ whose conflict size exceeds the “natural” value n/r by at least the factor t :

$$\mathcal{T}_t(R) := \{\Delta \in \mathcal{T}(S) \mid |K(\Delta)| \geq tn/r\}.$$

The following exponential-decay lemma [AMS98] states that the number of such configurations decreases exponentially with t :

THEOREM 40.5.2 *Exponential decay lemma*

Let $(X, \mathcal{T}, D, K)$ be a configuration space satisfying axioms (i), (ii), (iii), and let R be a random sample of X of size r . For any t with $1 \leq t \leq r/d$ (where d is as in axiom (i)), we have

$$E[|\mathcal{T}_t(R)|] = O(2^{-t}) \cdot E[|\mathcal{T}(R')|],$$

where $R' \subseteq X$ denotes a random sample of size $\lfloor r/t \rfloor$.

The exponential decay lemma implies both the higher-moments bound, by adding over t , and the pointwise bound, by Markov's inequality.

RANDOMIZED INCREMENTAL CONSTRUCTION

Many, if not most, randomized incremental algorithms in the literature can be analyzed using the configuration space framework. Given the set X , the goal of the randomized incremental algorithm is to compute $\mathcal{T}(X)$. This is done by maintaining $\mathcal{T}(X^i)$, for $1 \leq i \leq n$, where $X^i = \{x_1, x_2, \dots, x_i\}$ and the x_i form a random permutation of X .

To bound the number of configurations created during the insertion of x_i into X^{i-1} , we observe that by axiom (iii) these configurations are exactly those $\Delta \in \mathcal{T}(X^i)$ with $x_i \in D(\Delta)$. The expected number of these can be bounded by

$$\frac{d}{i} E[|\mathcal{T}(X^i)|]$$

using backwards analysis. Here, d is the maximum degree of the configuration space.

The expected total change in the conflict graph or history graph can be bounded by summing $|K(\Delta)|$ over all Δ created during the course of the algorithm. Using axioms (i) to (iii'), we can derive the following bound:

$$\sum_{i=1}^n d^2 \frac{n-i}{i} \frac{E[|\mathcal{T}(X^i)|]}{i}.$$

(The exact form of this expression depends on the model used.) The book [Mul93] treats randomized incremental algorithms systematically using the configuration space framework (assuming axiom (iii')).

LAZY RANDOMIZED INCREMENTAL CONSTRUCTION

In problems that have nonlocal definition, such as the computation of a single cell in an arrangement of segments, single cells in arrangements of surface patches, or zones in arrangements, the update step of a randomized incremental construction becomes more difficult. Besides the local updates in the neighborhood of the newly inserted object, there may also be global changes. For instance, when a line segment is inserted into an arrangement of line segments, it may cut the single cell being computed into several pieces, only one of which is still interesting. The technique of lazy randomized incremental construction [BDS95] deals with these problems by simply postponing the global changes to a few "clean-up" stages. Since the setting of all these problems is nonlocal, the analysis uses only axioms (i), (ii), (iii).

OPEN PROBLEM

The canonical framework of randomized incremental algorithms sketched above is sometimes too restrictive. For instance, to make a problem fit into the framework, one often has to assume that objects are in general position. While many algorithms

could deal with special cases (e.g., four points on a circle in the case of Delaunay triangulations) directly, the analysis does not hold for those situations, and one has to resort to a symbolic perturbation scheme to save the analysis. Can a more relaxed framework for randomized incremental construction be given [Sei93]?

40.6 DERANDOMIZATION TECHNIQUES

Even when an efficient randomized algorithm for a problem is known, researchers still find it worthwhile to obtain a deterministic algorithm of the same efficiency. The reasons for doing this are varied, from scientific curiosity (what is the real power of randomness?), to practical reasons (truly random bits are quite expensive), to a preference for “deterministic” that may not be strictly rational. Sometimes a deterministic algorithm for a given problem may be obtained by “simulating” or “derandomizing” a randomized algorithm. Derandomization has turned out to be a powerful theoretical tool: for several problems the only known worst-case optimal deterministic algorithm has been obtained by derandomization. The most famous example is computing the convex hull of n points in d -dimensional space (Section 22.3).

General derandomization techniques can be used to produce a deterministic counterpart of random sampling in both configuration spaces and range spaces. As a result, it is possible to obtain in polynomial time a sample that satisfies the higher-moment bound, or that is a net or an approximation. Taking advantage of separability and composition properties of approximations, these constructions can be made efficient. In most applications, deterministic sampling is the base of a deterministic divide-and-conquer algorithm or data structure, which is almost as efficient as the randomized counterpart.

On the other hand, incremental algorithms are considerably harder to derandomize: the convex hull algorithm mentioned above is essentially the only successful case. The problem is that in an incremental algorithm each insertion must be “globally good,” while in the divide-and-conquer case, items are chosen locally in a neighborhood that shrinks as the algorithm progresses. In some cases, such as linear programming, a derandomized divide-and-conquer approach leads to a deterministic algorithm with better dependency on the dimension than previously known methods (prune-and-search), but there still remains a large gap with respect to the best randomized algorithm (which is an incremental one).

METHOD OF CONDITIONAL PROBABILITIES

The *method of conditional probabilities* (also called the *Raghavan-Spencer method*) [Spe87, Rag88] implements a binary search of the probability space to determine an event with the desired properties (guaranteed by a probabilistic analysis). Given a configuration space $(X, \mathcal{T}, D, K)$, the goal is to obtain a random sample of size (approximately) r that satisfies the higher-moments bound. Let $X = \{x_1, \dots, x_n\}$ and Ω be the probability space on $\{0, 1\}^n$, and consider the probability distribution on Ω induced by selecting each component equal to 1 independently with probability $p = r/n$ (for convenience, we use Bernoulli sampling). Let $F : \Omega \rightarrow \mathbb{R}$ be the random variable that assigns to the vector $(q_1, \dots, q_n)$ the

value $\sum_{\Delta \in \mathcal{T}(R)} f(|K(\Delta) \cap X|)$, where $x_i \in R$ iff $q_i = 1$, and $f(x) = x^k$ (for the k th moment; using $f(x) = e^{c(r/n)x}$ with an appropriate constant c , one can achieve the exponential decay bound). We know that $E[F] \leq M$ with $M = Cf(n/r)t(r)$, where $t(r)$ is an upper bound for $E[|\mathcal{T}(R)|]$. The method is based on the following relation, for $0 \leq i < n$:

$$\begin{aligned} E[F|q_1 = v_1, \dots, q_i = v_i] &= p \cdot E[F|q_1 = v_1, \dots, q_i = v_i, q_{i+1} = 1] + \\ &\quad (1-p) \cdot E[F|q_1 = v_1, \dots, q_i = v_i, q_{i+1} = 0] \\ &\geq \min\{E[F|q_1 = v_1, \dots, q_i = v_i, q_{i+1} = 1], E[F|q_1 = v_1, \dots, q_i = v_i, q_{i+1} = 0]\} \end{aligned}$$

If these conditional expectations can be computed *efficiently*, then this implies an efficient procedure to select v_{i+1} so that

$$E[F|q_1 = v_1, \dots, q_i = v_i] \geq E[F|q_1 = v_1, \dots, q_i = v_i, q_{i+1} = v_{i+1}].$$

Iterating this procedure, one finally obtains a solution $(v_1, \dots, v_n)$ that satisfies the probabilistic bound

$$M \geq E[F] \geq E[F|q_1 = v_1, \dots, q_n = v_n].$$

If the locality property holds, the conditional probabilities involved can indeed be computed in polynomial time: Let $X_i = \{x_1, x_2, \dots, x_i\}$ and $R_i = \{x_j \in X : q_j = 1, j \leq i\}$, then $E[F|q_1 = v_1, \dots, q_i = v_i]$ is equal to

$$\begin{aligned} &\sum_{\Delta \in \Pi(X)} \Pr\{\Delta \in \mathcal{T}(R)|q_1 = v_1, \dots, q_i = v_i\} f(|K(\Delta) \cap X|) \\ &= \sum_{\Delta \in \Pi(X): D(\Delta) \cap X_i \subseteq R_i, K(\Delta) \cap R_i = \emptyset} p^{|D(\Delta) \setminus S_i|} (1-p)^{|K(\Delta) \cap (X \setminus X_i)|} f(|K(\Delta) \cap X|), \end{aligned}$$

which can be approximated with sufficient accuracy. Similarly, $(1/r)$ -nets and $(1/r)$ -approximations of sizes $O(r \log r)$ and $O(r^2 \log r)$ can be computed in polynomial time.

k -WISE INDEPENDENT DISTRIBUTIONS

The method of conditional probabilities is highly sequential. An approach that is more suitable for parallel algorithms is to construct a probability space of polynomial size, and to execute the algorithm on each vector of this space. This is possible, for example, when the variables q_i need only be k -wise independent rather than being fully independent: for any indices $i_1, \dots, i_k$, and 0-1 values, $v_1, \dots, v_k$,

$$\Pr\{q_{i_1} = v_1, \dots, q_{i_k} = v_k\} = \prod_{j=1}^k \Pr\{q_{i_j} = v_{i_j}\} = \prod_{j=1}^k p^{v_j} (1-p)^{1-v_j}.$$

A probability space and distribution of size $O(n^k)$ with such k -wise independence can be computed effectively [Jof74, KM94]. Let $\rho \geq n$ be a prime number and suppose that $p_1, \dots, p_n \in [0, 1]$ satisfy $p_i = j_i/\rho$, for some integers j_i . Define a probability space with at most n^k points, as follows. For each $\langle a_0, a_1, \dots, a_{k-1} \rangle$ in $\{0, 1, \dots, \rho-1\}^k$, let

$$X_i = a_0 + a_1 i + a_2 i^2 + \dots + a_{k-1} i^{k-1} \bmod \rho,$$

for $1 \leq i \leq n$, assign probability $1/\rho^k$ and associate the vector $\langle Y_1, \dots, Y_n \rangle$ where $Y_i = 1$ if $X_i \in \{0, 1, \dots, j_i - 1\}$ and $Y_i = 0$ otherwise. The 0-1 probability space defined by the vectors $\langle Y_1, \dots, Y_n \rangle$ is a k -wise independent 0-1 probability space for $p_1, \dots, p_n$. With this construction, arbitrary probabilities can be approximated (within a factor of 2) by an appropriate choice of ρ . Using a larger space of size $O(n^{2k})$, arbitrary probabilities can be achieved exactly [KM94].

For some randomized algorithms one can show that they still work under k -wise independency for an appropriate k . For example, a quasi-random permutation with k -wise independence suffices for the randomized incremental approach to work [Mul96] (thus $O(\log n)$ random bits suffice rather than the $\Omega(n \log n)$ bits needed to define a fully random permutation). To verify that k -wise independence suffices, a tail inequality under k -independence is used [SSS93, BR94]. Let $q_1, \dots, q_n$ be a sequence of k -wise independent random variables in $\{0, 1\}$, with $k \geq 2$ even, let $Q = \sum_{i=1}^n q_i$, $\mu = E[Q]$ and assume that $\mu \geq k$, then

$$\Pr\{Q = 0\} < \frac{C_k}{\mu^{k/2}} \quad (40.6.1)$$

where C_k is a constant depending on k . Let R be a $2k$ -wise independent random sample from X with uniform probability p . For $\Delta \in \Pi(X)$, note that (no independence assumption needed)

$$\Pr\{D(\Delta) \subseteq R, K(\Delta) \cap R = \emptyset\} = \Pr\{D(\Delta) \subseteq R\} \cdot \Pr\{K(\Delta) \cap R = \emptyset | D(\Delta) \subseteq R\}.$$

Let d be an upper bound on $|D(\Delta)|$. The first factor can be computed using $2k$ -wise independence assuming $2k \geq d$:

$$\Pr\{D(\Delta) \subseteq R\} = p^{|D(\Delta)|}.$$

To upper bound the second factor, let $t_\Delta = p|K(\Delta)|$; then using the tail bound above, for $t_\Delta \geq k$:

$$\Pr\{K(\Delta) \cap R = \emptyset | D(\Delta) \subseteq R\} \leq \frac{C}{t_\Delta^{k-d/2}},$$

since after fixing $D(\Delta) \subseteq R$, the remaining random variables are still $(2k - d)$ -wise independent. Choosing k so that $c \leq k - d/2 + 2$, one can verify that the c th moment bound holds. Similarly, $1/r$ -nets and $1/r$ -approximations with sizes $O(rn^\delta)$ and $O(r^2n^\delta)$ can be computed in polynomial time (or fast in parallel with polynomial work), where $\delta = O(1/k)$. It does not seem possible, however, to achieve the exponential decay bound with a limited-independence space of polynomial size.

For fixed k , the size of the space can be reduced if a certain deviation from k -wise independence is allowed [NN90]. Furthermore, the approach of testing all the vectors in the probability space can be combined with the approach of performing a binary search so that even a space of superpolynomial size is usable [MNN89, BRS89]. Still, these approaches do not lead to the exponential decay bound, or to nets or approximations of size matching the probabilistic analysis.

CONSTRAINT-BASED PROBABILITY SPACES

An alternative approach that is implementable in parallel constructs a probability distribution tailored to a particular algorithm and even to a specific input [Nis92,

KM93, KK94, MRS01], leading to smaller probability spaces. The approach models the sampling process using *randomized finite automata* (RFA), and fools the automaton using a probability distribution D_n with support of size E_0 that depends polynomially on the error and on the size of the problem. Once the probability distribution has been constructed, it is only a matter of testing the algorithm for each point in D_n .

For each configuration Δ we construct an RFA M_Δ as follows: It consists of $n + 1$ levels $N_{\Delta,j}$, $0 \leq j \leq n$, each with two states $\langle j, \text{Yes} \rangle$ and $\langle j, \text{No} \rangle$, with transitions that reflect whether $\Delta \in \mathcal{T}(R)$: $\langle j - 1, \text{No} \rangle$ is always connected to $\langle j, \text{No} \rangle$; if $x_j \in D(\Delta)$ then $\langle j - 1, \text{Yes} \rangle$ is connected to $\langle j, \text{Yes} \rangle$ under $q_j = 1$ and to $\langle j, \text{No} \rangle$ under $q_j = 0$; if $x_j \in K(\Delta)$ then $\langle j - 1, \text{Yes} \rangle$ is connected to $\langle j, \text{Yes} \rangle$ under $q_j = 0$ and to $\langle j, \text{No} \rangle$ under $q_j = 1$; if $x_j \notin D(\Delta) \cup K(\Delta)$ then $\langle j - 1, \text{Yes} \rangle$ is connected to $\langle j, \text{Yes} \rangle$, and $\langle j - 1, \text{No} \rangle$ is connected to $\langle j, \text{No} \rangle$, in either case. D_n is determined by a recursive approach in which the generic procedure $\text{fool}(l, l')$ constructs a distribution that fools the transition probabilities between level l and l' in *all* the RFAs as follows. It computes, using $\text{fool}(l, l'')$ and $\text{fool}(l'', l')$ recursively, distributions D_1 and D_2 , each of size at most $E_0(1 + o(1))$, that fool the transitions between states in levels l and $l'' = \lfloor (l + l')/2 \rfloor$, and between states in levels l'' and l ; a procedure $\text{reduce}(D_1 \times D_2)$ then combines D_1 and D_2 into a distribution D of size at most $E_0(1 + o(1))$ that fools the transitions between states in levels l and l' in all the RFAs. Let $\tilde{D} = D_1 \times D_2$ be the product distribution with $\text{support}(\tilde{D}) = \{w_1 w_2 : w_i \in \text{support}(D_i)\}$ and $\Pr_{\tilde{D}}\{w_1 w_2\} = \Pr_{D_1}\{w_1\} \Pr_{D_2}\{w_2\}$, a randomized version of reduce is to retain each $w \in \tilde{D}$ with probability $q(w) = E_0/|\text{support}(\tilde{D})|$ into $\text{support}(D)$ with $\Pr_D\{w\} = \Pr_{\tilde{D}}\{w\}/q(w)$. Thus, for all pairs of states s, t in the RFAs the transition probabilities are preserved in expectation:

$$\mathbb{E}[\Pr_D\{s \rightarrow t\}] = \sum_{w : s \xrightarrow{w} t} \frac{\Pr_{\tilde{D}}\{w\}}{q(w)} q(w) = \Pr_{\tilde{D}}\{s \rightarrow t\}, \quad (40.6.2)$$

where the sum is over all the strings w that lead from state s to state t . This selection also implies that the expected size of $\text{support}(D)$ is $\sum_w q(w) = E_0$. This randomized combining can be derandomized using a 2-wise independent probability space. The bottom of the recursion is reached when the number of levels between l and l' is at most $\log E_0$, and then the distribution (of size E_0) is implemented by $\log E_0$ unbiased bits. E_0 depends polynomially on $1/\delta$, where δ is the relative error that is allowed for the transition probabilities. Taking δ as a small constant suffices to obtain a constant approximation of the moment bounds.

Similarly, this method can be used to compute, fast and in parallel, $(1/r)$ -nets and $(1/r)$ -approximations whose sizes nearly match the probabilistic bounds.

APPLICATIONS

Some interesting examples for which optimal deterministic algorithms have been obtained using derandomization are the following:

- *Convex hulls*: The only optimal deterministic algorithm for the computation of the convex hull of n points in $\mathbb{R}^d$ space is the derandomization of a randomized-incremental algorithm. The reader is referred to [BCM99] for the details (this reference is much more readable than the original paper [Cha93b]) ([Chapter 22](#)).
- *Output-sensitive convex hull in $\mathbb{R}^d$* : An optimal algorithm was obtained us-

ing derandomization [CM95]; afterward a surprisingly simple solution avoiding derandomization was found [Cha96].

- *Diameter of a point set in $\mathbb{R}^d$* : After a sequence of improvements, an optimal algorithm using derandomization was found [Ram01]. Currently, the best solution that avoids derandomization has a running time with an extra $\log n$ factor [Bes98].
- *Linear programming*: In $\mathbb{R}^d$, the best deterministic solution is achieved through derandomization and has running time $O(C_d n)$ with $C_d = \exp(O(d \log d))$ [CM96]; in contrast, with randomization $C_d \approx \exp(\sqrt{d})$ is possible [MSW96].
- *Segment intersection*: A first algorithm for reporting segment intersections in linear space and optimal time used derandomization [AGR95], followed shortly by a relatively simple algorithm that avoids derandomization [Bal95]. Optimal parallel algorithms have been obtained with derandomization and have not been matched by other approaches.

OPEN PROBLEMS

Is derandomization truly necessary to obtain an optimal algorithm in cases such as the convex hull in d dimensions or the diameter in dimension 3?

40.7 DETERMINISTIC APPROXIMATIONS, NETS, AND CUTTINGS

APPROXIMATIONS

Method of conditional probabilities. Direct application of the method leads to a sequential polynomial-time construction of approximations with optimal size (almost matching the probabilistic bound). A more efficient construction [Mat95, CM96, BCM99] is based on the following two properties, which are easily verified:

- **Separability:** Let $X_1, X_2 \subseteq X$ be disjoint subsets of (almost) equal cardinality with $X = X_1 \cup X_2$, and let A_i be an ϵ -approximation for (X_i, Γ_{X_i}) , for $i = 1, 2$. Then $A = A_1 \cup A_2$ is an ϵ -approximation for (X, Γ) .
- **Composition:** Let A_1 be an ϵ_1 -approximation for (X, Γ) and let A_2 be an ϵ_2 -approximation for (A_1, Γ_{A_1}) . Then A_2 is an $(\epsilon_1 + \epsilon_2)$ -approximation for (X, Γ) .

Let **Poly-Approx** (X, r) be an algorithm that computes a $(1/r)$ -approximation for X of size $Cr^2 \log r$ using time $O(n^{D+1})$, where $n = |X|$. The two properties naturally lead to a divide-and-conquer approach to compute an approximation:

Approx (X, r) :

If $|X| \leq Cr^2 \log r$ then return X .

Split X into two subsets X_1 and X_2 of (almost) equal size.

Let $A_1 \leftarrow \mathbf{Approx}(X_1, r)$; $A_2 \leftarrow \mathbf{Approx}(X_2, r)$.

Return **Poly-Approx** $(A_1 \cup A_2, r)$.

Approx returns a $(1/r')$ -approximation, where $r' = r / \log n$ (an approximation

factor $1/r$ accumulates over each of the $\log n$ levels) of size $Cr^2 \log r$. The running time is dominated by the work required at the bottom of the recursion and so is $O(n \cdot (r^2 \log r)^D)$. To obtain the $(1/r)$ -approximation that we actually want it is necessary to decrease the approximation factor as the computation progresses from the bottom to the top of the recursion tree (starting with $1/r$ at the leaves). This is possible without affecting the running time because the total size of the sets that are handled in each level is decreasing. This approach also leads to fast parallel algorithms, noting that the separability property can be extended to many sets X_i .

Construction via simplicial partitions. For linearizable range spaces, including most applications, a more efficient construction is possible [Mat91b]. Let P be a set of n points in the plane, a simplicial (triangle) partition is a tuple $\Pi = ((P_1, \Delta_1), \dots, (P_m, \Delta_m))$ where the P_i 's (classes) form a disjoint partition of P and Δ_i is a triangle (simplex) with $P_i \subseteq \Delta_i$. The **crossing number** of Π is defined as the maximum number of Δ_i 's that can be simultaneously crossed by a line. Simplicial partitions with small crossing number exist and can be computed efficiently:

THEOREM 40.7.1 *Simplicial Partition Theorem*

Let P be a set of n points in $\mathbb{R}^2$, let s be an integer parameter with $2 \leq s < n$, and let $r = n/s$. Then there exists a partition $\Pi = (P_1, \dots, P_m)$ of P whose classes satisfy $s \leq |P_i| < 2s$ (so $m = \Theta(r)$) and whose crossing number is $O(r^{1/2})$. Furthermore, the construction can be performed in time $O(n \log r)$ for $s \geq n^\delta$, any $\delta > 0$.

The construction makes heavy use of cuttings. Given a set P of n points, the partition Π for parameter s with crossing number $\kappa = O(r^{1/2})$, guaranteed by the theorem, can be used to construct an approximation A (with respect to triangles) by taking an arbitrary point from each class into A : Let Δ be a triangle, the number of classes intersecting the boundary of T is at most 3κ . Therefore, we obtain the following bound for the error:

$$\left| \frac{|A \cap \Delta|}{|A|} - \frac{|P \cap \Delta|}{|P|} \right| = O\left(\frac{\kappa}{m}\right) = O\left(\frac{1}{r^{1/2}}\right).$$

Thus, this approach provides a $(1/r)$ -approximation of size $O(r^2)$. This is interesting, of course, only when r is small, $r \leq n^{1/2}$. The construction time is $O(n \log r)$.

NETS

Method of conditional probabilities. Again, direct application of the method leads to a polynomial-time construction of a $(1/r)$ -net of size $O(r \log r)$. A more efficient construction uses the following observation: A $(1/2r)$ -net for a $(1/2r)$ -approximation is a $(1/r)$ -net. Therefore, efficient algorithms for computing approximations translate into efficient algorithms for computing nets. The running time is dominated by the computation of the $(1/2r)$ -approximation.

Construction using sensitive approximations. A random sample of size $O(r^2 \log r)$ satisfies the bound [BCM99]:

$$\left| \frac{|A \cap R|}{|A|} - \frac{|P \cap R|}{|P|} \right| \leq \frac{1}{2r} \left(\sqrt{\frac{|R|}{|X|}} + \frac{1}{r} \right).$$

Such a sample is called a *sensitive* $(1/r)$ -approximation. Sensitive approximations have the separability and composition properties, and can be computed in time $O(n \cdot (r^2 \log r)^D)$ as usual approximations. Now, a sensitive $(1/r)$ -approximation is also a $(1/r)^2$ -net, so a $(1/r)$ -net of size $O(r \log r)$ can be computed in time $O(n \cdot (r \log r)^D)$. For a linearizable range space and r small, construction in time $O(n \log r)$ is possible via approximations based on simplicial partitions.

Construction using greedy-cover algorithm. The problem of finding a $(1/r)$ -net for a range space (X, Γ) can be posed as the problem of finding a vertex cover for a hypergraph. The latter problem is solved by Lovász's *greedy cover algorithm*, resulting in a sample N of size $s = O(r \log n)$. A net of size $O(r \log r)$ can be constructed with a modified version of the greedy algorithm [CF90], without recurring to derandomization at all.

CUTTINGS

Derandomizing constructions. The method of splitting the excess (Section 40.1) can be derandomized in polynomial time to obtain a $(1/r)$ -cutting of optimal size. More efficiently, one can first compute a $(1/2r)$ -approximation and then a $(1/2r)$ -cutting for the approximation. This still does not lead to an optimal running time.

For the case of hyperplane arrangements, cuttings of optimal size can be computed in optimal time using a hierarchical subdivision [Cha93a]. It uses nets that are sensitive: as expected from a random sample, the number of vertices in the net is proportional to the number of vertices in the original set of hyperplanes. The idea is that the number of “spurious” vertices introduced by the hierarchical subdivision remains asymptotically smaller than the number of vertices actually in the arrangement, as in the “global accounting” technique of Section 40.4.

Direct constructions. A cutting for lines in the plane can be obtained without derandomization by splitting the levels in the arrangement of the lines [Mat98]. In higher dimensions, a direct construction is possible that follows the prune-and-search approach of Meggido [Mat91a, DS00]; this method produces cuttings of size much larger than optimal.

DETERMINISTIC SAMPLING

The basic divide-and-conquer approach uses a sample of size r satisfying the higher-moment bound. Such a “ $(1/r)$ -sample” can be constructed deterministically in polynomial time via derandomization. A more efficient construction first constructs a $(1/2r)$ -approximation, and then a $(1/2r)$ -sample for the approximation. The result is a $(1/r)$ -sample. If $r \leq n^\delta$ for certain $\delta > 0$, then the construction time is dominated by the computation of the $(1/2r)$ -approximation.

OPEN PROBLEMS

Can one obtain deterministically in polynomial time a sample out of a configuration space satisfying axiom (iii) (but not (iii')), so that the higher-moment bound holds?

Can samples be obtained in parallel nearly satisfying the probabilistic bounds using a general approach that does not tailor the space and distribution to the particular algorithm and input?

40.8 OPTIMAL DIVIDE-AND-CONQUER

Divide-and-conquer based on sampling, either random or deterministic, rarely results directly in optimal algorithms. As discussed in Section 40.1, the running time includes an extra factor n^ϵ in most cases. If the size r of the sample is a function of n , say $r = n^\delta$, then the extra factor can often be reduced to $\log^c n$.

The main problem is the fact that in principle the total conflict list size can grow beyond what is permissible for optimality. We illustrate some tricks that are useful to avoid this, using our running example, the computation of the trapezoidal map of n segments S in the plane.

Pruning. We consider the case in which the segments in S are non-intersecting. We want to enforce that the total conflict list size remains $O(n)$. We use a $(1/r)$ -cutting with $r = n^\delta$ for $\delta > 0$ appropriately small. For every trapezoid $\Delta \in \mathcal{T}(R)$, we determine the list S_Δ of segments intersecting Δ . Instead of directly recursing on S_Δ , we determine those segments in S_Δ that have an endpoint in Δ , and those that “cross” Δ , that is, intersect it without having an endpoint in Δ . Some of the crossing segments are then used to further subdivide Δ into *noncrossing* trapezoids Δ_n for which S_{Δ_n} has only noncrossing segments, and *crossing* trapezoids Δ_c for which S_{Δ_c} has only crossing segments. This takes time $O(n_\Delta \log n_\Delta)$, and we then recurse on the smaller trapezoids Δ_n . In a crossing trapezoid, the segments cross without intersecting and so they form a “stair” from which the output can be produced directly. The total conflict size for noncrossing trapezoids is at most $2n$ at each level, and each level generates crossing trapezoids with total conflict list size $O(n)$. Since the size of a subproblem at the i th level of recursion is at most $n_i = n^{(1-\epsilon)^i}$, then $\sum_i \log n_i = O(\log n)$ and the total construction time is $O(n \log n)$. This technique has been used in the deterministic computation of 2D Voronoi diagrams [RS92, AGR94]

Global accounting. We consider the case in which all the segments intersect. Let T_0 consist of a single sufficiently large trapezoid containing all the segments. Given $\Delta \in T_{i-1}$, if $|S_\Delta| \leq n/r_0^i$ then Δ is not subdivided and remains in T_i unaltered, otherwise Δ is subdivided using a sample N_Δ of size $C_N r_0 \log r_0$, where r_0 is a sufficiently, such that (i) R_Δ is a $(1/r_0)$ -net for S_Δ and (ii) the number of vertices of the arrangement of R_Δ inside Δ is at most twice the expected number for a random sample, that is $2(C_N r_0 \log r_0 / |S_\Delta|)^2 v(S, \Delta)$, where $v(S, \Delta)$ is the number of vertices of S inside Δ . The size of the decomposition in Δ is proportional to the number of vertices of R_Δ inside Δ plus the number of intersections of R_Δ with the boundary of Δ . Thus, assuming R_Δ has properties (i) and (ii),

$$\begin{aligned}
 |T_i| &\leq \sum_{\Delta \in T_{i-1}} \left\{ A \left(\frac{r_0 \log r_0}{n_\Delta} \right)^2 v(S, \Delta) + B r_0 \log r_0 \right\} \\
 &\leq A \left(\frac{r_0 \log r_0}{n/r_0^i} \right)^2 \sum_{\Delta \in T_{i-1}} v(S, \Delta) + B \sum_{\Delta \in T_{i-1}} r_0 \log r_0 \\
 &\leq A r_0^{2i+2} \log^2 r_0 + B r_0 \log r_0 |T_{i-1}|,
 \end{aligned}$$

using that $|S_\Delta| \geq n/r_0^i$ and $\sum_{\Delta \in T_{i-1}} v(S, \Delta) \leq n^2$, the total number of vertices in the arrangement. The solution to this recurrence is $|T_i| = O(r_0^{2i+2} \log^2 r_0)$,

and so $|T_l| = O(n^2)$ for the last level l . This approach can be derandomized, the verification of the number of vertices in the sample is then made with the help of a suitable approximation (Section 40.7). This approach has been used to compute cuttings of hyperplanes [Cha93a].

Clustering. We consider again the case of non-intersecting segments. The idea is to group trapezoids into subproblems so that the size of the boundary between subproblems is small and, hence, the number of elements shared by subproblems is small. Let $\mathcal{T} = \mathcal{T}(R)$ be the trapezoidal decomposition for a sample $R \subseteq S$ and let $\mathcal{G} = (V, E)$ be the dual graph of $\mathcal{T}$: nodes in $\mathcal{G}$ correspond to trapezoids in $\mathcal{T}$, and two nodes are connected by an arc if the corresponding trapezoids share a vertical edge. The separator theorem for planar graphs guarantees the existence of a set of $O(\sqrt{|V|})$ nodes that separates the graph into two disconnected subgraphs each with at most $1/2$ of the nodes and, because of the bounded vertex degree, this implies an arc separator of the same size. The clustering is performed by iterating the separator theorem, until *clusters* (groups) consisting of at most t nodes are obtained. Thus, with $l = \lceil \log(|V|/t) \rceil$ the total separator size is

$$O\left(\sum_{i=0}^l 2^i \left(\frac{|V|}{2^i}\right)^{1/2}\right) = O\left(\frac{|V|}{t^{1/2}}\right).$$

Let Λ be the set of resulting clusters. For $\square \in \Lambda$, let $S_{\square}$ denote the conflict list of $\square$ with respect to S (the set of $s \in S$ that intersect $\square$). Let's assume that $|S_{\Delta}| \leq \kappa$ for $\Delta \in \mathcal{T}$. To bound $\sum_{\square \in \Lambda} |S_{\square}|$, the total conflict list size for the clustering, note that a segment that does not intersect boundaries between clusters conflicts with only one cluster. Thus,

$$\sum_{\square \in \Lambda} |S_{\square}| = n + O\left(\frac{|V|}{t^{1/2}} \cdot \kappa\right).$$

In our application R is a $(1/r)$ -net, so $|V| = O(r \log r)$ and $\kappa = n/r$. Choosing $t = r^{1/2}$, we have

$$\sum_{\square \in \Lambda} |S_{\square}| = n \cdot \left(1 + O\left(\frac{\log r}{r^{1/4}}\right)\right),$$

and for each $\square \in \Lambda$, $|S_{\square}| \leq \kappa \cdot t = n/r^{1/2}$. Choosing $r = r(n)$ sufficiently large, $r = \Omega(\log^c n)$ for some constant c , the total subproblem size remains $O(n)$ through all levels of the recursive computation. This approach has been used for computing in parallel convex-hulls in $\mathbb{R}^3$ [DDD⁺95] and for computing optimally the diameter in $\mathbb{R}^3$ [Ram01].

40.9 OPTIMIZATION

In some problems that seek to optimize some parameter r , randomization is useful to perform efficiently a search for the optimal value r^* without explicitly building the space in which the search is performed. Normally, the search is among the vertices in an arrangement too large to build explicitly. To obtain a deterministic algorithm, derandomized sampling is often used in combination with *parametric search* (Chapter 43): Derandomization is used to obtain an algorithm that decides

whether the optimal value r^* is larger than, equal to, or smaller than a given value r , and also another *generic* algorithm whose computation for the value r^* is different than for any other r . The decision algorithm is then used as a guiding oracle to run the generic algorithm until the value r^* is determined. For efficiency, the generic algorithm must perform comparisons that involve r in few batches. Several examples of this application can be found in [CEGS93, AST92]. In some cases parametric search has been successfully replaced with a search in an appropriate cutting of the arrangement in which the search is performed. The *slope selection* problem is an example of this [BC98].

40.10 BETTER GUARANTEES

Bounds for the expected performance of randomized algorithms are usually available. Sometimes stronger results are desired. If the analysis of the algorithm cannot be extended to provide such bounds, then some techniques may help to achieve them:

Randomized space vs. deterministic space. Any randomized algorithm using expected space S and expected time T can be converted to an algorithm that uses deterministic space $2S$, and whose expected running time is at most $2T$. We simply need to maintain a count of the memory allocated by the algorithm. Whenever it exceeds $2S$, we stop the computation and restart it again with fresh choices for the random variables. The expected number of retrials is one.

Tail estimates. The knowledge that the expected running time of a given program is one second does not exclude the possibility that it sometimes takes one hour. Markov's inequality implies that the probability that this happens is at most $1/3600$. While this seems innocuous, it implies that it is likely to occur if we repeat this particular computation, say, 10000 times.

For randomized incremental construction, better tail estimates are available only for the *space complexity* [CMS93, MSW93b], and for the running time of segment intersection in the plane [MSW93a] and LP-type optimization [GW00]. In other cases, one can still apply a simple modification to the algorithm to yield a stronger bound. We run it for two seconds. If it does not finish the computation within two seconds, then we abandon the computation and restart with fresh choices for the random variables. Clearly, the probability that the algorithm does not terminate within one hour is at most 2^{-1800} . Alt et al. [AGM⁺96] work out this technique in detail.

40.11 PROBABILISTIC PROOF TECHNIQUES

Randomized algorithms are related to probabilistic proofs and constructions in combinatorics, which precede them historically. Conversely, the concepts developed to design and analyze randomized algorithms in computational geometry can be used as tools in proving purely combinatorial results. Many of these results are based on the following theorem:

THEOREM 40.11.1

Let $(X, \mathcal{T}, D, K)$ be a configuration space satisfying axioms (i), (ii), (iii), and (iii') of Section 40.5. For $S \subseteq X$ and $0 \leq k \leq n$, let

$$\Pi^k(S) := \{\Delta \in \Pi(X) \mid |K(\Delta) \cap S| \leq k\}$$

denote the set of configurations with at most k conflicts in S .

Then $|\Pi^k(S)| = O(k^d)E[|\mathcal{T}(R)|]$, where R is a random sample of S of size n/k , and d is as in axiom (i).

Note that $\Pi^0(S) = \mathcal{T}(S)$. The theorem relates the number of configurations with at most k conflicts to those without conflict.

An immediate application is to prove a bound on the number of vertices of level at most k in an arrangement of lines in the plane (the level of a vertex is the number of lines lying above it; see Section 21.2). We define a configuration space $(X, \mathcal{T}, D, K)$ where X is the set of lines, $\mathcal{T}(S)$ is the set of vertices of the upper envelope of the lines, $D(\Delta)$ are the two lines forming the vertex Δ (so $d = 2$), and $K(\Delta)$ is the set of lines lying above Δ . Theorem 40.11.1 implies that the number of vertices of level up to k is bounded by $O(nk)$. The same argument works in any dimension.

Sharir and others have proved a number of combinatorial results using this technique [Sha94, AES99, ASS96, SS97]. They define a configuration space and need to bound $|\mathcal{T}(S)|$. They do this by proving a geometric relationship between the configurations with zero conflicts (the ones appearing in $\mathcal{T}(S)$) and the configurations with at most k conflicts. Applying Theorem 40.11.1 yields a recursion that bounds $|\mathcal{T}(S)|$ in terms of $|\mathcal{T}(R)|$. A refined approach that uses a sample of size $n - 1$ (instead of n/k) has been suggested by Tagansky [Tag96].

Sharir [Sha01] reviews this technique and gives a new proof for Theorem 40.11.1 based on the *Crossing lemma* (Chapter 24).

40.12 SOURCES AND RELATED MATERIAL

SURVEYS

All results not given an explicit reference above may be traced in these surveys.

[Cla92, Mul00]: General surveys of randomized algorithms in computational geometry.

[Sei93]: An introduction to randomized incremental algorithms using backwards analysis.

[GS93]: Surveys computations with arrangements, including randomized algorithms.

[AS01] Surveys randomized techniques in geometric optimization problems.

[Aga91]: A survey on geometric partitions.

[Mul93]: This monograph is an extensive treatment of randomized algorithms in computational geometry.

[Mat00]: An introduction to derandomization for geometric algorithms, with many references.

[Kar91, MR95]: A survey and a book on randomized algorithms and their analysis in computer science, including derandomization techniques.

[AS92]: This monograph is a good reference on probabilistic proof techniques in combinatorics. It also deals with derandomization.

RELATED CHAPTERS

Because randomized algorithms have been used successfully in nearly all areas of computational geometry, they are mentioned throughout Parts C and D of this Handbook. Areas where randomization plays a particularly important role include:

41 ROBUST GEOMETRIC COMPUTATION

Chee K. Yap

INTRODUCTION

Nonrobustness refers to qualitative or catastrophic failures in geometric algorithms arising from numerical errors. Section 41.1 provides background on these problems. Although nonrobustness is already an issue in “purely numerical” computation, the problem is compounded in “geometric computation.” In Section 41.2 we characterize such computations. Researchers trying to create robust geometric software have tried two approaches: making fixed-precision computation robust (Section 41.3), and making the exact approach viable (Section 41.4). Another source of nonrobustness is the phenomenon of degenerate inputs. General methods for treating degenerate inputs are described in Section 41.5.

41.1 NUMERICAL NONROBUSTNESS ISSUES

Numerical nonrobustness in scientific computing is a well-known and widespread phenomenon. The root cause is the use of *fixed-precision numbers* to represent real numbers, with precision usually fixed by the machine word size (e.g., 32 bits). The unpredictability of floating-point code across architectural platforms in the 1980’s was resolved through a general adoption of the IEEE standard 754-1985. But this standard only makes program behavior predictable and consistent across platforms; the errors are still present. Ad hoc methods for fixing these errors (such as treating numbers smaller than some ϵ as zero) cannot guarantee their elimination.

If nonrobustness is problematic in purely numerical computation, it apparently becomes intractable in “geometric” computation. In Section 41.2, we elucidate the concept of geometric computations. Based on this understanding, we conclude that nonrobustness problems within fixed-precision computation cannot be solved by purely arithmetic solutions (better arithmetic packages, etc.). Rather, a suitable *fixed-precision geometry* is needed to substitute for the original geometry (which is usually Euclidean). We describe such approaches in Section 41.3.

In Section 41.4, we describe the *exact approach* for achieving robust geometric computation. This demands some type of *big number* package as well as further considerations. Indeed, current research is converging on an exciting new form of computational model that we may call *guaranteed precision computation*.

In Section 41.5, we address a different but common cause of numerical nonrobustness, namely, *data degeneracy*. Although this problem has some connection to fixed-precision arithmetic, it is an issue even with the exact approach.

GLOSSARY

Fixed-precision computation: A mode of computation in which every number is represented using some fixed number L of bits, usually 32 or 64. For floating point numbers, L is partitioned into $L = L_M + L_E$ for the mantissa and the exponent respectively. **Double-precision mode** is a relaxation of fixed precision: the intermediate values are represented in $2L$ bits, but these are finally truncated back to L bits.

Nonrobustness: The property of code failing on certain kinds of inputs. Here we are mainly interested in nonrobustness that has a numerical origin: the code fails on inputs containing certain patterns of numerical values. Degenerate inputs are just extreme cases of these “bad patterns.”

Benign vs. catastrophic errors: Fixed-precision numerical errors are fully expected and so are normally considered to be “benign.” In purely numerical computations, errors become “catastrophic” when there is a severe loss of precision. In geometric computations, errors are “catastrophic” when the computed results are qualitatively different from the true answer (e.g., the combinatorial structure is wrong) or when they lead to unexpected or *inconsistent* states of the programs.

Big number packages: Software packages for representing arbitrary precision numbers (usually integers or rational numbers), and in which some basic operations on these numbers are performed exactly. For instance, $+$, $-$, $\times$ are implemented exactly with *BigIntegers*. With *BigRationals*, division can also be exact. Other operations such as $\sqrt{}$ still need approximations or rounding.

41.2 THE NATURE OF GEOMETRIC COMPUTATION

If the root cause of numerical nonrobustness is arithmetic, then it may appear that the problem can be solved with the right kind of arithmetic package. We may roughly divide the approaches into two camps, depending on whether one uses finite precision arithmetic or insists on exactness (or at least the possibility of computing to arbitrary precision). While arithmetic is an important topic in its own right, our focus here will be on geometric rather than purely arithmetic approaches for achieving robustness.

To understand why nonrobustness is especially problematic for geometric computation, we need to understand what makes a computation “geometric.” Indeed, we are revisiting the age-old question “*What is Geometry?*” that has been asked and answered many times in mathematical history, by Euclid, Descartes, Hilbert, Dieudonné and others. But as in many other topics, the perspective stemming from modern computational viewpoint sheds new light. Geometric computation clearly involves numerical computation, but there is something more. We use the aphorism $\text{GEOMETRIC} = \text{NUMERIC} + \text{COMBINATORIAL}$ to capture this. Instead of “combinatorial” we could have substituted “discrete” or sometimes “topological.” What is important is that this combinatorial part is concerned with discrete relations among geometric objects. Examples of discrete relations are “a point lies on a line,” “a point lies inside a simplex,” “two disks intersect.” The geometric

objects here are points, lines, simplices and disks. Following Descartes, each object is defined by numerical parameters. Each discrete relation is reduced to the truth of suitable numerical inequalities involving these parameters. Geometry arises when such discrete relations are used to characterize configurations of geometric objects.

The mere presence of combinatorial structures in a numerical computation does not make a computation “geometric.” There must be some nontrivial **consistency condition** holding between the numerical data and the combinatorial data. Thus, we would not consider the classical shortest-path problems on graphs to be geometric: the numerical weights assigned to edges of the graphs are not restricted by any consistency condition. Note that common restrictions on the weights (positivity, integrality, etc.) are not consistency restrictions. But the related **Euclidean shortest-path problem** (Chapter 27) is geometric. See Table 41.2.1 for further examples from well-known problems.

TABLE 41.2.1 Examples of geometric and nongeometric problems.

PROBLEM	GEOMETRIC?
Matrix multiplication, determinant	no
Hyperplane arrangements	yes
Shortest paths on graphs	no
Euclidean shortest paths	yes
Point location	yes
Convex hulls, linear programming	yes
Minimum circumscribing circles	yes

Alternatively, we can characterize a computation as “geometric” if it involves constructing or searching a geometric structure (which may only be implicit). The incidence graph of an arrangement of hyperplanes (Chapter 24), with suitable additional labels and constraints, is a primary example of such a structure. A **geometric structure** is comprised of four components:

$$D = (G, \lambda, \Phi(\mathbf{z}), I), \quad (41.2.1)$$

where $G = (V, E)$ is a directed graph, λ is a labeling function on the vertices and edges of G , Φ is the consistency predicate, and I the input assignment. Intuitively, G is the combinatorial part, λ the geometric part, and Φ constrains λ based on the structure of G . The **input assignment** is $I : \{z_1, \dots, z_n\} \rightarrow \mathbb{R}$ where the z_i ’s are called **structural variables**. We informally identify I with the sequence “ $\mathbf{c} = (c_1, \dots, c_n)$ ” where $I(z_i) = c_i$. The c_i ’s are called (**structural**) **parameters**. For each $u \in V \cup E$, the label $\lambda(u)$ is a Tarski formula of the form $\xi(\mathbf{x}, \mathbf{z})$, where $\mathbf{z} = (z_1, \dots, z_n)$ are the structural variables and $\mathbf{x} = (x_1, \dots, x_d)$. This formula defines a **semialgebraic set** (Chapter 33) parameterized by the structural variables. For given $\mathbf{c}$, the semialgebraic set is $f_{\mathbf{c}}(v) = \{\mathbf{a} \in \mathbb{R}^d \mid \xi(\mathbf{a}, \mathbf{c}) \text{ holds}\}$. Following Tarski, we are identifying semialgebraic sets in $\mathbb{R}^d$ with d -dimensional geometric objects. The consistency relation $\Phi(\mathbf{z})$ is another Tarski formula. In practice $\Phi(\mathbf{z})$ has the form $(\forall x_1, \dots, x_d) \phi(\lambda(u_1), \dots, \lambda(u_m))$ where $u_1, \dots, u_m$ ranges over elements of $V \cup E$ and ϕ can be systematically constructed from the graph G .

As an example of this notation, consider an arrangement S of hyperplanes in $\mathbb{R}^d$. The combinatorial structure $D(S)$ is the incidence graph $G = (V, E)$ of

the arrangement and V is the set of faces of the arrangement. The parameter $\mathbf{c}$ consists of the coefficients of the input hyperplanes. If $\mathbf{z}$ is the corresponding structural parameters then the input assignment is $I(\mathbf{z}) = \mathbf{c}$. The geometric data associates to each node v of the graph the Tarski formula $\lambda(v)$ involving $\mathbf{x}, \mathbf{z}$. When $\mathbf{c}$ is substituted for $\mathbf{z}$, then the formula $\lambda(v)$ defines a face $f_{\mathbf{c}}(v)$ (or $f(v)$ for short) of the arrangement. We use the convention that an edge $(u, v) \in E$ represents an “incidence” from $f(u)$ to $f(v)$, where the dimension of $f(u)$ is one more than that of $f(v)$. So $f(v)$ is contained in the closure of $f(u)$. Let $\text{aff}(X)$ denote the affine span of a set $X \subseteq \mathbb{R}^d$. Then $(u, v) \in E$ implies $\text{aff}(f(v)) \subseteq \text{aff}(f(u))$ and $f(u)$ lies on one of the two open halfspaces defined by $\text{aff}(f(u))$. We let $\lambda(u, v)$ be the Tarski formula $\xi(\mathbf{x}, \mathbf{z})$ that defines the open halfspace in $\text{aff}(f(u))$ that contains $f(u)$. Again, let $f(u, v) = f_{\mathbf{c}}(u, v)$ denote this open halfspace. The consistency requirement is that (a) the set $\{f(v) : v \in V\}$ is a partition of $\mathbb{R}^d$, and (b) for each $u \in V$, the set $f(u)$ is nonempty with an irredundant representation of the form

$$f(u) = \bigcap \{f(u, v) \mid (u, v) \in E\}.$$

Although the above definition is complicated, all of its elements are necessary in order to capture the following additional concepts. We can suppress the input assignment I , so there are only structural variables $\mathbf{z}$ (which is implicit in λ and Φ) but no parameters $\mathbf{c}$. The triple

$$\hat{D} = (G, \lambda, \Phi(\mathbf{z}))$$

becomes an **abstract geometric structure**, and $D = (G, \lambda, \Phi(\mathbf{z}), I)$ is an **instance** of $\hat{D}$. The structure D in Equation 41.2.1 is **consistent** if the predicate $\Phi(\mathbf{c})$ holds. An abstract geometric structure $\hat{D}$ is **realizable** if it has some consistent instance. Two geometric structures D, D' are **structurally similar** if they are instances of a common abstract geometric structure. We can also introduce metrics on structurally similar geometric structures: if $\mathbf{c}$ and $\mathbf{c}'$ are the parameters of D, D' then define $d(D, D')$ to be Euclidean norm of $\mathbf{c} - \mathbf{c}'$.

41.3 FIXED-PRECISION APPROACHES

This section surveys the various approaches within the fixed-precision paradigm. Such approaches have strong motivation in the modern computing environment where fast floating point hardware has become a de facto standard in every computer. If we can make our geometric algorithms robust within machine arithmetic, we are assured of the fastest possible implementation. We may classify the approaches into several basic groups. We first illustrate our classification by considering the simple question: “What is the concept of a line in fixed-precision geometry?” Four basic answers to this question are illustrated in [Figure 41.3.1](#) and in [Table 41.3.1](#).

WHAT IS A FINITE-PRECISION LINE?

We call the first approach **interval geometry** because it is the geometric analogue of interval arithmetic. Segal and Sequin [SS85] and others define a zone surrounding the line composed of all points within some ϵ distance from the actual line.

FIGURE 41.3.1

Four concepts of finite-precision lines.

The second approach is called **topologically consistent distortion**. Greene and Yao [GY86] distorted their lines into polylines, where the vertices of these polylines are constrained to be at grid points. Note that although the “fixed-precision representation” is preserved, the number of bits used to represent these polylines can have arbitrary complexity.

TABLE 41.3.1 Concepts of a finite-precision line.

	APPROACH	SUBSTITUTE FOR IDEAL LINE	SOURCE
(a)	Interval geometry	a line fattened into a tubular region	[SS85]
(b)	Topological distortion	a polyline	[GY86]
(c)	Rounded geometry	a line whose equation has bounded coefficients	[Sug89]
(d)	Discretization	a suitable set of pixels	computer graphics

The third approach follows a tack of Sugihara [Sug89]. An ideal line is specified by a linear equation, $ax + by + c = 0$. Sugihara interprets a “fixed-precision line” to mean that the coefficients in this equation are integer and bounded: $|a|, |b| < K$, $|c| < K^2$ for some constant K . Call such lines *representable* (see Figure 41.3.1(c) for the case $K = 2$). There are $O(K^4)$ representable lines. An arbitrary line must be “rounded” to the closest (or some nearby) representable line in our algorithms. Hence we call this **rounded geometry**.

The last approach is based on *discretization*: in traditional computer graphics and in the pattern recognition community, a “line” is just a suitable collection of pixels. This is natural in areas where pixel images are the central objects of study, but less applicable in computational geometry, where compact line representations are desired. This approach will not be considered further in this chapter.

INTERVAL GEOMETRY

In interval geometry, we thicken a geometric object into a zone containing the object. Thus a point may become a disk, and a line becomes a strip between two parallel lines: this is the simplest case and is treated by Segal and Sequin [SS85, Seg90]. They called these “toleranced objects,” and in order to obtain correct predicates, they enforce *minimum feature separations*. To do this, features that are too close must be merged (or pushed apart).

Guibas, Salesin, and Stolfi [GSS89] treat essentially the same class of thick objects as Segal and Sequin, although their analysis is mostly confined to geometric data based on points. Instead of insisting on minimum feature separations, their predicates are allowed to return the DON’T KNOW truth value. Geometric predicates (called ϵ -predicates) for objects are systematically treated in this paper.

In general we can consider zones with nonconstant descriptive complexity, e.g., a planar zone with polygonal boundaries. As with interval arithmetic, a zone is generally a conservative estimate because the precise region of uncertainty may be too complicated to compute or to maintain. In applications where zones expand rapidly, there is danger of the zone becoming catastrophically large: Segal [Seg90] reports that a sequence of duplicate-rotate-union operations repeated eleven times to a cube eventually collapsed it to a single vertex.

TOPOLOGICALLY-CONSISTENT DISTORTION

Sugihara and Iri [SI89b, SIII00] advocates an approach based on preserving topological consistency. These ideas have been applied to several problems, including geometric modeling [SI89a] and Voronoi diagrams for point sets [SI92]. In their approach, one first chooses some topological property (e.g., planarity of the underlying graph) and construct geometric algorithms that preserve the chosen property. Two difficulties in this prescription are (1) how to choose appropriate topological properties, and (2) in what sense does this “work”? Greene and Yao consider the problem of maintaining certain “topological properties” of an arrangement of finite-precision line segments. They introduce polylines as substitutes for ideal line segments in order to preserve certain properties of ideal arrangements (e.g., two line segments intersect in a *connected* subset). Each polyline is a distortion of an ideal segment σ when constrained to pass through the “hooks” of σ (i.e., grid points nearest to the intersections of σ with other line segments). But this may generate new intersections (derived hooks) and the cascaded effects must be carefully controlled. The grid model of Greene-Yao has been taken up by several other authors [Hob99, GM95, GGHT97]. Extension to higher dimensions is harder: there is a solution of Fortune [For98] in 3-dimension. Further developments include the numerically stable algorithms in [FM91]. The interesting twist here is the use of pseudolines rather than polylines.

Hoffmann, Hopcroft, and Karasick [HHK88] address the problem of intersecting polygons in a consistent way. Phrased in terms of our notion of “geometric structure” (Section 41.2) their goal is to compute a combinatorial structure G that is *consistent* in the sense that G is the structure underlying a consistent geometric structure $D = (G, \lambda, \Phi, \mathbf{c}')$. Here, $\mathbf{c}'$ need not equal the actual input parameter vector $\mathbf{c}$. They show that the intersection of two polygons R_1, R_2 can be efficiently

computed, i.e., a consistent G representing $R_1 \cap R_2$ can be computed. However, in their framework, $R_1 \cap (R_2 \cap R_3) \neq (R_1 \cap R_2) \cap R_3$. Hence they need to consider the triple intersection $R_1 \cap R_2 \cap R_3$. Unfortunately, this operation seems to require a nontrivial amount of geometric theorem proving ability.

This suggests that the problem of verifying consistency of combinatorial structures (the “reasoning paradigm” [HHK88]) is generally hard. Indeed, the NP-hard existential theory of reals can be reduced to such problems. In some sense, the ultimate approach to ensuring consistency is to design “parsimonious algorithms” in the sense of Fortune [For89]. This also amounts to theorem proving as it entails deducing the consequences of all previous decisions along a computation path.

STABILITY

This is a metric form of topological distortion where we place a priori bounds on the amount of distortion. It is analogous to backward error analysis in numerical analysis. Framed as the problem of computing the graph G underlying some geometric structure D (as above, for [HHK88]), we could say an algorithm is **ϵ -stable** if there is a consistent geometric structure $D = (G, \lambda, \Phi, \mathbf{c}')$ such that $\|\mathbf{c} - \mathbf{c}'\| < \epsilon$ where $\mathbf{c}$ is the input parameter vector. We say an algorithm has **strong** (resp. **linear**) stability if ϵ is a constant (resp., $O(n)$) where n is the input size. Fortune and Milenkovic [FM91] provide both linearly stable and strongly stable algorithms for line arrangements. Stable algorithms have been achieved for two other problems on planar point sets: maintaining a triangulation of a point set [For89], and Delaunay triangulations [For92, For95a]. The latter problem can be solved stably using either an incremental or a diagonal-flipping algorithm that is $O(n^2)$ in the worst case. Jaromczyk and Wasilkowski [JW94] presented stable algorithms for convex hulls. Stability is a stronger requirement than topological consistency, e.g., the topological algorithms ([SI92]) have not been proved stable.

ROUNDED GEOMETRY

Sugihara [Sug89] shows that the above problem of “rounding a line” can be reduced to the classical problem of *simultaneous approximation by rationals*: given real numbers $a_1, \dots, a_n$, find integers $p_1, \dots, p_n$ and q such that $\max_{1 \leq i \leq n} |a_i q - p_i|$ is minimized. There are no efficient algorithms to solve this exactly, although lattice reduction techniques yield good approximations. The above approach of Greene and Yao can also be viewed as a geometric rounding problem. The “rounded lines” in the Greene-Yao sense is a polyline with unbounded combinatorial complexity; but rounded lines in the Sugihara sense still have constant complexity. Milenkovic and Nackman [MN90] show that rounding a collection of disjoint simple polygons while preserving their combinatorial structure is NP-complete. In Section 41.5, rounded geometry is seen in a different light.

ARITHMETICAL APPROACHES

Certain approaches might be described as mainly based on arithmetic considerations (as opposed to geometric considerations). Ottmann, Thiemt, and Ullrich [OTU87] show that the use of an accurate scalar product operator leads to improved

robustness in segment intersection algorithms; that is, the onset of qualitative errors is delayed. A case study of Dobkin and Silver [DS88] shows that permutation of operations combined with random rounding (up or down) can give accurate predictions of the total round-off error. By coupling this with a multiprecision arithmetic package that is invoked when the loss in significance is too severe, they are able to improve the robustness of their code. There is a large literature on computation under the interval arithmetic model (e.g., [Ull90]). It is related to what we call interval geometry above. There are also systems providing programming language support for interval analysis.

41.4 EXACT APPROACH

As the name suggests, this approach proposes to compute without any error. The initial interpretation is that every numerical quantity is computed exactly. While this has an natural meaning when all numerical quantities are rational, it is not obvious what this means for values such as $\sqrt{2}$ which cannot be exactly represented “explicitly.” Informally, a number representation is explicit if it facilitates efficient comparison operations. In practice, this amounts to representing numbers by one or more integers in some positional notation (this covers the usual representation of rational numbers as well as floating point numbers). Although we could achieve numerical exactness in some modified sense, this turns out to be unnecessary. The solution to the nonrobustness only requires a weaker notion of exactness: it is enough to ensure “geometric exactness.” In the “Geometric = Numeric + Combinatorial” formulation, the exactness is not to be found in the numeric part, but in the combinatorial part, as this encodes the geometric relations. Hence this approach is called ***Exact Geometric Computation*** (EGC), and it entails the following:

Input is exact. We cannot speak of exact geometry unless this is true. This assumption can be an issue if the input is inherently approximate. Sometimes we can simply treat the approximate inputs as “nominally” exact, as in the case of an input set of points without any constraints. Otherwise, there are two options: (1) “clean up” the inexact input, by transforming it to data that is exact; or (2) formulate a related problem in which the inexact input can be treated as exact (e.g., inexact input points can be viewed as the *exact* centers of small balls). So the convex hull of a set of points becomes the convex hull of a set of balls. The cleaning up process in (1) may be nontrivial as it may require perturbing the data to achieve some consistency property and lies outside our present scope. The transformation (2) typically introduces a computationally harder problem. Not much research is currently available for such transformed problems. In any case, (1) and (2) still end up with exact inputs for a well-defined computational problem.

Numerical quantities may be implicitly represented. This is necessary if we want to represent irrational values exactly. In practice, we will still need explicit numbers for various purposes (e.g., comparison, output, display, etc). So a corollary is that numerical approximations will be important, a remark that was not obvious in the early days of EGC.

All branching decisions in a computation are errorless. At the heart of EGC is the idea that all “critical” phenomena in geometric computations are determined by the particular sequence branches taken in a *computation tree*. The key observation is that the sequence of branching decisions completely decides the combinatorial nature of the output. Hence if we make only errorless branches, the combinatorial part of a geometric structure D (see [Section 41.2](#)) will be correctly computed. To ensure this, we only need to evaluate *test values* to one bit of relative precision, i.e., enough to determine the sign correctly.

For problems (such as convex hulls) requiring only rational numbers, exact computation is possible. In other applications rational arithmetic is not enough. The most general setting in which exact computation is known to be possible is the framework of *algebraic problems* [Yap97].

GLOSSARY

Computation tree: A geometric algorithm in the algebraic framework can be viewed as an infinite sequence $T_1, T_2, T_3, \dots$ of computation trees. Each T_n is restricted to inputs of size n , and is a finite tree with two kinds of nodes: (a) nonbranching nodes, (b) branching nodes. Assume the input to T_n is a sequence of n real parameters $x_1, \dots, x_n$. A nonbranching node at depth i computes a value v_i , say $v_i \leftarrow f_i(v_1, \dots, v_{i-1}, x_1, \dots, x_n)$. A branching node tests a previous computed value v_i and makes a 3-way branch depending on the sign of v_i . In case v_i is a complex value, we simply take the sign of the real part of v_i . Call any v_i that is used solely in a branching node a **test value**. The branch corresponding to a zero test value is the **degenerate branch**.

Exact Geometric Computation (EGC): Preferred name for the general approach of “exact computation,” as it accurately identifies the goal of determining geometric relations exactly. The exactness of the computed numbers is either unnecessary, or should be avoided if possible.

Composite Precision Bound: This is specified by a pair $[r, a]$ where $r, a \in \mathbb{R} \cup \{\infty\}$. For any $z \in \mathbb{C}$, let $z[r, a]$ denote the set of all $\tilde{z} \in \mathbb{C}$ such that $|z - \tilde{z}| \leq \max\{2^{-a}, |z|2^{-r}\}$. When $r = \infty$, then $z[\infty, a]$ comprises all the numbers $\tilde{z}$ that approximates z with an absolute error of 2^{-a} ; we say this approximation $\tilde{z}$ has a **absolute bits**. Similarly, $z[r, \infty]$ comprises all numbers $\tilde{z}$ that approximates z with a relative error of 2^{-r} ; we say this approximation $\tilde{z}$ has r **relative bits**.

Constant Expressions: Let Ω be a set of complex algebraic operators; each operator $\omega \in \Omega$ is a partial function $\omega : \mathbb{C}^{a(\omega)} \rightarrow \mathbb{C}$ where $a(\omega) \in \mathbb{N}$ is the arity of ω . If $a(\omega) = 0$, then ω is identified with a complex number. Let $\mathcal{E}(\Omega)$ be the set of expressions over Ω where an expression E is a rooted DAG (directed acyclic graph) and each node with outdegree $n \in \mathbb{N}$ is labeled with an operator of Ω of arity n . There is a natural **evaluation function** $\text{val} : \mathcal{E}(\Omega) \rightarrow \mathbb{R}$. If Ω has partial functions, then $\text{val}()$ is also partial. If $\text{val}(E)$ is undefined, we write $\text{val}(E) = \uparrow$ and say E is **invalid**. When $\Omega = \Omega_2 = \{+, -, \times, \div, \sqrt{}\} \cup \mathbb{Z}$ we get the important class of **constructible expressions**, so called because their values are precisely the constructible reals.

Constant Zero Problem, ZERO(Ω): Given $E \in \mathcal{E}(\Omega)$, decide if $\text{val}(E) = \uparrow$; if not, decide if $\text{val}(E) = 0$.

Guaranteed Precision Evaluation Problem, GVAL(Ω): Given $E \in \mathcal{E}(\Omega)$ and $a, r \in \mathbb{Z} \cup \{\infty\}$, $(a, r) \neq (\infty, \infty)$, compute some approximate value in $\text{val}(E)[r, a]$,

Schanuel’s Conjecture: If $z_1, \dots, z_n \in \mathbb{C}$ are linearly independent over $\mathbb{Q}$, then the set $\{z_1, \dots, z_n, e^{z_1}, \dots, e^{z_n}\}$ contains a subset $B = \{b_1, \dots, b_n\}$ that is algebraically independent, i.e., there is no polynomial $P(X_1, \dots, X_n) \in \mathbb{Q}[X_1, \dots, X_n]$ such that $P(b_1, \dots, b_n) = 0$. This conjecture generalizes several deep results in transcendental number theory, and implies many other conjectures.

NAIVE APPROACH

For lack of a better term, we call the approach to exact computation in which every numerical quantity is computed exactly (explicitly if possible) the *naive approach*. Thus an exact algorithm that relies solely on the use of a big number package is probably naive. This approach, even for rational problems, faces the “bugbear of exact computation,” namely, high numerical precision. Using an off-the-shelf big number package does not appear to be a practical option [FvW93a, KLN91, Yu92]. There is evidence (surveyed in [YD95]) that just improving current big number packages alone is unlikely to gain a factor of more than 10.

BIG EXPRESSION PACKAGES

The most common examples of expressions are determinants and the distance $\sqrt{\sum_{i=1}^n (p_i - q_i)^2}$ between two points p, q . A big expression package allows a user to construct and evaluate expressions with big number values. They represent the next logical step after big number packages, and are motivated by the observation that the numerical part of a geometric computation is invariably reduced to repeated evaluations of a few variable¹ expressions (each time with different constants substituted for the variables). When these expressions are test values, then it is sufficient to compute them to one bit of relative precision. Some implementation efforts are shown in Table 41.4.1.

TABLE 41.4.1 Expression packages.

SYSTEM	DESCRIPTION	REFERENCES

¹These expressions involve variables, unlike the constant expressions in $\mathcal{E}(\Omega)$.

One of LN's goals is to remove all overhead associated with function calls or dynamic allocation of space for numbers with unknown sizes. It incorporates an effective floating-point filter based on static error analysis. The experience in [CM93] suggests that LN's approach is too aggressive as it leads to code bloat. The LEA system philosophy is to delay evaluating an expression until forced to, and to maintain intervals of uncertainty for values. Upon complete evaluation, the expression is discarded. It uses root bounds to achieve exactness and floating point filters for speed.

The **Real/Expr Package** is the first system to achieve guaranteed precision for a general class of nonrational expressions. It introduces the “precision-driven mechanism” whereby a user-specified precision at the root of the expression is transformed and downward-propagated toward the leaves, while approximate values generated at the leaves are evaluated and error bounds upward-propagated up to the root. This upward-downward process may need to be iterated. **LEDA Real** is a number type with a similar mechanism. It is part of a much more ambitious system of data structures for combinatorial and geometric computing (see [Chapter 65](#)). The semantics of **Real/Expr** of expression assignment is akin to constraint propagation in the constraint programming paradigm. The **Core Library (CORE)** is derived from **Real/Expr** with the goal of making the system as easy to use as possible. The two pillars of this transformation are the adoption of conventional assignment semantics and the introduction of a simple **Numerical Accuracy API** [Yap98].

The **CGAL Library** ([Chapter 65](#)) is a major library of geometric algorithms which are designed according to the EGC principles. While it has some native number types supporting rational expressions, the current distribution relies on **LEDA Real** or **CORE** for more general algebraic expressions. Shewchuk [She96] implements an arithmetic package that uses adaptive-precision floating-point representations. While not a big expression package, it has been used to implement polynomial predicates and shown to be extremely efficient.

THEORY

The class of algebraic computational problems encompasses most problems in contemporary computational geometry. Such problems can be solved exactly in singly-exponential space [Yap97]. This general result is based on recent progress in the decision problem for Tarski's language, on the associated cell decomposition problems, as well as cell adjacency computation ([Chapter 33](#)). However, general EGC libraries such as **Core Library** and **LEDA Real** depend directly on the algorithms for the guaranteed precision evaluation problem $\text{GVAL}(\Omega)$ (see Glossary), where Ω is the set of operators in the computation model. The possibility of such algorithms can be reduced to the recursiveness of a constellation of problems that might be called the **Fundamental Problems of EGC**. The first is the Constant Zero Problem $\text{ZERO}(\Omega)$. But there are two closely related problems. In the **Constant Validity Problem** $\text{VALID}(\Omega)$, we are to decide if a given $E \in \mathcal{E}(\Omega)$ is valid, i.e., $\text{val}(E) \neq \uparrow$. The **Constant Sign Problem** $\text{SIGN}(\Omega)$ is to compute $\text{sign}(E)$ for any given $E \in \mathcal{E}(\Omega)$, where $\text{sign}(E) \in \{\uparrow, -1, 0, +1\}$. In case $\text{val}(E)$ is complex, define $\text{sign}(E)$ to be the sign of the real part of $\text{val}(E)$.

There is a natural hierarchy of the expression classes, each corresponding to a class of complex numbers as shown in 41.4.2. In Ω_3 , $P(X)$ is any polynomial with integer coefficients and I is some means of identifying a unique root of $P(X)$: I may be a complex interval bounding a unique root of $P(X)$, or an integer i

TABLE 41.4.2 Expression hierarchy.

OPERATORS	NUMBER CLASS	EXTENSIONS
$\Omega_0 = \{+, -, \times\} \cup \mathbb{Z}$	Integers	
$\Omega_1 = \Omega_0 \cup \{\div\}$	Rational Numbers	$\Omega_1^+ = \Omega_1 \cup \mathbb{Q}$
$\Omega_2 = \Omega_1 \cup \{\sqrt{\cdot}\}$	Constructible Numbers	$\Omega_2^+ = \Omega_2 \cup \{\sqrt[k]{\cdot} : k \geq 3\}$
$\Omega_3 = \Omega_2 \cup \{\text{RootOf}(P(X), I)\}$	Algebraic Numbers	Use of $\diamond(E_1, \dots, E_d, i)$, [BFM ⁺ 01]
$\Omega_4 = \Omega_3 \cup \{\exp(\cdot), \ln(\cdot)\}$	Elementary Numbers (cf. [Cho99])	

to indicate the i th largest real root of $P(X)$. The operator $\text{RootOf}(P, I)$ can be generalized to allow allowing expressions as coefficients of $P(X)$ as in Burnikel et al. [BFM⁺01], or by introducing systems of polynomial equations as in Richardson [Ric97]. Although Ω_4 can be treated as a set of real operators, it is more natural to treat Ω_4 (and sometimes Ω_3) as complex operators. Thus the elementary functions $\sin x$, $\cos x$, $\arctan x$, etc., are available as expressions in Ω_4 .

It is clear $\text{ZERO}(\Omega)$ and $\text{VALID}(\Omega)$ is reducible to $\text{SIGN}(\Omega)$. For Ω_4 , all three problems are recursively equivalent. The fundamental problems related to Ω_i are decidable for $i \leq 3$. It is a major open question whether the fundamental problems for Ω_4 are decidable. These questions have been studied by Richardson and others [Ric97, Cho99, MW96]. The most general positive result is that $\text{SIGN}(\Omega_3)$ is decidable. An intriguing conditional result is that $\text{ZERO}(\Omega_4)$ is decidable if Schanuel's conjecture is true; this may be deduced from Richardson's work [Ric97].

CONSTRUCTIVE ROOT BOUNDS

In practice, algorithms for the guaranteed precision problem $\text{GVAL}(\Omega_3)$ can exploit the fact that algebraic numbers have computable root bounds. A **root bound** for Ω is a total function $\beta : \mathcal{E}(\Omega) \rightarrow \mathbb{R}_{\geq 0}$ such that for all $E \in \mathcal{E}(\Omega)$, if E is valid and $\text{val}(E) \neq 0$ then $|\text{val}(E)| \geq \beta(E)$. More precisely, β is called an **exclusion root bound**; it is an **inclusion root bound** when the inequality becomes “ $|\text{val}(E)| \leq \beta(E)$.” We use the (exclusion) root bound β to solve $\text{ZERO}(\Omega)$ as follows: to test if an expression E evaluates to zero, we compute an approximation α to $\text{val}(E)$ such that $|\alpha - \text{val}(E)| < \beta(E)/2$. While computing α , we can recursively verify the validity of E . If E is valid, we compare α with $\beta/2$. It is easy to conclude that $\text{val}(E) = 0$ if $|\alpha| \leq \beta/2$. Otherwise $|\alpha| > \beta/2$, and the sign of $\text{val}(E)$ is that of α . An important remark is that the root bound β determines the worst-case complexity. This is unavoidable if $\text{val}(E) = 0$. But if $\text{val}(E) \neq 0$, the worst case may be avoided by iteratively computing α_i with increasing absolute precision ε_i . If for any $i \geq 1$, $|\alpha_i| > \varepsilon_i$, we stop and conclude $\text{sign}(\text{val}(E)) = \text{sign}(\alpha_i) \neq 0$.

There is an extensive classical mathematical literature on root bounds, but they are usually not suitable for computation. Recently, new root bounds have been introduced that explicitly depend on the structure of expressions $E \in \mathcal{E}(E)$. In [LY01], such bounds are called **constructive** in the following sense: (i) There are easy-to-compute recursive rules for maintaining a set of numerical parameters $u_1(E), \dots, u_m(E)$ based on the structure of E , and (ii) $\beta(E)$ is given by an explicit formula in terms of these parameters. The first constructive bounds in EGC were

the degree-length and degree-height bounds of Yap and Dubé [YD95, Yap00] in their implementation of **Real/Expr**. The (Mahler) Measure Bound was introduced even earlier by Mignotte [Mig82, BFMS00] for the problem of “identifying algebraic numbers.” A major improvement was achieved with the introduction of the BFMS Bound [BFMS00]. Li-Yap [LY01] introduced another bound aimed at improving the BFMS Bound in the presence of division. Comparison of these bounds is not easy: but let us say a bound β *dominates* another bound β' if for every $E \in \mathcal{E}(\Omega_2)$, $\beta(E) \leq \beta'(E)$. Burnikel et al. [BFM⁺01] generalized the BFMS Bound to the BFMSS Bound. Yap noted that if we incorporate a symmetrizing trick for the $\sqrt{x/y}$ transformation, then BFMSS will dominate BFMS. Among current constructive root bounds, three are not dominated by other bounds: BFMSS, Measure, and Li-Yap Bounds. In general, BFMSS seems to be the best. Other root bounds include a multivariate root bound of Canny [Can88] (see extension in [Yap00, Chapter XI]) and an Eigenvalue Bound of Scheinerman [Sch00]. A recent factoring technique of Pion and Yap [PY03] can be used to improve the existing bounds (in particular, BFMSS). This technique can exploit the presence of k -ary input numbers, and is thus favorable for the majority of realistic inputs (which are binary or decimal).

FILTERS

An extremely effective technique for speeding up predicate evaluation is based on the filter concept. Since evaluating the predicate amounts to determining the sign of an expression E , we can first use machine arithmetic to quickly compute an approximate value α of E . For a small overhead, we can simultaneously determine an error bound ε where $|\text{val}(E) - \alpha| \leq \varepsilon$. If $|\alpha| > \varepsilon$, then the sign of α is the correct one and we are done. Otherwise, we evaluate the sign of E again, this time using a sure-fire if slow evaluation method. The algorithm used in the first evaluation is called a (floating-point) *filter*. The expected cost of the two-stage evaluation is small if the filter is efficient with a high probability of success. This idea was first used by Fortune and van Wyk [FvW96]. Floating-point filters can be classified along the static-to-dynamic dimension: *static filters* compute the bound ε solely from information that are known at compile time while *dynamic filters* depend on information available at run time. There is an *efficiency-efficacy tradeoff*: static filters (e.g., FvW Filter [FvW96]) are more efficient, but dynamic filters (e.g., BFS Filter [BFS98]) are more accurate (efficacious). Interval arithmetic has been shown to be an effective way to implement dynamic filters [BBP01]. Automatic tools for generating filter code are treated in [FvW93b, Fun97]. Filters can be elaborated in several ways. First, we can use a cascade of filters [BFS98]. The “steps” of an algorithm which are being filtered can be defined at different levels of granularity. One extreme is to consider an entire algorithm as one step [MNS⁺96, KW98]. A general formulation “structural filtering” is proposed in [FMN99]. Probabilistic analysis [DP99] shows the efficacy of arithmetic filters. The filtering of determinants is treated in several papers [Cla92, BBP01, PY01, BY00].

Filtering is related to program checking [BK95, BLR93]. View a computational problem P as an input-output relation, $P \subseteq I \times O$ where I, O is the input and output spaces, respectively. Let be A a (standard) *algorithm* for P which, viewed as a total function $A : I \rightarrow O \cup \{NaN\}$, has the property that for all $i \in I$, $(i, A(i)) \in P$ iff there is some $o \in O$ such that $(i, o) \in P$. Let $H : I \rightarrow O \cup \{NaN\}$ be another algorithm with no restrictions; call H a *heuristic algorithm* for P .

Let $F : I \times O \rightarrow \{true, false\}$. Then F is **checker** for P if F computes the characteristic function for P , $F(i, o) = true$ iff $(i, o) \in P$. Note that F is a checker for the problem P , and not for any purported program for P . Hence, unlike program checking, we do not require any special properties of P such as self-reducibility. We call F a **filter** for P if $F(i, o) = true$ implies $(i, o) \in P$. So filters are less restricted than checkers. A **filtered program** for P is therefore a triple (H, F, A) where H is heuristic algorithm, A a standard algorithm and F a filter. To run this program on input i , we first compute $H(i)$ and check if $F(i, H(i))$ is true. If so, we output $H(i)$; otherwise compute and output $A(i)$. Filtered programs can be extremely effective when H, F are both efficient and efficacious. Usually H is easy—it is just a machine arithmetic implementation of an exact algorithm. The filter F can be more subtle, but it is still more readily constructed than any checker. The problem P_{sdet} of computing the sign of determinants illustrates this: the only checker we know here is trivial, amounting to computing the determinant itself. On the other hand, effective filters for P_{sdet} are known [BBP01, PY01].

PRECISION COMPLEXITY

An important goal of EGC is to control the cost of high-precision computation. We describe two approaches based on modifying the algorithmic specification.

In predicate evaluation, there is an in-built precision of 1-relative bit (this precision guarantees the correct sign in the predicate evaluation). But in construction steps, any precision guarantees must be explicitly requested by the user. For optimization problems, a standard method to specify precision is to incorporate an extra input parameter $\epsilon > 0$. Assume the problem is to produce an output x to minimizes the function $\mu(x)$. An **ϵ -approximation algorithm** will output a solution x such that $\mu(x) \leq (1 + \epsilon)\mu(x^*)$ for some optimum x^* . An example is the **Euclidean Shortest-path Problem in 3-space** (3ESP). Since this problem is NP-hard (Section 27.5), we seek an ϵ -approximation algorithm. A simple way to implement an ϵ -approximation algorithm is to directly implement any *exact* algorithm in which the underlying arithmetic has guaranteed precision evaluation (using, e.g., **Core Library**). However, the bit complexity of such an algorithm may not be obvious. The more conventional approach is to explicitly build the necessary approximation scheme directly into the algorithm. One such scheme was given by Papadimitriou [Pap85] which is polynomial time in n and $1/\epsilon$. Choi et al. [CSY97] give an improved scheme, and perform a rare bit-complexity analysis.

Another way to control precision is to consider output complexity. In geometric problems, the input and output **sizes** are measured in two independent ways: combinatorial size and bit sizes. Let the input combinatorial and input bit sizes be n and L , respectively. By an L -bit input, we mean each of the numerical parameters in the description of the geometric object (see Section 41.2) is an L -bit number. Now an extremely fruitful concept in algorithmic design is this: an algorithm is said to be **output-sensitive** if the complexity of the algorithm can be made a function of the output size as well as of the input size parameters. In the usual view of output-sensitivity, only the output combinatorial size is exploited. Choi et al. [SCY00] introduced the concept of **precision-sensitivity** to remedy this gap. They presented the first precision-sensitive algorithm for 3ESP, and gave some experimental results. Using the framework of **pseudo-approximation algorithms**, Asano et al. [AKY04] gave new precision-sensitive algorithms for 3ESP, as well as for an optimal d_1 -motion for a rod.

GEOMETRIC ROUNDING

We saw rounded geometry as one of the fixed-precision approaches (Section 41.3) to robustness. But geometric rounding is also important in EGC, with a difference. The EGC problem is to “round” a geometric structure (Section 41.2) D to a geometric structure D' with lower precision. In fixed-precision computation, one is typically asked to construct D' from some input S that *implicitly* defines D . In EGC, D is explicitly given (e.g., D may be computed from S by an EGC algorithm). The EGC view should be more tractable since we have separated the two tasks: (a) computing D and (b) rounding D . We are only concerned with (b), the ***pure rounding problem***. For instance, if S is a set of lines that are specified by linear equations with L -bit coefficients, then the arrangement $D(S)$ of S would have vertices with $2L + O(1)$ -bit coordinates. We would like to round the arrangement, say, back to L bits. Such a situation, where the output bit precision is larger than the input bit precision, is typical. If we pipeline several of these computations in a sequence, the final result could have a very high bit precision unless we perform rounding.

If D rounds to D' , we could call D' a ***simplification*** of D . This viewpoint connects to a larger literature on simplification of geometry (e.g., simplifying geometric models in computer graphics and visualization (Chapter 54)). Two distinct objectives goals in simplification are ***combinatorial*** versus ***precision simplification***. For example, a problem that has been studied in a variety of contexts (e.g., Douglas-Peucker algorithm in computational cartography) is that of simplifying a polygonal line P . We can use ***decimation*** to reduce the combinatorial complexity (i.e., number of vertices $\#(P)$), for example, by omitting every other vertex in P . Or we can use ***clustering*** to reduce the bit-complexity of P to L -bits, e.g., we collapse all vertices that lie within the same grid cell, assuming grid points are L -bit numbers. Let $d(P, P')$ be the Hausdorff distance between P and another polyline P' ; other similar measures of distance may be used. In any simplification P' of P , we want to keep $d(P, P')$ small. In [BCD⁺02], two optimization problems are studied: in the ***Min-# Problem***, given P and ε , find P' to minimize $\#(P')$, subject to $d(P, P') \leq \varepsilon$. In the ***Min- ε Problem***, the roles of $\#(P)$ and $d(P, P')$ are reversed. For EGC applications, optimality can often be relaxed to simple feasibility. Path simplification can be generalized to the simplification of any cell complexes.

BEYOND ALGEBRAIC

Non-algebraic computation over Ω_4 is important in practice. This includes the use of elementary functions such as $\exp x$, $\ln x$, $\sin x$, etc, which are found in standard libraries (`math.h` in C/C++). Elementary functions can be implemented via their representation as ***hypergeometric functions***, an approach taken by Du et al. [DEMY02]. They described solutions for fundamental issues such as automatic error analysis, hypergeometric parameter processing and argument reduction. If f is a hypergeometric function and x is an explicit number, one can compute $f(x)$ to any desired absolute accuracy. But in the absence of root bounds for Ω_4 , we cannot solve the guaranteed precision problem $\text{GVAL}(\Omega_4)$. One systematic way to get around this is to invoke the uniformity conjecture [Ric00]: this conjecture provides us with a bound. If this bound ever led to an error, we would have produced a

counterexample to the uniformity conjecture.

There are situations where we can either avoid the use of transcendental functions, or their apparent need turns out to be non-essential (e.g., in motion planning). For instance, rigid transformations are important in solid modeling, but they involve trigonometric functions. We can get arbitrarily good approximations by using *rational rigid transformations*. Solutions in 2 and 3 dimensions are given by Canny et al. [CDR92] and Milenkovic and Milenkovic [MM93], respectively.

APPLICATIONS

We now consider issues in implementing specific algorithms under the EGC paradigm. The rapid growth in the number of such algorithms means the following list is quite partial. We attempt to illustrate the range of activities in several groups: **(i)** The early EGC algorithms produced were those that are easily reduced to integer arithmetic and polynomial predicates, such convex hulls or Delaunay triangulations. The goal was to demonstrate that such algorithms are implementable and relatively efficient (e.g., [FvW96]). To treat irrational predicates, the careful analysis of root bounds were needed to ensure efficiency. Thus, Burnikel, Mehlhorn, and Schirra [BMS94, Bur96] gave sharp bounds in the case of Voronoi diagrams for line segments. Similarly, Dubé and Yap [DY93] analyzed the root bounds in Fortune's sweepline algorithm, and first identified the usefulness of floating point approximations in EGC. Another approach is to introduce algorithms that use new predicates with low algebraic degrees. This line of work was initiated by Liotta, Preparata, and Tamassia [LPT97, BS00]. **(ii)** Polyhedral modeling is a natural domain for EGC techniques. Two efforts are [CM93, For97]. The most general viewpoint here uses Nef polyhedra [See01] in which open, closed or half-open polyhedral sets are represented. This is a radical departure from the traditional solid modeling based on *regularized sets* and the associated *regularized operators*. The regularization of a set $S \subseteq \mathbb{R}^d$ is obtained as the closure of the interior of S ; regularized sets do not allow lower dimensional features, e.g., a line sticking out of a solid is not permitted. Treatment of Nef polyhedra was previously impossible outside the EGC framework. **(iii)** An interesting domain is optimization problems such as linear and quadratic programming [Gae99, GS00] and the smallest enclosing cylinder problem [SSTY00]. In linear programming, there is a tradition of using benchmark problems for evaluating algorithms and their implementations. But what is lacking in the benchmarks is *reference solutions* with guaranteed accuracy to (say) 16 digits. One application of EGC algorithms is to produce such solutions. **(iv)** An area of major challenge is computation of algebraic curves and surfaces. Krishnan et al. [KFC⁺01] implemented a library of algebraic primitives to support the manipulation of algebraic curves. Algorithms for low degree curves and surfaces are beginning to be addressed, e.g., [BEH⁺02, GHS01, Wei02]. **(v)** The development of general geometric libraries such as CGAL [HHK⁺01] or LEDA [MN95] exposes a range of issues peculiar to EGC. For instance, in EGC we want a framework where various number kernels and filters can be used for a single algorithm.

41.5 TREATMENT OF DEGENERACIES

Suppose the input to an algorithm is a set of planar points. Depending on the context, any of the following scenarios might be considered “degenerate”: two cover-
tial points, three collinear points, four cocircular points. Intuitively, these are
degenerate because arbitrarily small perturbations can result in qualitatively dif-
ferent geometric structures. Degeneracy is basically a discontinuity [Yap90b, Sei98].
Sedgewick [Sed83] calls degeneracies the “bugbear of geometric algorithms.” De-
generacy is a major cause of nonrobustness for two reasons. First, it presents severe
difficulties for approximate arithmetic. Second, even under the EGC paradigm, im-
plementors are faced with a large number of special degenerate cases that must be
treated (this number grows exponentially in the dimension of the underlying space).
Thus there is a need to develop general techniques for handling degeneracies.

GLOSSARY

Inherent and induced degeneracy: This is illustrated by the planar convex
hull problem: an input set S with three collinear points p, q, r is inherently
degenerate if it lies entirely in one halfplane determined by the line through p, q, r .
If p, q, r are collinear but S does not lie on one side of the line through p, q, r ,
then we may have an induced degeneracy for a divide-and-conquer algorithm.
This happens when the algorithm solves a subproblem $S' \subseteq S$ containing p, q, r
with all the remaining points on one side. Induced degeneracy is algorithm-
dependent. In this chapter, we simply say “degeneracy” for induced degeneracy.
More precisely, an input is ***degenerate*** if it leads to a path containing a vanishing
test value in the computation tree [Yap90b]. A nondegenerate input is also said
to be ***generic***.

Generic algorithm: One that is only guaranteed to be correct on generic inputs.

General algorithm: One that works correctly for all (legal) inputs. Note that
“general” and “generic” are often used synonymously in other literature (e.g.,
“generic inputs” often means inputs in general position).

THE BASIC ISSUES

1. One basic goal of this field is to provide a *systematic transformation* of a
generic algorithm A into a general algorithm A' . Since generic algorithms are
widespread in the literature, the availability of general tools for this $A \mapsto A'$
transformation is useful for implementing robust algorithms.
2. Underlying any transformations $A \mapsto A'$ is some kind of perturbation of the
inputs. This raises the issue of *controlled perturbations*. For example, if A is
an algorithm for intersecting two convex polytopes, then we would like the
perturbation to expand the input polytopes so that the incidence of a vertex
in the relative interior of a face will be detected by A' .
3. There is a *postprocessing issue*: although A' is “correct” in some technical

sense, it need not necessarily produce the same outputs as an ideal algorithm A^* . For example, suppose A computes the Voronoi diagram of a set of points in the plane. Four cocircular points are a degeneracy and are not treated by A . The transformed A' can handle four cocircular points but it may output two Voronoi vertices that have identical coordinates and are connected by a Voronoi edge of length 0. This may arise if we use infinitesimal perturbations. The postprocessing problem amounts to cleaning up the output of A' (removing the length-0 edges in this example) so that it conforms to the ideal output of A^* .

CONVERTING GENERIC TO GENERAL ALGORITHMS

We have two general methods for converting a generic algorithm to a general one:

Blackbox sign evaluation schemes. We postulate a *sign blackbox* that takes as input a function $f(\mathbf{x}) = f(x_1, \dots, x_n)$ and parameters $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{R}^n$, and outputs a nonzero sign (either $+$ or $-$). In case $f(\mathbf{a}) \neq 0$, this sign is guaranteed to be the sign of $f(\mathbf{a})$, but the interesting fact is that we get a nonzero sign even if $f(\mathbf{a}) = 0$. We can formulate a consistency property for the blackbox, both in an algebraic setting [Yap90b] or in a geometric setting [Yap90a]. The transformation $A \mapsto A'$ amounts to replacing all evaluations of test values by calls to this blackbox. In [Yap90b], a family of *admissible schemes* for blackboxes is given in case the functions $f(\mathbf{x})$ are polynomials.

Perturbation toward a nondegenerate instance. A fundamentally different approach is provided by Seidel [Sei98], based on the following idea. For any problem, if we know one nondegenerate input $\mathbf{a}^*$ for the problem, then every other input $\mathbf{a}$ can be made nondegenerate by perturbing it in the direction of $\mathbf{a}^*$. We can take the perturbed input to be $\mathbf{a} + \epsilon \mathbf{a}^*$ for some infinitesimal ϵ . For example, for the convex hull of points in $\mathbb{R}^n$, we can choose $\mathbf{a}^*$ to be distinct points on the moment curve $(t, t^2, \dots, t^n)$.

We compare these two approaches. We currently only have blackbox schemes for rational functions, while Seidel's method would apply even in nonalgebraic settings. Blackbox schemes are independent of particular problems, while the nondegenerate instances $\mathbf{a}^*$ depend on the problem (and on the input size); no systematic method to choose $\mathbf{a}^*$ is known.

The first work in this area is the SoS (“simulation of simplicity”) technique of Edelsbrunner and Mücke [EM90]. The method amounts to adding powers of an indeterminate ϵ to each input parameter. Such ϵ -methods were first used in linear programming in the 1950s. The SoS scheme (for determinants) turns out to be an admissible scheme [Yap90b]. Intuitively, sign blackbox invocations should be almost as fast as the actual evaluations with high probability [Yap90b]. But the worst-case exponential behavior led Emiris and Canny to propose more efficient numerical approaches [EC95]. To each input parameter a_i in $\mathbf{a}$, they add a perturbation $b_i \epsilon$ (where $b_i \in \mathbb{Z}$ and ϵ is again an infinitesimal): these are called *linear perturbations*. In case the test values are determinants, they show that a simple choice of the b_i 's will ensure nondegeneracy and efficient computation. For general rational function tests, a lemma of Schwartz shows that a random choice of the b_i 's

is likely to yield nondegeneracy. Emiris, Canny, and Seidel [ECS97, Sei98] give a general result on the validity of linear perturbations, and apply it to common test polynomials.

APPLICATIONS AND PRACTICE

Michelucci [Mic95] describes implementations of blackbox schemes, based on the concept of “ ϵ -arithmetic.” One advantage of his approach is the possibility of controlling the perturbations. Experiences with the use of perturbation in the beneath-beyond convex hull algorithm in arbitrary dimensions are reported in [ECS97]. Neuhauser [Neu97] improved and implemented the rational blackbox scheme of Yap. He also considered controlled perturbation techniques. Comes and Ziegelmann [CZ99] implemented the linear perturbation ideas of Seidel in CGAL.

In solid modeling systems, it is very useful to systematically avoid degenerate cases (numerous in this setting). Fortune [For97] uses symbolic perturbation to allow an “exact manifold representation” of nonregularized polyhedral solids (see [Section 56.1](#)). The idea is that a dangling rectangular face (for instance) can be perturbed to look like a very flat rectangular solid, which has a manifold representation. Here, controlling the perturbation is clearly necessary.

Hertling and Weihrauch [HW94] define “levels of degeneracy” and use this to obtain lower bounds on the size of decision computation trees.

In contrast to our general goal of eliminating *explicit* handling of degeneracies, there are a few papers on “perturbation” that proposes to directly handle degeneracies. Burnikel, Mehlhorn, and Schirra [BMS95] describe the implementation of a line segment intersection algorithm and semidynamic convex hull maintenance in arbitrary dimensions. Based on this experience, they question the usefulness of perturbation methods using three observations: (i) perturbations may increase the running time of an algorithm by an arbitrary amount; (ii) the postprocessing problem can be significant; and (iii) it is not hard to handle degeneracies directly. But the probability of (i) occurring in a drastic way (e.g., for a degenerate input of n identical points) is so negligible that it may not deter most users when they have the option of writing a generic algorithm, especially when the general algorithm is very complex or not readily available. Other experiences suggest that property (iii) is the exception rather than the rule. In any case, users must weigh these considerations (cf. [Sch94]).

A weaker form of the [BMS95] approach is illustrated by work of Halperin and co-workers [HS98, Raa99]. Again, the algorithm must explicitly detect the presence of degeneracies, but now we explicitly perturb the input to remove all degeneracies. Their problem may be framed as follows: given a sequence $S = (O_1, \dots, O_n)$ of geometric objects, let A_i ($i = 1, \dots, n$) be the arrangement formed by $S_i = (O_1, \dots, O_i)$. The goal is to compute $A_n = A(S_n)$. For any object O and $\varepsilon > 0$, consider a predicate $P_1(O, \varepsilon)$ with this **monotonicity property**: if $\varepsilon' > \varepsilon$ and $P_1(O, \varepsilon')$ is true then $P_1(O, \varepsilon)$ is true. Call P_1 an **approximate degeneracy predicate**. If $P_1(O, \varepsilon)$ is true, we say O is ε -**degenerate**. Also, $P_1(O, 0^+)$ reduces to standard notions of degeneracy. Such predicates may be defined by a Boolean combination of polynomial inequalities. For instance, let O be a curve and $P_1(O, \varepsilon)$ is true iff there is a δ -ball B centered at a point of O , $\delta \leq \varepsilon$, such that $B \cap O$ is not connected. Thus $P_1(O, 0^+)$ is the property that O is self-intersecting. In general, let P_k denote an approximate degenerate predicate on $k \geq 1$ distinct objects. If P_k and

P'_k are two such predicates, then so is $P_k \vee P'_k$ and $P_k \wedge P'_k$. For instance, $P_2(O_1, O_1, \varepsilon)$ might say that O_1, O_2 are ε -close. Fix a collection $\mathcal{P}$ of approximate degeneracy predicates. We say that S is ε -**degenerate** if for some $P_k \in \mathcal{P}$, $P_k(O_1, \dots, O_k, \varepsilon)$ is true for some choice of k distinct objects $O_1, \dots, O_k \in S$. The following ε - δ **perturbation estimation problem** is basic: given $\varepsilon > 0$, find $\delta = \delta(\varepsilon, S, O) > 0$ such that if S is non ε -degenerate, and O is any object, with probability $> 1/2$, a random δ -perturbation O' of O will form a non ε -degenerate configuration with S . By general principles, we know that δ exists; but we would like good bounds on δ (say polynomial in $|S|$, etc). Using this, we can solve the **perturbed arrangement problem**: given S and $\varepsilon > 0$, compute an arrangement $A(S')$ where S' is not ε -degenerate and S' is a δ -perturbation of S . The cited papers above solve the perturbed arrangement problem in two situations, when the objects are spheres and polyhedral surfaces, respectively. The idea is to use a form of randomized incremental construction.

41.6 OPEN PROBLEMS

1. The main theoretical question in EGC is whether the Constant Zero Problem for Ω_4 is decidable. A related, possibly simpler, question is whether $\text{ZERO}(\Omega_3 \cup \{\sin(\cdot), \pi\})$ is decidable.
2. In constructive root bounds, it is unknown if there exists a root bound $\beta : \mathcal{E}(\Omega_2) \rightarrow \mathbb{R}_{\geq 0}$ where $-\lg(\beta(E)) = O(D(E))$ and $D(E)$ is the degree of E . In current bounds, we only know a quadratic bound, $-\lg(\beta(E)) = O(D(E)^2)$. The Uniformity Conjecture of Richardson [Ric00], if true, would be a very deep result with practical applications.
3. Give a optimal algorithm for the guaranteed precision evaluation problem $\text{GVAL}(\Omega)$ for, say, $\Omega = \Omega_2$. The solution includes a reasonable cost model.
4. In geometric rounding, we pose two problems: (a) Extend the Greene-Yao rounding problem to non-uniform grids (e.g., the grid points are L -bit floating point numbers). (b) Round simplicial complexes. The preferred notion of rounding here should not increase combinatorial complexity (unlike Greene-Yao), but rather allow features to collapse (triangles can degenerate to a vertex), but disallow inversion (triangles cannot flip its orientation).
5. Give good bounds for the ε - δ perturbation estimation problem.
6. Give a systematic treatment of inexact (dirty) data. Held [Hel01a, Hel01b] describes the engineering of reliable algorithms to handle such inputs.

41.7 SOURCES AND RELATED MATERIAL

SURVEYS

Forrest [For87] is an influential overview of the field of computational geometry. He deplores the gap between theory and practice and describes the open problem of robust intersection of line segments (expressing a belief that robust solutions do not exist). Other surveys of robustness issues in geometric computation are Schirra [Sch99], Yap and Dubé [YD95] and Fortune [For93]. Robust geometric modelers are surveyed in [PCH⁺95].

42 PARALLEL ALGORITHMS IN GEOMETRY

Michael T. Goodrich

INTRODUCTION

The goal of parallel algorithm design is to develop parallel computational methods that run very fast with as few processors as possible, and there is an extensive literature of such algorithms for computational geometry problems. There are several different parallel computing models, and in order to maintain a focus in this chapter, we will describe results in the Parallel Random Access Machine (PRAM) model, which is a synchronous parallel machine model in which processors share a common memory address space (and all inter-processor communication takes place through this shared memory). Although it does not capture all aspects of parallel computing, it does model the essential properties of parallelism. Moreover, it is a widely accepted model of parallel computation, and all other reasonable models of parallel computation can easily simulate a PRAM.

Interestingly, parallel algorithms can have a direct impact on efficient sequential algorithms, using a technique called *parametric search*. This technique, which is discussed in [Chapter 43](#), involves the use of a parallel algorithm to direct searches in a parameterized geometric space so as to find a critical location (e.g., where an important parameter changes sign or achieves a maximum or minimum value).

The PRAM model is subdivided into submodels based on how one wishes to handle concurrent memory access to the same location. The Exclusive-Read, Exclusive-Write (EREW) variant does not allow for concurrent access. The Concurrent-Read, Exclusive-Write (CREW) variant permits concurrent memory reads, but memory writes must be exclusive. Finally, the Concurrent-Read, Concurrent-Write (CRCW) variant allows for both concurrent memory reading and writing, with concurrent writes being resolved by some simple rule, such as having an arbitrary member of a collection of conflicting writes succeed. One can also define randomized versions of each of these models (e.g., an rCRCW PRAM), where in addition to the usual arithmetic and comparison operations, each processor can generate a random number from 1 to n in one step.

Early work in parallel computational geometry, in the way we define it here, began with the work of Chow [Cho80], who designed several parallel algorithms with polylogarithmic running times using a linear number of processors. Subsequent to this work, several researchers initiated a systematic study of work-efficient parallel algorithms for geometric problems, including Aggarwal *et al.* [ACG⁺88], Akl [Akl82, Akl84, Akl85], Amato and Preparata [AP92, AP95], Atallah and Goodrich [AG86, Goo87], and Reif and Sen [RS92, Sen89].

In Section 42.1 we give a brief discussion of general techniques for parallel geometric algorithm design. We then partition the research in parallel computational geometry into problems dealing with convexity (Section 42.2), arrangements and decompositions (Section 42.3), proximity (Section 42.4), geometric searching (Section 42.5), and visibility, envelopes, and geometric optimization (Section 42.6).

42.1 SOME PARALLEL TECHNIQUES

The design of efficient parallel algorithms for computational geometry problems often depends upon the use of powerful general parallel techniques (e.g., see [AL93, Já92, KR90, Rei93]). We review some of these techniques below.

PARALLEL DIVIDE-AND-CONQUER

Possibly the most general technique is parallel divide-and-conquer. In applying this technique one divides a problem into two or more subproblems, solves the subproblems recursively in parallel, and then merges the subproblem solutions to solve the entire problem. As an example application of this technique, consider the problem of constructing the upper convex hull of a S set of n points in the plane presorted by x -coordinates. Divide the list S into $\lceil \sqrt{n} \rceil$ contiguous sublists of size $\lfloor \sqrt{n} \rfloor$ each and recursively construct the upper convex hull of the points in each list. Assign a processor to each pair of sublists and compute the common upper tangent line for the two upper convex hulls for these two lists, which can be done in $O(\log n)$ time using a well-known “binary search” computation [Ede87, O’R98, PS85]. By maximum computations on the left and right common tangents, respectively, for each subproblem S_i , one can determine which vertices on the upper convex hull of S_i belong to the upper convex hull of S . Compressing all the vertices identified to be on the upper convex hull of S constructs an array representation of this hull, completing the construction.

The running time of this method is characterized by the recurrence relation $T(n) \leq T(\sqrt{n}) + O(\log n)$, which implies that $T(n)$ is $O(\log n)$. It is important to note that the coefficient for the $T(\sqrt{n})$ term is 1 even though we had $\lceil \sqrt{n} \rceil$ subproblems, for all these subproblems were processed simultaneously in parallel. The number of processors needed for this computation can be characterized by the recurrence relation $P(n) \leq \max\{\lceil \sqrt{n} \rceil P(\sqrt{n}), n\}$, which implies that $P(n)$ is $O(n)$. Thus, the *work* needed for this computation is $O(n \log n)$, which is not quite optimal. Still, this method can be adapted to result in an optimal work bound [BSV96, Che95, GG97].

BUILD-AND-SEARCH

Another important technique in parallel computational geometry is the build-and-search technique. It is a paradigm that often yields efficient parallel adaptations of sequential algorithms designed using the powerful plane sweeping technique. In the build-and-search technique, the solution to a problem is partitioned into a *build* phase, where one constructs in parallel a data structure built from the geometric data present in the problem, and a *search* phase, where one searches this data structure in parallel to solve the problem at hand. An example of an application of this technique is for the trapezoidal decomposition problem: given a collection of nonintersecting line segments in the plane, determine the first segments intersected by vertical rays emanating from each segment endpoint (cf. Figure 40.0.1). The existing efficient parallel algorithm for this problem is based upon first building in parallel a data structure on the input set of segments that allows for such vertical

ray-shooting queries to be answered in $O(\log n)$ time by a single processor, and then querying this structure for each segment endpoint in parallel. This results in a parallel algorithm with an efficient $O(n \log n)$ work bound and fast $O(\log n)$ query time.

42.2 CONVEXITY

Results on the problem of constructing the convex hull of n points in $\mathbb{R}^d$ are summarized in Table 42.2.1, for various fixed values of d , and, in the case of $d = 2$, under assumptions about whether the input is presorted. We restrict our attention to parallel algorithms with efficient work bounds, where we use the term **work** of an algorithm here to refer to the product of its running time and the number of processors used by the algorithm. A parallel algorithm has an **optimal** work bound if the work used asymptotically matches the sequential lower bound for the problem. In the table, h denotes the size of the hull, and c is some fixed constant. Also, we use (throughout this chapter) $\bar{O}(f(n))$ to denote an asymptotic bound that holds with high probability.

TABLE 42.2.1 Parallel convex hull algorithms.

PROBLEM	MODEL	TIME	WORK	REF
2D presorted	rand-CRCW	$\bar{O}(\log^* n)$	$\bar{O}(n)$	[GG91]
2D presorted	CRCW	$O(\log \log n)$	$O(n)$	[BSV96]
2D presorted	EREW	$O(\log n)$	$O(n)$	[Che95]
2D polygon	EREW	$O(\log n)$	$O(n)$	[Che95]
2D	rand-CRCW	$\bar{O}(\log n)$	$\bar{O}(n \log h)$	[GG91]
2D	EREW	$O(\log n)$	$O(n \log n)$	[MS88]
2D	EREW	$O(\log^2 n)$	$O(n \log h)$	[GG91]
3D	rand-CRCW	$\bar{O}(\log n)$	$\bar{O}(n \log n)$	[RS92]
3D	CREW	$O(\log n)$	$O(n^{1+1/c})$	[AP93]
3D	EREW	$O(\log^2 n)$	$O(n \log n)$	[AGR94]
3D	EREW	$O(\log^3 n)$	$O(n \log h)$	[AGR94]
Fixed $d \geq 4$	rand-EREW	$\bar{O}(\log^2 n)$	$\bar{O}(n^{\lfloor d/2 \rfloor})$	[AGR94]
Even $d \geq 4$	EREW	$O(\log^2 n)$	$O(n^{\lfloor d/2 \rfloor})$	[AGR94]
Odd $d > 4$	EREW	$O(\log^2 n)$	$O(n^{\lfloor d/2 \rfloor} \log^c n)$	[AGR94]

We discuss a few of these algorithms to illustrate their flavor.

2-DIMENSIONAL CONVEX HULLS

The two-dimensional convex hull algorithm of Miller and Stout [MS88] is based upon a parallel divide-and-conquer scheme where one presorts the input and then divides it into many subproblems ($O(n^{1/4})$ in their case), solves each subproblem independently in parallel, and then merges all the subproblem solutions together

in $O(\log n)$ parallel time. Of course, the difficult step is the merge of all the sub-problems, with the principal difficulty being the computation of common tangents between hulls. The total running time is characterized by the recurrence

$$T(n) \leq T(n^{1/4}) + O(\log n),$$

which solves to $T(n) = O(\log n)$.

3-DIMENSIONAL CONVEX HULLS

All of the 3D convex hull algorithms listed in [Table 42.2.1](#) are also based upon this many-way, divide-and-conquer paradigm, except that there is no notion of presorting in three dimensions, so the subdivision step also becomes nontrivial. Reif and Sen [RS92] use a random sample to perform the division, and the methods of Amato, Goodrich, and Ramos [AGR94] derandomize this approach. Amato and Preparata [AP93] use parallel separating planes, an approach extended to higher dimension in [AGR94].

LINEAR PROGRAMMING

A problem strongly related to convex hull construction, which has also been addressed in a parallel setting, is d -dimensional linear programming, for fixed dimensions d (see [Chapter 45](#)). Of course, one could solve this problem by transforming it to its dual problem, constructing a convex hull in this dual space, and then evaluating each vertex in the simplex that is dual to this convex hull. This would be quite inefficient, however, for $d \geq 4$. The best parallel bounds for this problem are listed in [Table 42.2.2](#). See [Section 45.6](#) for a detailed discussion.

TABLE 42.2.2 Fixed d -dimensional parallel linear programming.

MODEL	TIME	WORK	REF
Rand-CRCW	$\bar{O}(1)$	$\bar{O}(n)$	[AM90]
CRCW	$O((\log \log n)^{d-1})$	$O(n)$	[GR97]
EREW	$O(\log n (\log \log n)^{d-1})$	$O(n)$	[Goo96]

OPEN PROBLEMS

There are a number of interesting open problems regarding convexity:

1. Can d -dimensional linear programming be solved (deterministically) in $O(\log n)$ time using $O(n)$ work in the CREW PRAM model?
2. Is there an efficient output-sensitive parallel convex hull algorithm for $d \geq 4$?
3. Is there an optimal-work $O(\log^2 n)$ -time CREW PRAM convex hull algorithm for odd dimensions greater than 4?

42.3 ARRANGEMENTS AND DECOMPOSITIONS

Another important class of geometric problems that has been addressed in the parallel setting are arrangement and decomposition problems, which deal with ways of partitioning space. We review the best parallel bounds for such problems in Table 42.3.1.

GLOSSARY

Arrangement: The partition of space determined by the intersections of a collection of geometric objects, such as lines, line segments, or (in higher dimensions) hyperplanes. In this chapter, algorithms for constructing arrangements produce the *incidence graph*, which stores all adjacency information between the various primitive topological entities determined by the partition, such as intersection points, edges, faces, etc. See [Section 24.3.1](#).

Red-blue arrangement: An arrangement defined by two sets of objects A and B such that the objects in A (resp. B) are nonintersecting.

Axis-parallel: All segments/lines are parallel to one of the coordinate axes.

Polygon triangulation: A decomposition of the interior of a polygon into triangles by adding diagonals between vertices. See [Section 26.2](#).

Trapezoidal decomposition: A decomposition of the plane into trapezoids (and possibly triangles) by adding appropriate vertical line segments incident to vertices. See [Section 34.3](#).

Star-shaped polygon: A (simple) polygon that is completely visible from a single point. A polygon with nonempty kernel. See [Section 26.1](#).

$1/r$ -cutting: A partition of $\mathbb{R}^d$ into $O(r^d)$ simplices such that each simplex intersects at most n/r hyperplanes. See [Sections 36.2](#) and [40.1](#).

TABLE 42.3.1 Parallel arrangement and decomposition algorithms.

We sketch the one randomized algorithm in Table 42.3.1 to illustrate how randomization and parallel computation can be mixed. Let S be a set of segments in

the plane with k intersecting pairs. The goal is to construct $\hat{A}(S)$, the arrangement induced by S . First, an estimate $\hat{k}$ for k is obtained from a random sample. Then a random subset $R \subset S$ of a size r dependent on $\hat{k}$ is selected. $\hat{A}(R)$ is constructed using a suboptimal parallel algorithm, and processed (in parallel) for point location. Next the segments intersecting each cell of $\hat{A}(R)$ are found using a parallel point-location algorithm, together with some ad hoc techniques. Visibility information among the segments meeting each cell is computed using another suboptimal parallel algorithm. Finally, the resulting cells are merged in parallel. Because various key parameters in the suboptimal algorithms are kept small by the sampling, optimal expected work is achieved.

All of the algorithms for computing segment arrangements are *output-sensitive*, in that their work bounds depend upon both the input size and the output size. In these cases we must slightly extend our computational model to allow for the machine to request additional processors if necessary. In all these algorithms, this request may originate only from a single “master” processor, however, so this modification is not that different from our assumption that the number of processors assigned to a problem can be a function of the input size. Of course, to solve a problem on a real parallel computer, one would simulate one of these efficient parallel algorithms to achieve an optimal speed-up over what would be possible using a sequential method.

A related class of intersection-related problems is the class of problems dealing with methods for detecting intersections. Testing if a collection of objects has at least one intersection is frequently easier than finding all such intersections, and Table 42.3.2 reviews such results in the parallel domain.

GLOSSARY

Star-shaped polygon: A (simple) polygon that is completely visible from a single point; a polygon with non-empty kernel. See [Chapter 26](#).

TABLE 42.3.2 Parallel intersection detection algorithms.

PROBLEM	MODEL	TIME	WORK	REF
2 convex polygons	CREW	$O(1)$	$O(n^{1/c})$	[DK89a]
2 star-shaped polygons	CREW	$O(\log n)$	$O(n)$	[GM91]
2 convex polyhedra	CREW	$O(\log n)$	$O(n)$	[DK89a]

Given a collection of n hyperplanes in $\mathbb{R}^d$, another important decomposition problem is the construction of a $(1/r)$ -cutting. Here an EREW algorithm running in $O(\log n \log r)$ time using $O(nr^{d-1})$ work has been obtained [Goo93].

OPEN PROBLEMS

1. Is there an optimal-work $O(\log n)$ -time polygon triangulation algorithm that does not use concurrent writes?
2. Can a line segment arrangement be constructed in $O(\log n)$ time using $O(n \log n + k)$ work in the CREW PRAM model?

42.4 PROXIMITY

An important property of Euclidean space is that it is a metric space, and distance plays an important role in many computational geometry applications. For example, computing a closest pair of points can be used in collision detection, as can the more general problem of computing the nearest neighbor of each point in a set S , a problem we will call the ***all-nearest neighbors (ANN)*** problem. Perhaps the most fundamental problem in this domain is the subdivision of space into regions where each region $V(s)$ is defined by a *site* s in a set S of geometric objects such that each point in $V(s)$ is closer to s than to any other object in S . This subdivision is the ***Voronoi diagram*** (Chapter 23); its graph-theoretic dual, which is also an important geometric structure, is the ***Delaunay triangulation*** (Section 25.1). For a set of points S in $\mathbb{R}^d$, there is a simple “lifting” transformation that takes each point $(x_1, x_2, \dots, x_d) \in S$ to the point $(x_1, x_2, \dots, x_d, x_1^2 + x_2^2 + \dots + x_d^2)$, forming a set of points S' in $\mathbb{R}^{d+1}$ (Section 23.1). Each simplex on the convex hull of S' with a negative $(d+1)$ -st component in its normal vector projects back to a simplex of the Delaunay triangulation in $\mathbb{R}^d$. Thus, any $(d+1)$ -dimensional convex hull algorithm immediately implies a d -dimensional Voronoi diagram (VD) algorithm. Table 42.4.1 summarizes the bounds of efficient parallel algorithms for constructing Voronoi diagrams in this way, as well as methods that are designed particularly for Voronoi diagram construction or other specific proximity problems. (In the table, the underlying objects are points unless stated otherwise.)

GLOSSARY

Convex position: A set of points that are all on the boundary of their convex hull.

Voronoi diagram for line segments: A Voronoi diagram that is defined by a set of nonintersecting line segments, with distance from a point p to a segment s being defined as the distance from p to a closest point on s . See Section 23.3.

OPEN PROBLEMS

1. Can a 2D Voronoi diagram be constructed in $O(\log n)$ time using $O(n \log n)$ work under either the CREW or EREW PRAM models?

TABLE 42.4.1 Parallel proximity algorithms.

PROBLEM	MODEL	TIME	WORK	REF

3D VD	EREW	$O(\log^2 n)$	$O(n^2)$	[AGR94]

2. Is there an efficient output-sensitive parallel algorithm for constructing 3D Voronoi diagrams?

42.5 GEOMETRIC SEARCHING

Given a subdivision of space by a collection S of geometric objects, such as line segments, the point location problem is to build a data structure for this set that can quickly answer *vertical ray-shooting queries*, where one is given a point p and asked to report the first object in S hit by a vertical ray from p . We summarize efficient parallel algorithms for planar point location in Table 42.5.1. The time and work bounds listed, as well as the computational model, are for building the data structure to achieve an $O(\log n)$ query time. We do not list the space bounds for any of these methods in the table since, in every case, they are equal to the preprocessing work bounds.

GLOSSARY

- Arbitrary planar subdivision:** A subdivision of the plane (not necessarily connected), defined by a set of line segments that intersect only at their endpoints.
- Monotone subdivision:** A connected subdivision of the plane in which each face is intersected by a vertical line in a single segment.
- Triangulated subdivision:** A connected subdivision of the plane into triangles whose corners are vertices of the subdivision (see Chapter 25).
- Shortest path in a polygon:** The shortest path between two points that does not go outside of the polygon (see Section 26.4).
- Ray-shooting query:** A query whose answer is the first object hit by a ray oriented in a specified direction from a specified point.

TABLE 42.5.1 Parallel geometric searching algorithms.

QUERY PROBLEM	MODEL	TIME	WORK	REF
Point loc in arb subdivision	CREW	$O(\log n)$	$O(n \log n)$	[ACG89]
Point loc in monotone subdivision	EREW	$O(\log n)$	$O(n)$	[TV91]
Point loc in triangulated subdivision	CREW	$O(\log n)$	$O(n)$	[CZ90]
Point loc in d -dim hyp arr	EREW	$O(\log n)$	$O(n^d)$	[AGR94]
Shortest path in triangulated polygon	CREW	$O(\log n)$	$O(n)$	[GSG92]
Ray shooting in triangulated polygon	CREW	$O(\log n)$	$O(n)$	[HS93]
Line & convex polyhedra intersection	CREW	$O(\log n)$	$O(n)$	[DK89b, CZ90]

OPEN PROBLEMS

1. Is there an efficient data structure that allows n simultaneous point locations to be performed in $O(\log n)$ time using $O(n)$ processors in the EREW PRAM model?
2. Is there an efficient data structure for 3-dimensional point location in convex subdivisions that can be constructed in $O(n \log n)$ work and at most $O(\log^2 n)$ time and which allows for a query time that is at most $O(\log^2 n)$?

42.6 VISIBILITY, ENVELOPES, AND OPTIMIZATION

We summarize efficient parallel methods for various visibility and lower envelope problems for a simple polygon in Table 42.6.1. In the table, m denotes the number of edges in a visibility graph. For definitions see [Chapter 28](#).

TABLE 42.6.1 Parallel visibility algorithms for a simple polygon.

PROBLEM	MODEL	TIME	WORK	REF
Kernel	EREW	$O(\log n)$	$O(n)$	[Che95]
Vis from a point	EREW	$O(\log n)$	$O(n)$	[ACW91]
Vis from an edge	CRCW	$O(\log n)$	$O(n)$	[Her92]
Vis from an edge	CREW	$O(\log n)$	$O(n \log n)$	[GSG92, GSG93]
Vis graph	CREW	$O(\log n)$	$O(n \log^2 n + m)$	[GSG92, GSG93]

We sketch the algorithm for computing the point visibility polygon [ACW91], which is notable for two reasons: first, it is employed as a subprogram in many other algorithms; and second, it requires much more intricate processing and analysis than the relatively simple optimal sequential algorithm ([Section 25.3](#)). The parallel algorithm is recursive, partitioning the boundary into $n^{1/4}$ subchains, and computing *visibility chains* from the source point of visibility x . Each of these chains

is star-shaped with respect to x , i.e., effectively “monotone” (see [Section 26.1](#)). This monotonicity property is, however, insufficient to intersect the visibility chains quickly enough in the merge step to obtain optimal bounds. Rather, the fact that the chains are subchains of the boundary of a simple polygon must be exploited to achieve logarithmic-time computation of the intersection of two chains. This then leads to the optimal bounds quoted in [Table 42.6.1](#).

The bounds of efficient parallel methods for visibility problems on general sets of segments and curves in the plane are summarized in [Table 42.6.2](#).

GLOSSARY

- Lower envelope:** The function $F(x)$ defined as the pointwise minimum of a collection of functions $\{f_1, f_2, \dots, f_n\}$: $F(x) = \min_i f_i(x)$ (see [Section 21.2](#)).
- k -intersecting curves:** A set of curves every two of which intersect at most k times (where they cross).
- $\lambda_s(n)$:** The maximum length of a Davenport-Schinzel sequence [SA95, AS00] of order s on n symbols. If s is a constant, $\lambda_s(n)$ is $o(n \log^* n)$. See [Section 40.4](#).

TABLE 42.6.2 General parallel visibility and enveloping algorithms.

PROBLEM	MODEL	TIME	WORK	REF
Lower env for segments	EREW	$O(\log^2 n)$	$O(n \log n)$	[Her89]
Lower env for k -int curves	EREW	$O(\log^2 n)$	$O(\lambda_{k+2}(n) \log n)$	[BM87]

Finally, we summarize some efficient parallel algorithms for solving several geometric optimization problems in [Table 42.6.3](#).

GLOSSARY

- Largest-area empty rectangle:** For a collection S of n points in the plane, the largest-area rectangle that does not contain any point of S in its interior.
- All-farthest neighbors problem** in a simple polygon: Determine for each vertex p of a simple polygon the vertex q such that the shortest path from p is longest.
- Closest visible-pair between polygons:** A closest pair of mutually-visible vertices between two nonintersecting simple polygons in the plane.
- Minimum circular-arc cover:** For a collection of n arcs of a given circle C , a minimum-cardinality subset that covers C .
- Optimal-area inscribed/circumscribed triangle:** For a convex polygon P , the largest-area triangle inscribed in P , or, respectively, the smallest-area triangle circumscribing P .
- Min-link path in a polygon:** A piecewise-linear path of fewest “links” inside a simple polygon between two given points p and q ; see [Sections 23.4](#) and [24.3](#).

TABLE 42.6.3 Parallel geometric optimization algorithms.

PROBLEM	MODEL	TIME	WORK	REF
Largest-area empty rectangle	CREW	$O(\log^2 n)$	$O(n \log^3 n)$	[AKPS90]
All-farthest neighbors in polygon	CREW	$O(\log^2 n)$	$O(n \log^2 n)$	[Guh92]
Closest visible-pair btw polygons	CREW	$O(\log n)$	$O(n \log n)$	[HCL92]
Min circular-arc cover	EREW	$O(\log n)$	$O(n \log n)$	[AC89]
Opt-area inscr/circum triangle	CRCW	$O(\log \log n)$	$O(n)$	[CM92]
Opt-area inscr/circum triangle	CREW	$O(\log n)$	$O(n)$	[CM92]
Min-link path in a polygon	CREW	$O(\log n \log \log n)$	$O(n \log n \log \log n)$	[CGM ⁺ 90]

OPEN PROBLEMS

1. Can the visibility graph of a set of n nonintersecting line segments be constructed using $O(n \log n + m)$ work in time at most $O(\log^2 n)$ in the CREW model, where m is the size of the graph?
2. Can the visibility graph of a triangulated polygon be computed in $O(\log n)$ time using $O(n + m)$ work in the CREW model?

42.7 SOURCES AND RELATED MATERIAL

FURTHER READING

Our presentation has been results-oriented and has not provide much problem intuition or algorithmic techniques. There are several excellent surveys available in the literature [Ata92, AC94, AC00, AG93, RS93, RS00] that are more techniques-oriented. Another good location for related material is the book by Akl and Lyons [AL93].

43 PARAMETRIC SEARCH

Jeffrey S. Salowe

INTRODUCTION

Parametric search is a technique that can sometimes be used to solve an optimization problem when there is an efficient algorithm for the related decision problem. If successful, one creates an optimization algorithm that makes only a small number of calls to the decision algorithm. We provide a general description (Section 43.1) and four examples (Sections 43.2–43.5) to illustrate the technique.

43.1 PARAMETRIC SEARCH OVERVIEW

GLOSSARY

Monotonic function: A function $f(x)$ having the property that $f(y) \geq f(x)$ if $y > x$.

Root-finding problem: Determining the largest value θ^* of θ with the property that $f(\theta^*) = 0$.

Monotonic root-finding problem: A root-finding problem where $f(\theta)$ is monotonically increasing in θ .

Fixed-value problem: Evaluating $f(\theta)$ for a given value of θ .

Parametric search: A technique to solve efficiently suitable monotonic root-finding problems.

WHAT IS PARAMETRIC SEARCH?

The parametric search technique was invented by Megiddo [Meg79, Meg83] as a technique to solve certain optimization problems. Parametric search is particularly effective if the optimization problem can be phrased as a monotonic root-finding problem and if an efficient algorithm for the fixed-value problem can be constructed.

More specifically, let $f(\theta)$ be a monotonic function with a root, and suppose our optimization problem is to determine $\theta^* = \sup\{\theta \mid f(\theta) = 0\}$. (Our notation emphasizes the dependence on the parameter θ , but it obscures the dependence of certain functions on the problem inputs.) Let $A(\theta)$ be an algorithm that computes $f(\theta)$, written in the form of a binary *decision tree* whose nodes s correspond to inequalities $g_s(\theta) \geq 0$. The parametric search technique evaluates $f(\theta^*)$, and in the process discovers θ^* , by evaluating the sign of $f(\theta)$ at some of the roots of $g_s(\theta)$.

The technique works best when each $g_s(\theta)$ has at most a constant number of roots and when $A(\theta)$ is an efficient parallel algorithm.

WHAT IS ITS EFFECT?

Parametric search generally yields the following results. Suppose that the optimization problem has n inputs and the decision problem has $n + 1$ inputs, the additional input being for the parameter θ . If $A(\theta)$ computes $f(\theta)$ sequentially in $S(n)$ time, θ^* can be found in $O((S(n))^2)$ time. If $B(\theta)$ is an efficient parallel algorithm to compute $f(\theta)$ that runs in $T(n)$ time using $P(n)$ processors, θ^* can be found in $O(S(n)T(n)\log P(n) + T(n)P(n))$ time. Under favorable conditions, parametric search solves an optimization problem in $O(\log^c n)$ $f(\theta)$ evaluations, where c is a small constant.

HOW IS IT APPLIED?

It is sometimes difficult to determine whether a given problem can be phrased as a root-finding problem suitable for parametric search. As a guideline, we illustrate the parametric search technique through a series of examples. The examples are picked for their illustrative value, and we do not necessarily derive the most efficient results known. Instead, we demonstrate the efficacy of the technique by obtaining surprisingly efficient solutions. Parametric search was used on the problems mentioned in Sections 43.3–43.5 to substantially improve the time complexity over previous techniques.

43.2 EXAMPLE 1: QUARTERING THE PLANE

GLOSSARY

Planar ham-sandwich cut: A line that simultaneously bisects two planar sets. (See [Sections 11.2](#) and [31.2](#).)

Median: A number $x \in A$ with the property that at most half of the numbers in A are less than x , and at most half of the numbers in A are greater than x .

General position: A condition on a set of points that forbids certain configurations. A typical general position assumption is that no three points in the plane are collinear.

PROBLEM STATEMENT

- Input: Set $U = \{u_1, \dots, u_n\}$, consisting of n points in the plane, each point satisfying $y(u_i) > 0$, where $y(u)$ is the y -coordinate of point u . Set $L = \{l_1, \dots, l_n\}$, a set of n points in the plane, each point satisfying $y(l_i) < 0$.

- Output: A planar ham-sandwich cut for U and L .

We assume that the points are in general position (no three points collinear and no two points with the same y -coordinates), that the input values are rational, and that n is an odd positive integer. In this case, the ham-sandwich cut is unique. These conditions simplify the explanation of the algorithm.

CHOICE OF MONOTONIC FUNCTION

The quartering problem is not immediately in the form of a monotonic root-finding problem, but it can be converted to one in the following manner. Let θ be an angle with respect to the x -axis, $0 < \theta < \pi$, measured in the usual way, and let $m(\theta, U)$ denote the intersection of the x -axis with the line at angle θ that bisects U . Let $m(\theta, L)$ be the analogous quantity for set L . We seek an angle θ such that $f(\theta) = m(\theta, U) - m(\theta, L) = 0$. Because a ham-sandwich cut exists, there is a value θ^* of θ for which $f(\theta^*) = 0$; our assumptions above ensure that θ^* is unique.

With this choice of the $f(\theta)$ function, the quartering problem seems to be a good candidate for parametric search. The function $f(\theta)$ is monotonic in θ , the quartering problem is solved if and only if $f(\theta^*) = 0$, and the value of $f(\theta)$ is easily computed, as described below.

FIXED-VALUE EVALUATION

To compute $f(\theta)$, first consider the U points. If these points are projected onto the x -axis along lines at an angle of θ , we have n one-dimensional points. The median of these projected points is precisely $m(\theta, U)$. Similarly, the median of the projected L points is $m(\theta, L)$. The evaluation of $f(\theta)$ amounts to:

1. Determining $m(\theta, U)$ by a median-find procedure.
2. Determining $m(\theta, L)$ by a median-find procedure.
3. Calculating $f(\theta) = m(\theta, U) - m(\theta, L)$.

The median-find procedure is a comparison-based algorithm that runs sequentially in $O(n)$ time and in parallel in $O(\log n)$ time using $O(n/\log n)$ processors. This is our algorithm $A(\theta)$.

THE DECISION-TREE ALGORITHM

We now rewrite $A(\theta)$ as a decision-tree algorithm and examine its comparisons. The median-find algorithm is central to $A(\theta)$. The generic step $s(i, j)$ of the median-find algorithm is to compare α_i and α_j , where α_i and α_j are two of the inputs; here the input values $\alpha_i(\theta)$ and $\alpha_j(\theta)$ are the projections of points $u_i = (x_i, y_i)$ and $u_j = (x_j, y_j)$ along a line with angle θ . It is apparent that $\alpha_i(\theta) = x_i - y_i \cot \theta$ and $\alpha_j(\theta) = x_j - y_j \cot \theta$. The decision tree node $s(i, j)$ corresponds to $g_{s(i, j)}(\theta) = x_i - x_j + (y_j - y_i) \cot \theta \geq 0$. There are no other branch points in the algorithm that depend on θ .

The function $g_{s(i, j)}$ has one root, $\theta_{s(i, j)} = \tan^{-1} \frac{y_j - y_i}{x_j - x_i}$. This is because the function $\cot(\theta)$ is monotonically decreasing in the range $0 < \theta < \pi$ and takes on all

values. Although the exact numerical value of $\theta_{s(i,j)}$ is generally unavailable, the sign of $f(\theta_{s(i,j)})$ can be evaluated. Consider comparison $s(m, n)$ in the computation of $f(\theta_{s(i,j)})$. The value of the function

$$g_{s(m,n)}(\theta_{s(i,j)}) = x_m - x_n + (y_n - y_m) \frac{x_j - x_i}{y_j - y_i}$$

is rational if the inputs are rational. Furthermore, the truth value of $\theta_{s(i,j)} < \theta_{s(i',j')}$ can be determined without the actual numerical values of $\theta_{s(i,j)}$ and $\theta_{s(i',j')}$: the truth value of $\theta_{s(i,j)} < \theta_{s(i',j')}$ is the same as the truth value of

$$\frac{y_j - y_i}{x_j - x_i} < \frac{y_{j'} - y_{i'}}{x_{j'} - x_{i'}}.$$

These two observations are needed below.

EVALUATING $f(\theta^*)$

Recall that we seek θ^* , the value of θ for which $f(\theta^*) = 0$. Suppose we try to run the algorithm $A(\theta^*)$ for $f(\theta^*)$, even though we do not know θ^* . Our main difficulty is resolving comparisons that depend on the value of θ^* .

Algorithm $A(\theta^*)$ is in the form of a decision tree, where each node s is labeled with inequality $g_s(\theta^*) \geq 0$. In order to resolve these decisions, we must determine the truth values of $g_s(\theta^*) \geq 0$.

These truth values are determined as follows. (This is the crucial step in parametric search.) The function $g_s(\theta)$ has one root, θ_s . Furthermore, $g_s(\theta)$ is monotonically decreasing in θ , so we can therefore determine the truth value of $g_s(\theta^*) \geq 0$ by determining the relative values of θ^* and θ_s . The relative values of θ^* and θ_s can be inferred by evaluating the sign of the fixed-value problem $f(\theta_s)$. Because $f(\theta)$ is monotonic, $f(\theta_s) < 0$ implies that $\theta_s < \theta^*$, and $f(\theta_s) > 0$ implies that $\theta_s > \theta^*$. If $f(\theta_s) = 0$, then $\theta^* = \theta_s$, and we have the value we seek. As stated above, the sign of $f(\theta_s)$ can be determined at the roots of $g_s(\theta)$.

Let $A(\theta^*)$ be based on a sequential median-find algorithm. Algorithm $A(\theta^*)$ runs in $O(n)$ time, but each comparison s evaluates the truth value of inequality $g_s(\theta^*) \geq 0$ by computing the sign of $f(\theta_s)$. The sign of $f(\theta_s)$ can be found in $O(n)$ time, so $A(\theta^*)$ runs in $O(n^2)$ time, even though the exact value of θ^* is unknown until the end of the computation.

IMPROVEMENTS USING PARALLELISM

We can decrease the time complexity of the algorithm by replacing the usual median-find procedure with a sequentialized version of a parallel algorithm. It is possible to devise a median-find procedure that uses $O(n/\log n)$ processors, completes in $O(\log n)$ time, and can be simulated in $O(n)$ sequential time. (Note that there are algorithms with better bounds that cannot be simulated in $O(n)$ sequential time.)

The advantage of a parallel algorithm is that the comparisons on a particular time step can be evaluated in an arbitrary order. Let

$$g_{s_1}(\theta^*) \geq 0, g_{s_2}(\theta^*) \geq 0, \dots, g_{s_{n/\log n}}(\theta^*) \geq 0$$

be the comparisons on time step j . Rather than evaluating each of them by computing $f(\theta_{s_i})$, $1 \leq i \leq n/\log n$, we evaluate the one with median θ_s value. (This is where we need to order the θ_s values.) This comparison can be used to infer the truth value of half of the remaining comparisons. That is, we evaluate the comparisons by performing a binary search for θ^* among the θ_{s_i} values.

The time complexity of the new algorithm is as follows. A total of $O(n)$ comparisons must be evaluated, organized so that $O(n/\log n)$ comparisons are made per time step for a duration of $O(\log n)$ time steps. During each time step, binary search resolves $O(\log n)$ comparisons by actually computing the sign of $f(\theta_s)$, and the rest of the comparisons are decided by transitivity. There are consequently $O(n \log n)$ operations per time step, multiplied by $O(\log n)$ time steps, giving a total of $O(n \log^2 n)$ operations.

FURTHER IMPROVEMENTS

This problem can be attacked with the related “prune-and-search” technique. If the proper comparisons are done, it is possible to reduce the size of the original problem and solve a substantially-smaller subproblem. The resulting time complexity is $O(n)$.

43.3 EXAMPLE 2: SELECTING VERTICES IN ARRANGEMENTS

GLOSSARY

Selection problem: Given a totally ordered set S and an integer k , $1 \leq k \leq |S|$, the selection problem is to find θ^* , the k th smallest item in S .

Ranking problem: Given a totally ordered set S and a number θ , the ranking problem is to return the number of items $\text{rank}(\theta, S)$ in S whose value is less than or equal to θ .

Arrangement: The subdivision of space induced by a set of hyperplanes. (See [Chapter 24](#).)

Permutation: A sequence of n distinct integers in the range 1 through n .

Inversion: A pair (i, j) occurring in a permutation where $i < j$ but j precedes i in the permuted sequence.

PROBLEM STATEMENT

- Input: Set $H = \{h_1, \dots, h_n\}$ of lines in the plane, where h_i has equation $y = m_i x + b_i$, and the lines are indexed in order of increasing slope. Integer k , $1 \leq k \leq \binom{n}{2}$.
- Output: Let V be the intersection points (vertices) of the arrangement formed by H . The output is the vertex v^* whose x -coordinate has rank k among the x -coordinates in V .

We assume that m_i and b_i are rational, and that H is in general position, so that no three lines intersect in a single vertex, no two vertices have the same x -coordinate, no line is vertical, and no two lines are parallel.

CHOICE OF MONOTONIC FUNCTION

Consider the function $f(\theta) = \text{rank}(\theta, V) - k$. This function is monotonically non-decreasing in θ , and it has the property that θ^* , the x -coordinate of v^* , satisfies $\theta^* = \sup\{\theta \mid f(\theta) = 0\}$.

FIXED-VALUE EVALUATION

Evaluating $f(\theta) = \text{rank}(\theta, V)$ amounts to counting the number of vertices in V whose x -coordinates are less than input θ . This can be done in the following way. The y -intercepts of the intersections of H with the line $x = \theta$ are the numbers $m_i\theta + b_i$, $1 \leq i \leq n$. If these numbers are sorted in decreasing order and value $m_i\theta + b_i$ is replaced by index i , the result is a permutation $\pi(\theta)$. The key insight is that the number of inversions in $\pi(\theta)$ equals $\text{rank}(\theta, V)$.

Algorithm $A(\theta)$, the algorithm to determine $f(\theta)$, consists of:

1. Computing the permutation $\pi(\theta)$.
2. Counting the number of inversions in $\pi(\theta)$.
3. Subtracting k from this result.

The first step is essentially a sorting step, which can be done sequentially in $O(n \log n)$ time and in parallel in $O(\log n)$ time with $O(n)$ processors. The second step can be done by a mergesort-like procedure.

THE DECISION-TREE ALGORITHM

The first step of algorithm $A(\theta)$ depends on the value of θ . Once the permutation $\pi(\theta)$ is computed, the control flow of the second and third steps does not depend on θ .

The comparisons $s(i, j)$ in $A(\theta)$ ask whether i precedes j in the permutation: Is $m_i\theta + b_i \geq m_j\theta + b_j$? We rewrite this inequality as

$$g_{s(i,j)}(\theta) = (m_i - m_j)\theta + (b_i - b_j) \geq 0.$$

It is clear that $g_{s(i,j)}(\theta)$ has a root $\theta_{s(i,j)}$ at $\frac{b_j - b_i}{m_i - m_j}$ (recall that no two lines have the same slope). The sign of $m_i - m_j$ is negative, implying that the functions $g_{s(i,j)}(\theta)$ are monotonically nonincreasing. The root $\theta_{s(i,j)}$ is rational, so evaluating the sign of $f(\theta_{s(i,j)})$ or comparing $\theta_{s(i,j)}$ values poses no difficulty.

EVALUATING $f(\theta^*)$

Suppose we attempt to evaluate $f(\theta^*)$ at the unknown x -coordinate θ^* . The chief difficulty is resolving comparisons involving θ^* . These comparisons correspond to inequalities of the form $g_{s(i,j)}(\theta^*) \geq 0$.

The inequality $g_{s(i,j)}(\theta^*) \geq 0$ is the same as the inequality $\theta^* \geq \theta_{s(i,j)}$. We can determine the truth value of this inequality by evaluating $f(\theta_{s(i,j)})$. Because $f(\theta)$ is monotonic, $f(\theta_{s(i,j)}) < 0$ implies that $\theta_{s(i,j)} < \theta^*$, and $f(\theta_{s(i,j)}) > 0$ implies that $\theta_{s(i,j)} > \theta^*$. Otherwise, $f(\theta_{s(i,j)}) = 0$, and $\theta^* = \theta_{s(i,j)}$.

A sequential implementation of algorithm $A(\theta^*)$ evaluates $O(n \log n)$ comparisons. Each comparison at node $s(i, j)$ determines the sign of $f(\theta_{s(i,j)})$, an operation that takes $O(n \log n)$ time. Step one therefore takes $O(n^2 \log^2 n)$ time to simulate. The rest of the work, steps two and three, takes additional $O(n \log n)$ time steps. The total work is $O(n^2 \log^2 n)$.

IMPROVEMENTS USING PARALLELISM

There are efficient parallel sorting algorithms; it is possible to sort n numbers in $O(\log n)$ time using n processors. If we perform a binary search on the n comparisons per level, only $O(\log n)$ $f(\theta)$ -evaluations are done, and the remaining comparisons are resolved by transitivity. The work per level is $O(n \log^2 n)$. There are $O(\log n)$ levels, so the time complexity of this algorithm is $O(n \log^3 n)$.

FURTHER IMPROVEMENTS

Cole [Col87b] gave a general technique that can be used to remove a log factor from the time complexity. If a parallel algorithm can be described by a circuit with constant fan-out gates (say fan-out two), then the following trick can be applied. Suppose that $\frac{c-1}{c}$ of the comparisons on the first time step have been resolved; then the inputs of at least $\frac{c-2}{c}$ of the comparisons on the second time step are available, and these comparisons are also ready to be resolved. Cole's idea is to combine these newly-ready comparisons with the unresolved comparisons. The total number of comparisons that need to be resolved by actually evaluating $f(\theta)$ becomes $O(\log P(n) + T(n))$. With respect to the sorting problem, the parallel sorting algorithm can be written as a circuit with fan-out two, so a total of $O(\log n)$ function evaluations need to be performed.

A second log factor can be removed by approximate ranking. Rather than computing the number of inversions exactly, the number is approximated. This approximation is sufficiently precise to determine the relative values of θ_s and θ^* . The resulting time complexity is $O(n \log n)$.

It has recently been established experimentally [OV02] that, under realistic assumptions about the input, Cole's improvement may be unnecessary (here and elsewhere): QuickSort is superior to parallel sorting in many practical situations. For example, if the roots being sorted are uniformly distributed over the comparison batches, then QuickSort is provably better. Although this assumption is often unwarranted, it seems to hold in many situations, as evidenced by successful application to the Fréchet-distance algorithm of Alt and Godau [AG95].

43.4 EXAMPLE 3: SELECTING INTERDISTANCES

GLOSSARY

L_p interdistance: Given points $a = (a_1, a_2, \dots, a_d)$ and $b = (b_1, b_2, \dots, b_d)$, $1 \leq p < \infty$, the L_p interdistance between a and b is given by

$$\|a - b\|_p = \left(\sum_{i=1}^d |a_i - b_i|^p \right)^{1/p}.$$

L_∞ interdistance: Given points a and b as above, the L_∞ interdistance between a and b is given by

$$\|a - b\|_\infty = \max_{1 \leq i \leq d} \{|a_i - b_i|\}.$$

$\tilde{O}(f(n))$: The set of functions that are $O(f(n)^{1+\epsilon})$, for any $\epsilon > 0$.

PROBLEM STATEMENT

- Input: Set P of n points in the plane. Integer k , $1 \leq k \leq \binom{n}{2}$.
- Output: Let D be the L_p interdistances formed by the points in P . The output is the interdistance θ^* with rank k in D .

We assume that all interdistances are unique.

CHOICE OF MONOTONIC FUNCTION

As in the vertex selection problem, the function $f(\theta) = \text{rank}(\theta, D) - k$.

FIXED-VALUE EVALUATION

The ranking problem in either metric can be viewed as a problem involving balls and points. Place a ball of radius θ around each point in P ; then $\text{rank}(\theta, D)$ is one-half times the number of point-ball containments. Do not include the center point-ball containments in this total. In the L_∞ metric, the unit ball is a square, and in the L_2 metric, the unit ball is a circle.

We deal with the L_∞ problem first. Ranking can be done efficiently by merging the x -coordinates of the vertical box sides of radius θ with the x -coordinates $\{x_1, \dots, x_n\}$ of P , and then repeating this process with the y -coordinates. (Assume that $x_1, \dots, x_n$ are presorted.) Given these sorted orders, we can simulate a sweep-line algorithm that counts the number of point-square containments.

The L_2 ranking problem is somewhat harder, but the basic strategy is identical to the L_∞ case. To rank θ , we form an arrangement of circles, each circle of radius θ and centered about a distinct point in P . Assume that this arrangement can be

built and preprocessed for planar point location, and assume that each region of the arrangement is labeled with the number of circles that contain it. For each point in P , perform a point location query to determine how many circles contain it.

Suppose there are s circles and t points. The arrangement can be built in $O(s^2)$ time, and each point location query can be answered in $O(\log s)$ time. The total processing time is $O(s^2 + t \log s)$.

Our ranking problem consists of n circles and points. If we divide the set of circles into $O(\sqrt{n})$ groups of size $O(\sqrt{n})$ and perform the procedure above, ranking can be performed in $\tilde{O}(n^{3/2})$ time.

THE DECISION-TREE ALGORITHM

The first step in the L_∞ ranking algorithm is to sort the values $\{x_1, \dots, x_n, x_1 - \theta, \dots, x_n - \theta\}$ and to sort the analogous y -coordinates. Some of these comparisons $s(i, j)$ depend on θ ; they are of the form $x_i \geq x_j - \theta$. This implies that $g_{s(i, j)}(\theta) = \theta + x_i - x_j$, and the root of $g_{s(i, j)}(\theta)$ is $\theta_{s(i, j)} = x_j - x_i$. After these two sorted orders are known, the remainder of the algorithm does not depend on θ .

The L_2 algorithm is more complicated. The construction of the circular arrangement contains some steps that depend on θ . A typical such step $s(z, C)$ involves the comparison of a point with a circle: Does point $z = (z_1, z_2)$ lie inside circle C ? Let the center of circle C be (c_1, c_2) . Deciding if z lies on or inside circle C of radius θ is equivalent to determining the truth value of the inequality $(z_1 - c_1)^2 + (z_2 - c_2)^2 \leq \theta^2$, so $g_{s(z, C)}(\theta) = \theta^2 - (z_1 - c_1)^2 - (z_2 - c_2)^2$. Function $g_{s(z, C)}$ has roots at $\pm \theta_{s(z, C)} = \pm \sqrt{(z_1 - c_1)^2 + (z_2 - c_2)^2}$.

EVALUATING $f(\theta^*)$

As in vertex selection, we perform interdistance selection by ranking unknown interdistance θ^* . For the L_∞ problem, the only step that needs the value of θ^* is the merging step; here, comparisons of the form $x_i \geq x_j - \theta^*$ must be resolved. This comparison is precisely $\theta_{s(i, j)} \leq \theta^*$, which we can resolve by evaluating $f(\theta_{s(i, j)})$.

The cost of presorting the data is $O(n \log n)$, and there are $O(n)$ comparisons in the merging steps, each comparison taking $O(n)$ time. Parametric search takes $O(n \log n + n^2) = O(n^2)$ time.

For the L_2 problem, comparisons of the form $(z_1 - c_1)^2 + (z_2 - c_2)^2 \leq (\theta^*)^2$ must be resolved. This comparison is precisely $(\theta_{s(z, C)})^2 \leq (\theta^*)^2$. Since $f(-\theta_{s(z, C)}) = -k$, this comparison can be resolved by evaluating the sign of $f(+\theta_{s(z, C)})$. Note that the square root is not needed in this evaluation because θ is squared in the functions $g_{s(z, C)}$.

The description of the L_2 ranking problem included an analysis of its time complexity. The ranking algorithm makes $\tilde{O}(n^{3/2})$ comparisons, each taking $\tilde{O}(n^{3/2})$ time, for a total of $\tilde{O}(n^3)$ time.

IMPROVEMENTS USING PARALLELISM

In the L_∞ algorithm, only the merging step needs to be parallelized. This can be done in $O(\log n)$ time using $O(n/\log n)$ processors. A straightforward application

of parametric search gives an $O(n \log^3 n)$ time algorithm.

With respect to the L_2 algorithm, it is possible to devise a parallel algorithm that uses $O(n^{3/2})$ processors and $O(\log n)$ time. Consequently, only $O(\log^2 n)$ comparisons need to be resolved by ranking. The total time is only $\tilde{O}(n^{3/2})$.

FURTHER IMPROVEMENTS

Cole's trick removes one log factor from the L_∞ algorithm, giving an $O(n \log^2 n)$ time algorithm. A different ranking scheme, one based on epsilon nets (Sections 31.2 and 34.4), is used to obtain better ranking results for the L_2 problem. The resulting time complexity is $\tilde{O}(n^{4/3})$.

43.5 EXAMPLE 4: RAY SHOOTING

GLOSSARY

Ray shooting: Determining the first object intersected by a ray (Chapter 37).

Partition tree: A data structure for simplex range queries (Section 31.2).

PROBLEM STATEMENT

- Input: A set H of n hyperplanes in k -dimensional space. A query ray ρ with origin o .
- Output: The first hyperplane of H that ρ intersects.

It is intended that the queries be repeated many times, so we want a data structure with small query time. We assume that o is not contained in a hyperplane of h and that $\rho \cap H \neq \emptyset$.

CHOICE OF MONOTONIC FUNCTION

Let ray ρ be given by its origin o and an arbitrary point $o(1)$ on ρ . For nonnegative θ , let $\rho(\theta)$ be the open subsegment of ρ given by $(1 - \lambda)o + \lambda o(1)$, $0 < \lambda < \theta$. (We will call the nonorigin endpoint $o(\theta)$). Let

$$f(\theta) = \begin{cases} \lfloor |\{h \in H \mid \rho(\theta) \cap h \neq \emptyset\}| \rfloor, & \theta \geq 0 \\ 0, & \theta < 0. \end{cases}$$

Here, $[P(x)] = 1$ if predicate $P(x)$ is true and 0 if $P(x)$ is false. The set $\{h \in H \mid \rho(\theta) \cap h \neq \emptyset\}$ consists of the hyperplanes in H that $\rho(\theta)$ intersects.

FIXED-VALUE EVALUATION

We now address the issue of efficiently computing $f(\theta)$. A reasonable data structure for such a task is a partition tree, described in [Chapter 36](#).

Let X be a set of points. Each node r in the partition tree corresponds to a set $X(r) \subseteq X$; the root corresponds to X . Furthermore, each node r is associated with a region of space $J(r)$, usually a simplex.

The partition tree can be used to compute $f(\theta)$ by determining whether the endpoints of $\rho(\theta)$, o and $o(\theta)$, lie in the same cell of arrangement $\mathcal{A}(H)$. To do this, the hyperplanes in H are dualized to a set of points $\mathcal{D}(H)$, and a partition tree is constructed for $\mathcal{D}(H)$. Points o and $o(\theta)$ lie in the same cell of $\mathcal{A}(H)$ if the double-wedge, the dual of the segment connecting o and $o(\theta)$, does not contain any points of $\mathcal{D}(H)$.

THE DECISION-TREE ALGORITHM

The basic step of the algorithm above compares the position of hyperplane $\mathcal{D}(o(\theta))$ to a point p , one of the vertices of $J(r)$. This is tantamount to deciding whether point $o(\theta)$ and o are on the same side of a particular hyperplane $h = \mathcal{D}(p)$.

Let h be given by $n_h \cdot x = \alpha_h$, where n_h is the unit normal of h in the direction of o . Then $o(\theta)$ and o are on the same side of h if $g_h(\theta) = n_h \cdot o(\theta) - \alpha_h \geq 0$.

The function $g_h(\theta)$ has a single root at

$$\theta_h = \frac{\alpha_h - (n_h \cdot o)}{n \cdot (o(1) - o)}.$$

The sign of $f(\theta_h)$ can be evaluated when the components of n and $o(1)$ are rational.

EVALUATING $f(\theta^*)$

Given ray ρ , we seek the value of $o(\theta^*)$, the location of the first intersection of ρ with a hyperplane in h . The number of points inside the double-wedge for $\rho(\theta^*)$ can be computed by resolving comparisons of the form

$$g_h(\theta^*) = n_h \cdot \rho(\theta^*) - \alpha_h \geq 0 = g_h(\theta_h).$$

This comparison is the same as determining the truth value of $\theta^* \geq \theta_h$, which is decided by evaluating the sign of $f(\theta_h)$. As stated above, the partition tree is used to evaluate $f(\theta_h)$.

Let $B(n)$ be the cost of constructing a partition tree on H , let $C(n)$ be the amount of storage needed, and let $Q(n)$ be the cost of querying the partition tree. Preprocessing does not depend on θ , and it takes $B(n)$ time. After preprocessing, the number of operations necessary to evaluate each $f(\theta)$ is $Q(n)$, and there are $Q(n)$ such evaluations in computing θ^* . The total number of operations in the parametric search is $O(B(n) + Q(n)^2)$.

PARALLEL ALGORITHM

Suppose that the query algorithm can be parallelized so that it runs in $T(n)$ time on $P(n)$ processors. In this case, $B(n)$ time is spent preprocessing the data structure, and $T(n)P(n)$ comparisons are made. Of these comparisons, $T(n)\log P(n)$ are resolved by computing the sign of $f(\theta_h)$, and the rest are resolved by transitivity. This version of the parametric ray-shooting algorithm takes $D(n) = O(Q(n)T(n)\log P(n) + T(n)P(n) + B(n))$ time.

Using results on partition trees, one can construct a family of parametric search algorithms parameterized by m , $n \leq m \leq n^d$, whose preprocessing, storage, and query requirements are $B(n) = \tilde{O}(m)$, $C(n) = \tilde{O}(m)$, and $D(n) = \tilde{O}(\frac{n}{m^{1/d}})$, respectively.

43.6 OTHER RESULTS

We summarize in Table 43.6.1 some of the results obtained with the parametric search technique on computational geometry problems. Parametric search has been successfully applied in other domains as well.

TABLE 43.6.1 Selected parametric search results.

PROBLEM NAME	INPUT	COMPLEXITY	SOURCE
3-dim set diameter	n points in 3-dim	$O(n \log^3 n)$	[BCM93]
Minimum-width annulus	n points in plane	$\tilde{O}(n^{8/5})$	[AST94]
Collision btw two polyhedra	two polyhedra, n vertices total	$\tilde{O}(n^{8/5})$	[ST95]
Biggest stick	n -sided simple polygon	$\tilde{O}(n^{8/5})$	[AST94]
L_p interdistance selection	n points in plane, k	$\tilde{O}(n^{4/3})$	[AASS93]
L_∞ interdistance selection	n points in plane, k	$O(n \log^2 n)$	[Sal89]
Min Hausdorff dist btw polygons	n - and m -sided simple poly	$\tilde{O}((mn)^2)$	[AST94]
2-center	n points in plane	$O(n^2 \log n)$	[JK94]
Center point in plane	n points in plane	$O(n)$	[JM94]
Segment center in plane	n segments in plane	$\tilde{O}(n)$	[ES96]
Selecting verts in arrangements	n lines in plane, k	$O(n \log n)$	[CSSS89]

Parametric search is not limited to monotonic functions of a single parameter—there is also a multidimensional version of parametric search. An instance of its application in computational geometry appears in Matoušek [Mat93].

43.7 SOURCES AND RELATED MATERIAL

FURTHER READING

The example in Section 43.2 was drawn from Cole [Col87a], where it was used as the basis of a multidimensional partitioning algorithm. Megiddo [Meg85] discovered the linear-time algorithm for quartering the plane. The example in Section 43.3, usually known as *slope selection*, is from Cole et al. [CSSS89]. The interdistance examples in Section 43.4 are from Agarwal et al. [AASS93] and Salowe [Sal89]. Agarwal et al. discovered the L_2 algorithm, and Salowe described the L_∞ algorithm. Finally, the ray-shooting example in Section 43.5 is from Agarwal and Matoušek [AM93].

A good bibliography of parametric search in computational geometry appears in Agarwal et al. [AST94].

Parametric searching can be viewed as one among several techniques for geometric optimization. Agarwal and Sharir review the shortcomings of parametric search, and survey the alternatives in [AS98], including randomization ([Chapter 40](#)), expander graphs, cuttings, matrix searching, and the prune-and-search technique, which has been applied so successfully to linear programming ([Chapter 45](#)).

44 THE DISCREPANCY METHOD IN COMPUTATIONAL GEOMETRY

Bernard Chazelle

INTRODUCTION

Discrepancy theory investigates how uniform nonrandom structures can be. For example, given n points in the plane, how should we color them red and blue so as to minimize the difference between the number of red points and the number of blue ones within any disk? Or, how should we place n points in the unit square so that the number of points that lie within any given triangle in the square is as close as possible to n times the area of the triangle? Questions of this nature have direct relevance to computational geometry for two reasons. One of them is their close association with the problem of derandomizing probabilistic algorithms. Such algorithms are often based on random sampling, and discrepancy theory provides tools for carrying out the sampling deterministically. This has led to the intriguing fact that virtually all of the important problems in low-dimensional computational geometry can be solved as efficiently deterministically as probabilistically. The second application of discrepancy theory to computational geometry is in the area of lower bounds for multidimensional searching. The complexity of these problems is often tied to spectral properties of geometric set systems, which themselves lie at the heart of geometric discrepancy theory.

44.1 VC-DIMENSION THEORY

GLOSSARY

Set system: A pair $\Sigma = (X, \mathcal{R})$, where X is a set and $\mathcal{R}$ is a collection of subsets of X , is called a set system. The term *geometric set system* refers to the case where $X \subset \mathbb{R}^d$ and each $R \in \mathcal{R}$ is of the form $X \cap f(C)$, where C is a fixed region of $\mathbb{R}^d$ (e.g., a simplex) and f is any member of a fixed group F of transformations (e.g., a rotation).

VC-dimension: Given $Y \subseteq X$, the set system *induced* by Y is of the form $(Y, \mathcal{R}|_Y)$, where $\mathcal{R}|_Y = \{Y \cap R \mid R \in \mathcal{R}\}$. The *VC-dimension* of Σ is the maximum size of any Y such that $\mathcal{R}|_Y = 2^Y$. For example, the VC-dimension of the infinite set system formed by points in $\mathbb{R}^2$ and halfplanes is 3. The *shatter function* $\pi_{\mathcal{R}}(m)$ of a (usually infinite) set system $\Sigma = (X, \mathcal{R})$ is the maximum number of subsets in the set system $(Y, \mathcal{R}|_Y)$ induced by any $Y \subseteq X$ of size m . If $\pi_{\mathcal{R}}(m)$ is bounded by cm^d for some constants $c, d > 0$, then the set system is said to have a *shatter function exponent* of at most d .

Dual set system: The set system $\Sigma^* = (X^*, \mathcal{R}^*)$, where $X^* = \mathcal{R}$, $\mathcal{R}^* = \{R_x \mid x \in X\}$, and $R_x = \{R \in \mathcal{R} \mid x \in R\}$, is called the *dual set system* of Σ .

The shatter function of Σ^* is called the **dual shatter function** of Σ .

Discrepancy: The **incidence matrix** A of a finite set system $\Sigma = (X, \mathcal{R})$ is the matrix whose $|X|$ columns (resp. $|\mathcal{R}|$ rows) are indexed by the elements of X (resp. $\mathcal{R}$): A_{ij} is 1 if the i th set of $\mathcal{R}$ contains the j th element of X , and 0 otherwise. The (red-blue) **discrepancy** of Σ is $\min_{x \in \{-1, 1\}^{|X|}} \|Ax\|_\infty$.

The concept of VC-dimension was introduced by Vapnik and Chervonenkis [VC71]. The relation between VC-dimension and shatter function is a key component of the theory.

LEMMA 44.1.1 [VC71, Sau72, She72]

If the shatter function exponent is $O(1)$, then so is the VC-dimension. Conversely, if the VC-dimension is $d \geq 1$ then, for any $m \geq d$, $\pi_{\mathcal{R}(m)} < (em/d)^d$.

LEMMA 44.1.2 [Ass83]

If a set system has VC-dimension d , then its dual has VC-dimension less than 2^{d+1} .

Any set system of n elements and n sets has discrepancy $O(\sqrt{n})$, and this bound is sometimes tight. If the VC-dimension is bounded, the discrepancy falls below the $\sqrt{n}$ barrier. The bounds below are stated in terms of the shatter function exponent. In view of Lemma 44.1.1, we can replace the exponent by the VC-dimension if we wish. Matoušek, Welzl, and Wernisch [MWW93] established a bound of $O(n^{1/2 - 1/(2d)} (\log n)^{1 + 1/(2d)})$ on the discrepancy of set systems with shatter function exponent d . This was improved to $O(n^{1/2 - 1/(2d)})$ by Matoušek:

THEOREM 44.1.3 [Mat95b]

The discrepancy of a set system of n elements with shatter function exponent $d > 1$ is $O(n^{1/2 - 1/(2d)})$, which is optimal for $d \geq 2$.

Similar bounds can be obtained in terms of the dual shatter function. Matoušek, Welzl, and Wernisch proved a bound of $O(n^{1/2 - 1/(2d)} \sqrt{\log n})$ on the discrepancy of set systems with dual shatter function exponent d . It is surprising that an extra $\sqrt{\log n}$ should be needed. Optimality was shown by Matoušek for the cases $d = 2, 3$, and by Alon, Rónyai, and Szabó for $d > 3$.

THEOREM 44.1.4 [MWW93, Mat97, ARS99]

The discrepancy of a set system of n elements with dual shatter function exponent $d > 1$ is $O(n^{1/2 - 1/(2d)} \sqrt{\log n})$, which is optimal for $d \geq 2$.

44.2 SAMPLING IN BOUNDED VC-DIMENSION

GLOSSARY

ϵ -Net: Given a finite set system $(X, \mathcal{R})$ and any $0 < \epsilon < 1$, a set $N \subseteq X$ is called an ϵ -net for $(X, \mathcal{R})$ if $N \cap R \neq \emptyset$ for any $R \in \mathcal{R}$ with $|R|/|X| > \epsilon$.

ϵ -Approximation: Given a finite set system $(X, \mathcal{R})$ and any $0 < \epsilon < 1$, a set $A \subseteq X$ is called an ϵ -approximation for $(X, \mathcal{R})$ if, for any $R \in \mathcal{R}$,

$$\left| \frac{|R|}{|X|} - \frac{|A \cap R|}{|A|} \right| \leq \epsilon.$$

Product set system: Given two finite set systems $\Sigma_1 = (X_1, \mathcal{R}_1)$ and $\Sigma_2 = (X_2, \mathcal{R}_2)$, the *product set system* $\Sigma_1 \otimes \Sigma_2$ is defined as $(X_1 \times X_2, \mathcal{T})$, where $\mathcal{T}$ consists of all subsets $T \subseteq X_1 \times X_2$ such that each set of the form $T_{x_2}^1 = \{x \in X_1 \mid (x, x_2) \in T\}$ belongs to $\mathcal{R}_1$ and, similarly, $T_{x_1}^2 = \{x \in X_2 \mid (x_1, x) \in T\}$ belongs to $\mathcal{R}_2$.

To sample a set system Σ is to extract a (small) subset of the elements whose intersection with any set R of Σ is a good predictor of the size of R . This is the idea behind an ϵ -approximation. A weaker version of sampling, the ϵ -net, requires only that large enough sets R be intersected by the sample. The key result in VC-dimension theory is that if Σ has bounded VC-dimension, then for any given level of accuracy, the sample size need not depend on the size of the set system. This is rather counterintuitive. It says, for example, that if we want to estimate how many people live within 1 mile of a post office and, to go about it, we opt to pick a sample of the population, we should simply solve the problem for the sample, and then scale up the answer appropriately; the same sample size will work just as well whether the country is France or India!

LEMMA 44.2.1

Let X_1, X_2 be disjoint subsets of X of the same size, and let A_i be an ϵ -approximation for the subsystem induced by X_i . If $|A_1| = |A_2|$, then $A_1 \cup A_2$ is an ϵ -approximation for the subsystem induced by $X_1 \cup X_2$.

LEMMA 44.2.2

If A is an ϵ -approximation for $(X, \mathcal{R})$, then any ϵ' -approximation (resp. -net) for $(A, \mathcal{R}|_A)$ is also an $(\epsilon + \epsilon')$ -approximation (resp. -net) for $(X, \mathcal{R})$.

A greedy approach to sampling yields an effective algorithm for arbitrary set systems. Writing $\epsilon = 1/r$, choose some $1 \leq r \leq n$. First, remove all sets $R \in \mathcal{R}$ of size at most n/r . Second, initialize the set N to $\emptyset$. Next, find the element $x \in X$ that belongs to the most sets of $\mathcal{R}$ (in case of a tie, any one will do) and add it to N . Remove from $\mathcal{R}$ every set that contains x , discard x , and iterate in this fashion until $\mathcal{R}$ is empty. An elementary analysis shows that this produces a $(1/r)$ -net for $(X, \mathcal{R})$ of size $O(r \log |\mathcal{R}|)$. This was proven independently by Johnson [Joh74] and Lovász [Lov75]. A slightly more complicated “weighted” version of the greedy algorithm, due to Chazelle [Cha00], gives an analogous result for $(1/r)$ -approximations.

THEOREM 44.2.3

Given a set system $(X, \mathcal{R})$, where $|X| = n$ and $|\mathcal{R}| = m$, for any $1 \leq r \leq n$, it is possible to find, in time $O(nm)$, a $(1/r)$ -net for $(X, \mathcal{R})$ of size $O(r \log m)$ and a $(1/r)$ -approximation for $(X, \mathcal{R})$ of size $O(r^2 \log m)$.

The size of the sample depends (albeit weakly) on the size of the set system. In the presence of bounded VC-dimension, however, this dependency magically disappears. Again, we will base our results not on the VC-dimension but on the shatter function exponent d (but the same results hold if d denotes the VC-dimension). Geometric set systems often are defined implicitly and are accessible via an *oracle* function that takes any $Y \subseteq X$ as input and returns the list of sets in $\mathcal{R}|_Y$.

(each set represented explicitly). We assume that the time to complete this task is $O(|Y|^{d+1})$, which is linear in the maximum possible size of the oracle's output. The existence of such an oracle is quite realistic: For example, in the case of points and disks in the plane, we have $d = 3$, and so this assumes that, given n points, we can enumerate all subsets enclosed by a disk in time $O(n^4)$. To do this, enumerate all k -tuples of points ($k \leq 3$) and, for each tuple, find which points lie inside the smallest disk enclosing the k points.

THEOREM 44.2.4

Given a set system $(X, \mathcal{R})$ of shatter function exponent d , for any $r \geq 2$, a $(1/r)$ -approximation for $(X, \mathcal{R})$ of size $O(dr^2 \log dr)$ and a $(1/r)$ -net for $(X, \mathcal{R})$ of size $O(dr \log dr)$ can be computed in time $O(d)^{3d}(r^2 \log dr)^d |X|$.

A randomized construction of ϵ -approximations in bounded VC-dimension was given by Vapnik and Chervonenkis [VC71]. The deterministic construction cited above is due to Chazelle and Matoušek [CM96]. Earlier influential work can be found in [CF90, Mat90, Mat91, Mat95a]. The bound on the size of ϵ -nets was established by Haussler and Welzl [HW87]. The running time for computing a $(1/r)$ -net was improved to $O(d)^{3d}(r \log dr)^d |X|$ by Brönnimann, Chazelle, and Matoušek [BCM99], using the concept of a *sensitive ϵ -approximation*.

For fixed d , Komlós, Pach, and Woeginger [KPW92] showed that the bound of $O(r \log r)$ for $(1/r)$ -nets cannot be improved in general (see a nice discussion in [PA95]). The situation is different with ϵ -approximations, however, for which Theorems 44.1.3 and 44.1.4 can be put to use. Matoušek, Welzl, and Wernisch proved the following:

THEOREM 44.2.5 [MWW93]

Let $(X, \mathcal{R})$ be a set system of VC-dimension $d > 1$. There exists a $(1/r)$ -approximation for $(X, \mathcal{R})$ of size $O(r^{2-2/(d+1)}(\log r)^{2-1/(d+1)})$, for any $r \geq 2$.

The log factor can be removed by appealing to Theorem 44.1.3.

THEOREM 44.2.6 [MWW93]

Let $(X, \mathcal{R})$ be a set system with dual shatter function exponent $d > 1$. There exists a $(1/r)$ -approximation for $(X, \mathcal{R})$ of size $O(r^{2-2/(d+1)}(\log r)^{1-1/(d+1)})$, for any $r \geq 2$.

Given n lines in the plane, we can use an ϵ -approximation to estimate how many lines cut through an arbitrary line segment. Suppose that, instead, we wish to estimate the number of vertices in the induced arrangement that fall within an arbitrary triangle. Product set systems allow us to do that. Let Σ_1 be the set system induced by n blue lines in the plane and the set of all line segments: a set of the system is the subset of blue lines intersected by a given segment. We define Σ_2 similarly with n red lines. The product $\Sigma_1 \otimes \Sigma_2$ is a set system $(Z, \mathcal{T})$, where Z is the set of red-blue vertices of the induced arrangement (assuming general position). A set of $\Sigma_1 \otimes \Sigma_2$ is any subset T of Z such that, along any (blue or red) line ℓ , the vertices of T incident to ℓ (if any) appear consecutively among the red-blue vertices of ℓ . This suggests we can use ϵ -approximations to, say, estimate how many red-blue vertices fall in an arbitrary triangle, or even in an arbitrary convex region. One must be careful, however. The product of two set systems with bounded VC-dimension might not itself have bounded VC-dimension. Indeed, any bichromatic

matching of the lines gives a collection of n vertices, any of whose 2^n subsets is a valid set of $\mathcal{T}$. Although the product does not have bounded VC-dimension, it so happens that sampling in it is still possible: that is the beauty of product set systems.

LEMMA 44.2.7

Given any $0 \leq \epsilon_i \leq 1$, let A_i be an ϵ_i -approximation for a set system Σ_i , for $i = 1, 2$. Then the Cartesian product $A_1 \times A_2$ is an $(\epsilon_1 + \epsilon_2)$ -approximation for $\Sigma_1 \otimes \Sigma_2$.

The product operation is associative, and the theorem can be extended to multiple products of set systems. The notion of product set system was introduced by Brönnimann, Chazelle, and Matoušek, who also proved:

LEMMA 44.2.8 [BCM99]

Given an ϵ -approximation A for a set system Σ , the d -fold Cartesian product $A \times \cdots \times A$ is a $(d\epsilon)$ -approximation for the d -fold product $\Sigma \otimes \cdots \otimes \Sigma$.

One of the most important applications of the theorem above is to counting vertices in an arrangement of hyperplanes in $\mathbb{R}^d$. We consider the set system $\Sigma = (H, \mathcal{R})$ formed by a set H of hyperplanes in $\mathbb{R}^d$, where each $R \in \mathcal{R}$ is the subset of H intersected by an arbitrary line segment. Given a convex body σ (not necessarily full-dimensional), consider the arrangement formed by H within the affine span of σ , i.e., the lowest-dimensional flat that contains σ , and let $V(H, \sigma)$ be the set of vertices of this arrangement that lie inside σ .

THEOREM 44.2.9 [Cha93a, BCM99]

Given a set H of hyperplanes in $\mathbb{R}^d$ in general position, along with an ϵ -approximation A for $\Sigma = (H, \mathcal{R})$; for any convex body σ of dimension $k \leq d$, we have

$$\left| \frac{|V(H, \sigma)|}{|H|^k} - \frac{|V(A, \sigma)|}{|A|^k} \right| \leq \epsilon.$$

44.3 GEOMETRIC ALGORITHMS

GLOSSARY

ϵ -Cutting: Given a set H of n hyperplanes in $\mathbb{R}^d$ and $\epsilon > 0$, a collection $\mathcal{C}$ of closed full-dimensional simplices (some of them unbounded) is called an ϵ -cutting if: (i) their interiors are pairwise disjoint, and together they cover $\mathbb{R}^d$; (ii) the interior of any simplex of $\mathcal{C}$ is intersected by at most ϵn hyperplanes of H .

Simplicial partition: Given a finite set $P \subset \mathbb{R}^d$, a collection $\{(P_i, R_i)\}$ is a *simplicial partition*, if (i) the P_i 's partition P and (ii) each R_i is a relatively open simplex enclosing P_i . The R_i 's can be of any dimension and need not be disjoint, and P_i need not be equal to $P \cap R_i$. We say that a hyperplane *cuts* R_i if it intersects, but does not contain, R_i . The maximum number of R_i 's that a single hyperplane can cut is the **cutting number** of the simplicial partition.

Partition tree: Given a finite set $P \subset \mathbb{R}^d$, a *partition tree* for P is a rooted tree $\mathcal{T}$ whose root is associated with the point set P . The set P is partitioned into

subsets $P_1, \dots, P_m$, and each P_i is associated with a distinct child v_i of the root. There is a convex open set R_i , called the *region* of v_i , that contains P_i . The regions R_i are not necessarily disjoint. If $|P_i| > 1$, the subtree rooted at v_i is defined recursively with respect to P_i .

Point location: Preprocess an arrangement of n hyperplanes in $\mathbb{R}^d$ so that, given a query point, one can quickly find the face of the arrangement that contains the point. Note that the face need not be d -dimensional. The complexity of a point location algorithm is measured by the query time and the amount of storage needed for the data structure. The time it takes to do the preprocessing is also of importance.

Simplex range searching: Preprocess a set P of n points in $\mathbb{R}^d$ so that, given a query (closed) simplex σ , the size of $P \cap \sigma$ can be quickly evaluated. Simplex range searching refers to a slight generalization of the problem, in which weights in an additive group or semigroup are assigned to the points and the answer to a query is the sum of all of the weights within σ . This framework allows us to model both the counting and reporting versions of the problem, the latter requiring an explicit enumeration of the points in σ .

CUTTINGS

Clarkson [Cla87] and Haussler and Welzl [HW87] were among the first to introduce the notion of sparsely intersected space partitions for divide and conquer. The definition of an ϵ -cutting is due to Matoušek [Mat91]. Near-optimal ϵ -cutting constructions were given in two dimensions [Aga90, Aga91] and in arbitrary dimension [Mat90, Mat91, Mat95a]. The optimal ϵ -cutting construction cited below is due to Chazelle. It simplified an earlier design by Chazelle and Friedman in [CF90].

THEOREM 44.3.1 [Cha93a]

Given a set H of n hyperplanes in $\mathbb{R}^d$, for any $r > 0$ there exists a $(1/r)$ -cutting for H of size $O(r^d)$, which is optimal. The cutting, together with the list of hyperplanes intersecting the interior of each simplex, can be found deterministically in $O(nr^{d-1})$ time.

The standard proof of the theorem is based on a hierarchical construction of independent interest. Roughly, the cutting sought is the last one in a sequence of cuttings $\mathcal{C}_0, \dots, \mathcal{C}_m$ such that (i) $\mathcal{C}_0$ is of constant size; (ii) for $k > 0$, each simplex of $\mathcal{C}_k$ is enclosed in a unique simplex of $\mathcal{C}_{k-1}$, which itself contains at most a constant number of simplices of $\mathcal{C}_k$; and (iii) for some constant $c > 0$, $\mathcal{C}_k$ is a $(1/c^k)$ -cutting of size $O(c^{dk})$.

The simplest application of cuttings is point location in an arrangement of hyperplanes. Consider n hyperplanes in $\mathbb{R}^d$. Given a query point, how fast can we find the cell (or lower-dimensional face) of the arrangement that contains the point? Assuming general position for simplicity, we set $r = n$ in the theorem. From the nesting structure of $\mathcal{C}_0, \mathcal{C}_1$, etc, we can locate the query point in $\mathcal{C}_k$ (i.e., find the simplex that contains it) in constant time once we know its location within $\mathcal{C}_{k-1}$.

THEOREM 44.3.2 [Cha93a]

Point location among n hyperplanes can be done in $O(\log n)$ query time, using $O(n^d)$ preprocessing.

A nice application of cuttings is to the problem of deciding whether there exists any point/line incidence among n lines and n points in the plane. This is often called **Hopcroft's problem**. A well-known construction of Erdős provides an arrangement of n lines such that at least n of its vertices are each incident to $\Omega(n^{1/3})$ edges. Choosing these n lines as input to Hopcroft's problem and placing the n points very near the high-degree vertices suggests that to solve the problem should require checking each point against the $\Omega(n^{1/3})$ lines incident to the nearby vertex, for a total of $\Omega(n^{4/3})$ time. This argument can be made rigorous [Eri96]; it offers a strong hint that to beat $\Omega(n^{4/3})$ might not be easy. The bound itself has not been achieved, although an algorithm by Matoušek, based on a subtle use of cuttings, comes near.

THEOREM 44.3.3 [Mat93]

To decide whether n points and n lines in the plane are free of any incidence can be done in time $n^{4/3} 2^{O(\log^* n)}$.

SIMPLEX RANGE SEARCHING

Two essential tools in designing data structures for simplex range searching are the *simplicial partition* and the *spanning path*. We mention the key results about these constructions. As a matter of terminology, we say that a hyperplane cuts a line segment if it intersects it but neither of its endpoints. The n points of a square grid can easily be connected by a path so that no line cuts more than roughly $\sqrt{n}$ edges. The optimal low-cutting spanning path construction of Chazelle and Welzl generalizes this result to any set of points in any dimension.

LEMMA 44.3.4 [CW89]

Any set of n points in $\mathbb{R}^d$ can be ordered as $p_1, \dots, p_n$, in such a way that no hyperplane cuts more than $cn^{1-1/d}$ segments of the form $p_i p_{i+1}$, for some constant $c > 0$.

Simplicial partitions generalize the notion of a spanning path by considering not just edges, i.e., pairs of points, but larger subsets of them. Again, we wish to minimize the cutting number, i.e., the number of subsets a hyperplane can “cut through.” An optimal construction based on cuttings was discovered by Matoušek.

LEMMA 44.3.5 [Mat92]

Given a set P of n points in $\mathbb{R}^d$ ($d > 1$), for any integer $1 < r \leq n/2$ there exists a simplicial partition with cutting number $O(r^{1-1/d})$ such that $n/r \leq |P_i| < 2n/r$ for each (P_i, R_i) in the partition.

The partition tree offers a simple solution to simplex range searching. At each node, store the sum of the weights of the points associated with the corresponding region. Given a query simplex σ , we proceed to explore all children v_i of the root and check whether σ intersects the region R_i of v_i : (i) if the answer is yes, but σ does not completely enclose the region R_i of v_i , then we visit v_i and recurse; (ii) if the answer is yes, but σ completely encloses R_i , we simply add to our current weight count the sum of the weights within P_i , which happens to be stored at v_i ; (iii) if the answer is no, we do not recurse at v_i .

The application of Lemma 44.3.5 for a large enough constant r yields a partition

tree construction that allows us to perform simplex range searching in $O(n^{1-1/d+\epsilon})$ query time, for any fixed $\epsilon > 0$, using $O(n)$ storage. A more complex argument by Matoušek gets rid of the ϵ term in the exponent.

THEOREM 44.3.6 [Mat92]

Given n points in $\mathbb{R}^d$, there exists a linear size data structure with which simplex range searching can be performed in time $O(n^{1-1/d})$ per query.

If superlinear storage is available, then space-time tradeoffs are possible. Chazelle, Sharir, and Welzl [CSW92] proved that simplex range searching with respect to n points in $\mathbb{R}^d$ can be done in $O(n^{1+\epsilon}/m^{1/d})$ query time, using a data structure of size m , for any $n \leq m \leq n^d$. Matoušek [Mat93] slightly improved the query time to $O(n(\log m/n)^{d+1}/m^{1/d})$, for m/n large enough.

POLYHEDRAL ALGORITHMS

We discuss applications of the discrepancy method to convex hulls, Voronoi diagrams, halfspace intersection, linear programming, and other forms of convex programming.

The problem of computing the convex hull of n points in $\mathbb{R}^d$ reduces by duality to that of computing the intersection of n halfspaces. In addition, computing the Voronoi diagram (or, equivalently, the Delaunay triangulation) of a finite set of points in Euclidean d -space can be reduced in linear time to a convex hull problem in $(d+1)$ -space. An optimal halfspace intersection algorithm can then be used for both the convex hull and the Voronoi diagram problems. The intersection of n halfspaces is a convex polyhedron with $O(n^{\lfloor d/2 \rfloor})$ faces (and possibly as many as that).

A simple approach to the halfspace intersection problem is to insert each halfspace one after the other and maintain the current intersection as we go. A simple data structure consisting of a triangulation of the current intersection polyhedron, together with a bipartite graph indicating which hyperplane intersects which cell of the triangulation, is sufficient to make this process efficient. In fact, if the order of insertion is random, then it follows from the work of Clarkson and Shor [CS89] that, with the right supporting data structure, the expected complexity of the algorithm can be made to be optimal. By combining the use of ϵ -nets, ϵ -approximations, ϵ -cuttings, and product set systems, Chazelle [Cha93b] showed how to compute the intersection deterministically in optimal time (Theorem 44.3.7); his algorithm was subsequently simplified by Brönnimann, Chazelle, and Matoušek [BCM99].

THEOREM 44.3.7

The polyhedron formed by the intersection of n halfspaces in $\mathbb{R}^d$ can be computed in $O(n \log n + n^{\lfloor d/2 \rfloor})$ time.

As indicated earlier, this result has two important consequences: optimal algorithms for convex hulls and for Voronoi diagrams.

THEOREM 44.3.8

The convex hull of a set of n points in $\mathbb{R}^d$ can be computed deterministically in $O(n \log n + n^{\lfloor d/2 \rfloor})$ time.

THEOREM 44.3.9

The Voronoi diagram (or Delaunay triangulation) of a set of n points in $\mathbf{E}^d$ can be computed deterministically in $O(n \log n + n^{\lceil d/2 \rceil})$ time.

Linear programming is the problem of minimizing a linear function $c^T x$, subject to the constraints $Ax \leq b$ and $x \geq 0$, where A is an n -by- d matrix, $b \in \mathbb{R}^n$, and $c, x \in \mathbb{R}^d$. The discrepancy method can be used to derive a deterministic algorithm for linear programming that is linear in n and singly exponential in d .

The best route to this result is via an abstract formalism, called **LP-type programming**, due to Sharir and Welzl [SW92] (see also [MSW96]) that places the method in a much more general context and allows for even more surprising applications. For example, it can be used to prove that, given n points in, say, $\mathbb{R}^{99}$, the smallest enclosing ellipsoid can be found in $O(n)$ time.

An **LP-type problem** is specified by a pair (H, w) , where H is a finite set whose elements are the “constraints” of the problem, and w is a function mapping certain subsets of H to a totally ordered universe $(W, \leq)$. An element $h \in H$ is said to **violate** a subset $G \subseteq H$ if $w(G) < w(G \cup \{h\})$. A **basis** B of $G \subseteq H$ is a minimal set of constraints with the same cost as G , i.e., $w(B) = w(G)$ and $w(C) < w(B)$ for any $C \subset B$. The **combinatorial dimension** of (H, w) , denoted by δ , is the maximum size of any basis (of any subset of H). To solve the problem (H, w) is to find a basis of H . We need a few specific assumptions to make computational sense of this framework.

1. **MONOTONICITY.** Given any $F \subseteq G \subseteq H$, $w(F) \leq w(G)$.
2. **LOCALITY.** If $h \in H$ violates $G \subseteq H$, then it violates any basis of G .
3. **ORACLE.** Given a basis B of some subset of H , let $V(B)$ denote the set of violating constraints. Consider the set system $(H, \mathcal{R})$, where $\mathcal{R}$ is the collection of sets $V(B)$, for all bases B . It is assumed that $(H, \mathcal{R})$ has bounded VC-dimension, and let γ be its shatter function exponent. In practice, γ is either equal to or larger than δ . Given any subset $Y \subseteq H$, the oracle computes the set $\mathcal{R}|_Y$ in time $O(|Y|^{\gamma+1})$.

How does linear programming fit into the LP-type framework? For simplicity of explanation, we assume that the optimization function is of the form $(1, 0, \dots, 0)^T x$, and that the system is feasible: (i) H is the set of n closed halfspaces formed by the inequalities $Ax \leq b$; (ii) $W = \mathbb{R}^d$, ordered lexicographically; (iii) given $G \subseteq H$, $w(G)$ is the unique (lexicographically) minimal point with nonnegative coordinates in the halfspaces of G . A halfspace $h \in H$ violates $G \subseteq H$ if $w(G) < w(G \cup \{h\})$, which means that adding h to G would strictly increase the cost of the optimal solution: Geometrically, the hyperplane corresponding to h cuts off the old solution from the new feasible set. A basis consists of at most d halfspaces, and its combinatorial dimension is d . **MONOTONICITY** says that throwing in additional constraints cannot improve the optimal solution. **LOCALITY** means that the violation of a set of constraints can always be witnessed locally by focusing on any one of its bases. The oracle can be implemented easily so as to run in time $O(|Y|^{d+1})$.

Solving an LP-Type Problem

STEP 1. Let $D = \max\{\delta, \gamma\}$. If $|H| \leq cD^4 \log D$ for some suitably large constant c , compute a basis of H by checking all possible j -tuples of

constraints in the order $j = 1, \dots, \delta$, and picking the first one that is not violated by any constraint of H .

STEP 2. Compute a $(1/4D^2)$ -net N for $(H, \mathcal{R})$.

STEP 3. Find a basis B of N recursively. Let V be the set of constraints of H that violate B . If $V = \emptyset$, then return B and stop; else add all of the violating constraints to the set N and repeat Step 3.

Assuming that, given any basis B and a constraint $h \in H$, to test whether h violates B or not can be done in time $D^{O(D)}$, which is the case in typical applications, LP-type problems can be solved in time linear in the number of constraints and exponential in the number of variables. Chazelle and Matoušek proved the following:

THEOREM 44.3.10 [CM96]

An LP-type problem (H, w) can be solved in time $|H| \cdot O(D^7 \log D)^D$, where D is the combinatorial dimension or the exponent in the complexity of the oracle, whichever is larger.

We mention two applications of this result, also taken from [CM96]. The first one is a linear deterministic algorithm for linear programming with any fixed number of variables. The second one addresses the complexity of finding the **Löwner-John ellipsoid** of n points in d -space, i.e., the smallest ellipsoid enclosing the n points (which is known to be unique).

THEOREM 44.3.11

Linear programming with n constraints and d variables can be solved in $d^{O(d)}n$ time.

THEOREM 44.3.12

The ellipsoid of minimum volume that encloses a set of n points in $\mathbb{R}^d$ can be computed in time $d^{O(d^2)}n$.

LOWER BOUNDS FOR RANGE SEARCHING

An **off-line range searching** problem is specified by n points and m regions in $\mathbb{R}^d$. Each point p_i is assigned a *weight* x_i chosen in an additive group or semigroup. The output should be the sum of the weights of the points within each of the m regions. In the **on-line** version of the problem, the points and weights are preprocessed into a data structure and a query is a region whose weight sum constitutes the output.

From the algebraic perspective of adding weights, off-line range searching can be regarded as the problem of multiplying a fixed matrix by an arbitrary vector. The n points and m ranges form a set system Σ , whose incidence matrix we denote by A . The problem is to compute the map $x \in \mathbb{R}^n \mapsto Ax \in \mathbb{R}^m$. We use a linear circuit model with bounded coefficients. This is a directed acyclic graph whose nodes, the *gates*, have indegree 2. With each gate g is associated two complex numbers α_g, β_g of modulus $O(1)$. The gate g takes two complex numbers a, b as input and outputs $\alpha_g a + \beta_g b$. The size of the circuit is the number of edges. The *complexity* of the matrix A is the size of the smallest circuit for computing $x \mapsto Ax$. We note that the circuit depends only on A and must “work” for any input $x \in \mathbb{R}^n$.

It is not hard to prove that the size of the circuit is $\Omega(\log |\det B|)$, where B

is the square submatrix of A whose determinant is largest in absolute value: this is the classical **Morgenstern bound** [Mor73]. A stronger result, due to Chazelle, relates the size of the circuit to the singular values of the matrix A .

LEMMA 44.3.13 *Spectral Lemma* [Cha98]

Given an $n \times n$ $(0,1)$ -matrix A , any circuit for computing Ax has size at least $\Omega(k \log \lambda_k)$, where λ_k is the k th largest eigenvalue of $A^T A$.

A slightly weaker formulation of the spectral bound was given by Chazelle and Lvov [CL01b]. It involves only the traces of $A^T A$ and its square. This has the huge advantage that every component of the formula has a simple combinatorial interpretation: the trace of $A^T A$ (of its square) counts the number of ones (resp. rectangles of ones) in A .

LEMMA 44.3.14 *Trace Lemma* [CL01b]

Given an $n \times n$ $(0,1)$ -matrix A , any circuit for computing Ax has size

$$\Omega_\epsilon \left(n \log \left(\text{tr } M / n - \epsilon \sqrt{\text{tr } M^2 / n} \right) \right),$$

where $M = A^T A$ and $\epsilon > 0$ is an arbitrarily small constant.

The bounds can be made more general to accommodate a few “help” gates, i.e., gates that can compute any function whatsoever [Cha98]. The spectral and trace lemmas have been used to derive bounds for a number of classical range searching problems. The monotone model of computation, where essentially subtractions are disallowed, has also been investigated. We mention the main results below and explain their meaning. The proofs rely heavily on tools from discrepancy theory, in particular, on constructions of low-discrepancy point sets and techniques from harmonic analysis to analyze the spectrum of geometric incidence matrices.

TABLE 44.3.1 Circuit lower bounds for range searching.

TYPE	GENERAL	MONOTONE
Axis-parallel boxes	$\Omega(n \log \log n)$	$\Omega(n(\log n / \log \log n)^{d-1})$
Simplices	$\Omega(n \log n)$	$\tilde{\Omega}(n^{2-2/(d+1)})$
Lines	$\Omega(n \log n)$	$\Omega(n^{4/3})$

The table indicates some of the lower bounds known to date. In all cases, the problem consists of n points in $\mathbb{R}^d$ and n regions whose type is indicated in the first column. The GENERAL column refers to the circuit model discussed above. The proofs were given for $\alpha_g, \beta_g \in \{-1, 0, 1\}$, but extend trivially to any complex numbers with bounded modulus. The bounds for axis-parallel boxes [Cha97] and simplices [Cha98] were proven in dimension 2 and, hence, in any higher dimension. In the case of axis-parallel boxes, the lower bound jumps to $\Omega(n \log n)$ in dimension $\Theta(\log n)$ [CL01a]. The bound for lines was proven in [CL01b].

The MONOTONE column assumes that $\alpha_g, \beta_g \in \{0, 1\}$ at each gate of the circuit. The notation $\tilde{\Omega}(f(n))$ refers to $\Omega(f(n)/(\log n)^{O(1)})$. The bounds for axis-parallel boxes and simplices were given in [Cha97]. The bound for lines is mentioned in [Cha00]. All three bounds are essentially optimal in that model.

It is a fascinating open question how the wide gap between general and non-monotone complexity is to be resolved. For example, is line range searching in $O(n \log n)$ or $O(n^{4/3})$? Most of the lower bounds for the monotone case have nearly matching upper bounds; in other words, to make effective use of nonmonotone computation seems very difficult. This has led to the widely held belief that the monotone bounds are the true answers. Recent work by Chazelle [Cha02] casts doubt on this conjecture. By means of grid points and line queries that bounce off the grid boundary, the general complexity of the problem is shown to be $\Theta(n \log n)$, while the monotone complexity is $\Theta(n^{3/2})$.

In the on-line version of range searching, the n points are preprocessed so that, given a query region, the sum of the weights of the points in the region can be computed quickly. The following bounds, established by Chazelle in the monotone model, are essentially optimal. Both of them make heavy use of low-discrepancy constructions for point sets in bounded-dimensional space, as well as of related constructions arising from Heilbronn's problem [Rot51].

THEOREM 44.3.15 [Cha89]

Given n points in $\mathbb{R}^d$, on-line simplex range searching requires $\tilde{\Omega}(n/m^{1/d})$ query time, using a data structure of size m .

THEOREM 44.3.16 [Cha90]

Given n points in $\mathbb{R}^d$, on-line range searching with axis-parallel box queries requires $\Omega(\log n / \log(2m/n))^{d-1}$ per query, using a data structure of size m .

FURTHER READING

Many aspects of the discrepancy method, including nongeometric ones, are covered in [Cha00]. The related topic of derandomization is surveyed in [Mat96]. The main texts on discrepancy theory are [BC87, Nie92, DT97, Mat99]; see also [BS95].

APPLICATIONS OF DISCRETE AND COMPUTATIONAL GEOMETRY

45 LINEAR PROGRAMMING

Martin Dyer, Nimrod Megiddo, and Emo Welzl

INTRODUCTION

Linear programming has many important practical applications, and has also given rise to a wide body of theory. See Section 45.9 for recommended sources. Here we consider the linear programming problem in the form of maximizing a linear function of d variables subject to n linear inequalities. We focus on the relationship of the problem to computational geometry, i.e., we consider the problem in small dimension. More precisely, we concentrate on the case where $d \ll n$, i.e., $d = d(n)$ is a function that grows very slowly with n . By linear programming duality, this also includes the case $n \ll d$. This has been called *fixed-dimensional* linear programming, though our viewpoint here will not treat d as constant. In this case there are strongly polynomial algorithms, provided the rate of growth of d with n is small enough.

The plan of the chapter is as follows. In Section 45.2 we consider the simplex method, in Section 45.3 we review deterministic linear time algorithms, in Section 45.4 randomized algorithms, and in Section 45.5 we consider the derandomization of the latter. Section 45.6 discusses the combinatorial framework of LP-type problems, which underlie most current combinatorial algorithms and allows their application to a host of optimization problems. In Section 45.7 we examine parallel algorithms for this problem, and finally in Section 45.8 we briefly discuss related issues. The emphasis throughout is on complexity-theoretic bounds for the linear programming problem in the form 45.1.1.

45.1 THE BASIC PROBLEM

Any linear program (LP) may be expressed in the inequality form

$$\begin{aligned} \text{maximize} \quad & z = c \cdot x \\ \text{subject to} \quad & Ax \leq b, \end{aligned} \tag{45.1.1}$$

where $c \in \mathbb{R}^d$, $b \in \mathbb{R}^n$, and $A \in \mathbb{R}^{n \times d}$ are the input data and $x \in \mathbb{R}^d$ the variables. Without loss of generality, the columns of A are assumed to be linearly independent. The vector inequality in (45.1.1) is with respect to the componentwise partial order on $\mathbb{R}^n$. We will write a_i for the i th row of A , so the constraint may also be expressed in the form

$$a_i \cdot x = \sum_{j=1}^d a_{ij} x_j \leq b_i \quad (i = 1, \dots, n). \tag{45.1.2}$$

GLOSSARY

Constraint: A condition that must be satisfied by a solution.

Inequality form: The formulation of the linear programming problem where all the constraints are weak inequalities $a_i \cdot x \leq b_i$.

Feasible set: The set of points that satisfy all the constraints. In the case of linear programming, it is a convex polyhedron in $\mathbb{R}^d$.

Defining hyperplanes: The hyperplanes described by the equalities $a_i \cdot x = b_i$.

Tight constraint: An inequality constraint is tight at a certain point if the point lies on the corresponding hyperplane.

Infeasible problem: A problem with an empty feasible set.

Unbounded problem: A problem with no finite maximum.

Vertex: A feasible point where at least d linearly independent constraints are tight.

Nondegenerate problem: A problem where at each vertex precisely d constraints are tight.

Strongly polynomial-time algorithm: An algorithm for which the total number of arithmetic operations and comparisons (on numbers whose size is polynomial in the input length) is bounded by a polynomial in n and d alone.

We observe that (45.1.1) may be infeasible or unbounded, or have multiple optima. A complete algorithm for linear programming must take account of these possibilities. In the case of multiple optima, we assume that we have merely to identify *some* optimum solution. (The task of identifying *all* optima is considerably more complex; see [Dye83, AF92].) An optimum of (45.1.1) will be denoted by x^0 . At least one such solution (assuming one exists) is known to lie at a vertex of the feasible set. There is little loss in assuming nondegeneracy for theoretical purposes, since we may “infinitesimally perturb” the problem to ensure this using well-known methods [Sch86]. However, a complete algorithm must recognize and deal with this possibility.

It is well known that linear programs can be solved in time polynomial in the total length of the input data. However, it is not known in general if there is a *strongly* polynomial-time algorithm. This is true even if randomization is permitted. (Algorithms mentioned below may be assumed deterministic unless otherwise stated.) The “weakly” polynomial algorithms make crucial use of the size of the numbers, so seem unlikely to lead to strongly polynomial methods. However, strong bounds are known in some special cases. For example, if all a_{ij} are bounded by a constant, then É. Tardos [Tar86] has given a strongly polynomial algorithm.

45.2 THE SIMPLEX METHOD

GLOSSARY

Simplex method: For a nondegenerate problem in inequality form, this method seeks an optimal vertex by iteratively moving from one vertex to a better neighboring vertex.

Pivot rule: The rule by which a neighboring vertex is chosen.

Random-edge simplex algorithm: A randomized variant of the simplex method where the neighboring vertex is chosen uniformly at random.

Dantzig's simplex method is probably still the most commonly used method for solving large linear programs in practice, but (with standard pivot rules) Klee and Minty showed that Dantzig's pivot rule may require an exponential number of iterations in the worst case. For example, it may require $2^d - 1$ iterations when $n = 2d$. Other variants were subsequently shown to have similar behavior. While it is not known for certain that all suggested variants of the simplex method have this bad worst case, there seems to be no reason to believe otherwise. In our case $d \ll n$, the simplex method may require $\Omega(n^{\lfloor d/2 \rfloor})$ iterations [KM72, AZ99], and thus it is polynomial only for $d = O(1)$. This is asymptotically no better than enumerating all vertices of the feasible region.

By contrast, Kalai [Kal92] gave a randomized simplex-like algorithm that requires only $2^{O(\sqrt{d \log n})}$ iterations. (An identical bound was also given by Matoušek, Sharir, and Welzl [MSW96] for a closely related algorithm; see Section 45.4.) Combined with Clarkson's methods [Cla95], this results in a bound of $O(d^2 n) + e^{O(\sqrt{d \log d})}$ (cf. [MSW96]). This is the best "strong" bound known, other than for various special problems, and it is evidently polynomial provided $d = O(\log^2 n / \log \log n)$. No complete derandomization of these algorithms is known, and it is possible that randomization may genuinely help here. In this respect, the complexity of the so-called random-edge simplex method (where the pivot is chosen uniformly at random) is an open question. See [BDF⁺95, GHZ98, GST⁺01] for some limited information.

45.3 LINEAR-TIME LINEAR PROGRAMMING

The study of linear programming within computational geometry was initiated by Shamos [Sha78] as an application of an $O(n \log n)$ convex hull algorithm for the intersection of halfplanes. Muller and Preparata [MP78] gave an $O(n \log n)$ algorithm for the intersection of halfspaces in $\mathbb{R}^3$. Dyer [Dye84] and Megiddo [Meg83] found, independently, an $O(n)$ time algorithm for the linear programming problem in the cases $d = 2, 3$.

Megiddo [Meg84] generalized the approach of these algorithms to arbitrary d , arriving at an algorithm of complexity $O(2^{2^d} n)$, which is polynomial for $d \leq \log \log n + O(1)$. This was subsequently improved by Clarkson [Cla86b] and Dyer [Dye86] to $O(3^{d^2} n)$, which is polynomial for $d = O(\sqrt{\log n})$. Megiddo [Meg84, Meg89] and Dyer [Dye86, Dye92] showed that Megiddo's idea could be used for many related problems: Euclidean one-center, minimum ball containing balls, minimum volume ellipsoid, etc.; see also the derandomized methods and LP-type problems in the sections below.

GLOSSARY

Multidimensional search: Given a set of hyperplanes and an oracle for locating a point relative to any hyperplane, locate the point relative to all the input hyperplanes.

MEGIDDO'S ALGORITHMS

The basic idea in these algorithms is as follows. It follows from convexity considerations that either the constraints in a linear program are tight (i.e., satisfied with equality) at x^0 , or they are irrelevant. We need identify only d tight constraints to identify x^0 . We do this by discarding a fixed proportion of the irrelevant constraints at each iteration. Determining whether the i th constraint is tight amounts to determining which case holds in $a_i \cdot x^0 \geq b_i$. This is embedded in a multidimensional search problem. Given *any* hyperplane $\alpha \cdot x = \beta$, we can determine which case of $\alpha \cdot x^0 \geq \beta$ holds by (recursively) solving three linear programs in $d - 1$ variables.

These are (45.1.1) plus $a \cdot x = \gamma$, where $\gamma \in \{\beta - \epsilon, \beta, \beta + \epsilon\}$ for “small” $\epsilon > 0$. (We need not define ϵ explicitly; it can be handled symbolically.) In each of the three linear programs we eliminate one variable to get $d - 1$. The largest of the three objective functions tells us where x^0 lies with respect to the hyperplane. We call this an *inquiry* about $\alpha \cdot x = \beta$. The problem now reduces to locating x^0 with respect to a proportion $P(d)$ of the n hyperplanes using only $N(d)$ inquiries.

The method recursively uses the following observation in $\mathbb{R}^2$. Given two lines through the origin with slopes of opposite sign, knowing which quadrant a point lies in allows us to locate it with respect to *at least one* of the lines (see Figure 45.3.1).

FIGURE 45.3.1

Quadrants 1, 3 locate for l_2 ; quadrants 2, 4 locate for l_1 .

We use this on the first two coordinates of the problem in $\mathbb{R}^d$. First rotate until $\frac{1}{2}n$ defining hyperplanes have positive and $\frac{1}{2}n$ negative “slopes” on these coordinates. This can be done in $O(n)$ time using median-finding. Then arbitrarily pair a positive with a negative to get $\frac{1}{2}n$ pairs of the form

$$\begin{aligned} ax_1 + bx_2 + \cdots &= \cdots \\ cx_1 - dx_2 + \cdots &= \cdots, \end{aligned}$$

where a, b, c, d represent nonnegative numbers, and the $\cdots$ represent linear functions of $x_3, \dots, x_d$ on the left and arbitrary numbers on the right. Eliminating x_2 and x_1 in each pair gives two families S_1, S_2 of $\frac{1}{2}n$ hyperplanes each in $d - 1$ dimensions of the form

$$\begin{aligned} S_1 : \quad x_1 &+ \cdots = \cdots \\ S_2 : \quad x_2 &+ \cdots = \cdots. \end{aligned}$$

We recursively locate with respect to $\frac{1}{2}P(d-1)n$ hyperplanes with $N(d-1)$ inquiries in S_1 , and then locate with respect to a $P(d-1)$ -fraction of the corresponding paired hyperplanes in S_2 . We have then located $\frac{1}{2}P(d-1)^2n$ pairs with $2N(d-1)$ inquiries. Using the observation above, each pair gives us location with respect to at least

one hyperplane in d dimensions, i.e.,

$$P(d) = \frac{1}{2}P(d-1)^2, \quad N(d) = 2N(d-1). \quad (45.3.1)$$

Since $P(1) = \frac{1}{2}, N(1) = 1$ (by locating with respect to the median in $\mathbb{R}^1$), (45.3.1) yields

$$P(d) = 2^{-(2^d-1)}, \quad N(d) = 2^{d-1},$$

giving the following time bound $T(n, d)$ for solving (45.1.1).

$$T(n, d) \leq 3 \cdot 2^{d-1}T(n, d-1) + T((1 - 2^{-(2^d-1)})n, d) + O(nd),$$

with solution $T(n, d) = O(2^{2^d}n)$.

THE CLARKSON-DYER IMPROVEMENT

The Clarkson/Dyer improvement comes from repeatedly locating in S_1 and S_2 to increase $P(d)$ at the expense of $N(d)$.

45.4 RANDOMIZED ALGORITHMS

Dyer and Frieze [DF89] showed that, by applying an idea of Clarkson [Cla86a] to give a *randomized* solution of the multidimensional search in Megiddo's algorithm [Meg84], an algorithm of complexity $O(d^{3d+o(d)}n)$ was possible. Clarkson [Cla88, Cla95] improved this dramatically. We describe this below, but first outline a simpler algorithm subsequently given by Seidel [Sei91].

Suppose we order the constraints randomly. At stage k , we have solved the linear program subject to constraints $i = 1, \dots, k-1$. We now wish to add constraint k . If it is satisfied by the current optimum we finish stage k and move to $k+1$. Otherwise, the new constraint is clearly tight at the optimum over constraints $i = 1, \dots, k-1$. Thus, recursively solve the linear program subject to this equality (i.e., in dimension $d-1$) to get the optimum over constraints $i = 1, \dots, k$, and move on to $k+1$. Repeat until $k = n$.

The analysis hinges on the following observation. When constraint k is added, the probability it is not satisfied is exactly d/k (assuming, without loss, nondegeneracy). This is because only d constraints are tight at the optimum and this is the probability of writing one of these *last* in a random ordering of $1, 2, \dots, k$. This leads to an expected time of $O(d!n)$ for (45.1.1). Welzl [Wel91] extended Seidel's algorithm to solve other problems such as smallest enclosing ball or ellipsoid, and described variants that perform favorably in practice.

Sharir and Welzl [SW92] modified Seidel's algorithm, resulting in an improved running time of $O(d^3 2^d n)$. They put their algorithm in a general framework of solving "LP-type" problems (see Section 45.6 below). Matousek, Sharir, and Welzl [MSW96] improved the analysis further, essentially obtaining the same bound as for Kalai's "primal simplex" algorithm. The algorithm was extended to LP-type problems by Gärtner [Gär95], with a similar time bound.

CLARKSON'S ALGORITHM

The basic idea is to choose a random set of r constraints, and solve the linear program subject to these. The solution will violate “few” constraints among the remaining $n - r$, and, moreover, one of these must be tight at x^0 . We solve a new linear program subject to the violated constraints and a new random subset of the remainder. We repeat this procedure (aggregating the old violated constraints) until there are no new violated constraints, in which case we have found x^0 . Each repetition gives an extra tight constraint for x^0 , so we cannot perform more than d iterations.

Clarkson [Cla88] gave a different analysis, but using Seidel’s idea we can easily bound the expected number of violated constraints (see also [GW01] for further simplifications of the algorithm). Imagine all the constraints ordered randomly, our sample consisting of the first r . For $i > r$, let $I_i = 1$ if constraint i is violated, $I_i = 0$ otherwise. Now $\Pr(I_i = 1) = \Pr(I_{r+1} = 1)$ for all $i > r$ by symmetry, and $\Pr(I_{r+1} = 1) = d/(r + 1)$ from above. Thus the expected number of violated constraints is

$$\mathbf{E} \left(\sum_{i=r+1}^n I_i \right) = \sum_{i=r+1}^n \Pr(I_i = 1) = (n - r)d/(r + 1) < nd/r.$$

(In the case of degeneracy, this will be an upper bound by a simple perturbation argument.)

Thus, if $r = \sqrt{n}$, say, there will be at most $d\sqrt{n}$ violated constraints in expectation. Hence, by Markov’s inequality, with probability $\frac{1}{2}$ there will be at most $2d\sqrt{n}$ violated constraints in actuality. We must therefore recursively solve about $2(d + 1)$ linear programs with at most $(2d^2 + 1)\sqrt{n}$ constraints. The “small” base cases can be solved by the simplex method in $d^{O(d)}$ time. This can now be applied recursively, as in [Cla88], to give a bound for (45.1.1) of

$$O(d^2n) + (\log n)^{\log d+2} d^{O(d)}.$$

Clarkson [Cla95] subsequently modified his algorithm using a different “iterative reweighting” algorithm to solve the $d + 1$ small linear programs, obtaining a better bound on the execution time.

Each constraint receives an initial weight of 1. Random samples of total weight $10d^2$ (say) are chosen at each iteration, and solved by the simplex method. If W is the current total weight of all constraints, and W' the weight of the unsatisfied constraints, then $W' \leq 2Wd/10d^2 = W/5d$ with probability at least $\frac{1}{2}$ by the discussion above, regarding the weighted constraints as a multiset. We now double the weights of all violated constraints and repeat until there are no violated constraints. This terminates in $O(d \log n)$ iterations by the following argument. After k iterations we have

$$W \leq \left(1 + \frac{1}{5d}\right)^k n \leq ne^{k/5d},$$

and W^* , the total weight of the d optimal constraints, satisfies $W^* \geq 2^{k/d}$, since at least one is violated at each iteration. Now it is clear that $W^* < W$ only while $k < Cd \ln n$, for some constant C . Applying this to the $d + 1$ small linear programs gives overall complexity

$$O(d^2n + d^4\sqrt{n}\log n) + d^{O(d)}\log n.$$

This is almost the best time known for linear programming, except that Kalai's algorithm (or [MSW96]) can be used to solve the base cases rather than the simplex method. Then we get the improved bound (cf. [GW96])

$$O(d^2n) + e^{O(\sqrt{d\log d})}.$$

This is polynomial for $d = O(\log^2 n / \log \log n)$, and is the best bound to date.

45.5 DERANDOMIZED METHODS

Somewhat surprisingly, the randomized methods of Section 45.4 can also lead to the best *deterministic* algorithms for (45.1.1). Matoušek and Chazelle [CM96] produced a derandomized version of Clarkson's algorithm.

The idea, which has wider application, is based on finding (in linear time) *approximations* to the constraint set. If N is a constraint set, then for each $x \in \mathbb{R}^d$ let $V(x, N)$ be the set of constraints violated at x . A set $S \subseteq N$ is an ϵ -approximation to N if, for all x ,

$$\left| \frac{|V(x, S)|}{|S|} - \frac{|V(x, N)|}{|N|} \right| < \epsilon.$$

(See also [Chapters 36](#) and 40.) Since $n = |N|$ hyperplanes partition $\mathbb{R}^d$ into only $O(n^d)$ regions, there is essentially only this number of possible cases for x , i.e., only this number of different sets $V(x, N)$. It follows from the work of Vapnik and Chervonenkis that a (d/r) -approximation of size $O(r^2 \log r)$ always exists, since a random subset of this size has the property with nonzero probability. If we can find such an approximation deterministically, then we can use it in Clarkson's algorithm in place of random sampling. If we use a (d/r) -approximation, then, if x^* is the linear programming optimum for the subset S , $|V(x^*, S)| = 0$, so that

$$|V(x^*, N)| < |N|d/r = nd/r,$$

as occurs in expectation in the randomized version. The implementation involves a refinement based on two elegant observations about approximations, which both follow directly from the definition.

- (i) An ϵ -approximation of a δ -approximation is an $(\epsilon + \delta)$ -approximation of the original set.
- (ii) If we partition N into q equal sized subsets $N_1, \dots, N_q$ and take an (equal sized) ϵ -approximation S_i in each N_i ($i = 1, \dots, q$), then $S_1 \cup \dots \cup S_q$ is an ϵ -approximation of N .

We then *recursively* partition N into q equal sized subsets, to give a “partition tree” of height k , say, as in Figure 45.5.1 (cf. Section 36.2). The sets at level 0 in the partition tree are “small.” We calculate an ϵ_0 -approximation in each. We now take the union of these approximations at level 1 and calculate an ϵ_1 -approximation of this union. This is an $(\epsilon_0 + \epsilon_1)$ -approximation of the whole level

FIGURE 45.5.1

A partition tree of height k , with $q = 3$.

1 set, by the above observations. Continuing up the tree, we obtain an overall $(\sum_{i=0}^k \epsilon_i)$ -approximation of the entire set. At each stage, the sets on which we have to find the approximations remain “small” if the ϵ_i are suitably chosen. Therefore we can use a relatively inefficient method of finding an approximation. A suitable method is the *method of conditional probabilities* due to Raghavan and Spencer. It is (relatively) straightforward to implement this on a set of size m to run in $O(m^{d+1})$ time. However, since this has to be applied only to small sets (in comparison with n), the total work can be bounded by a linear function of n . Chazelle and Matoušek [CM96] used $q = 2$, and an ϵ_i that corresponds to roughly halving the union at each level $i = 1, \dots, k$.

The algorithm cannot completely mimic Clarkson’s, however, since we can no longer use $r = \sqrt{n}$. Such a large approximation cannot be determined in linear time by the above methods. But much smaller values of r suffice (e.g., $r = 10d^3$) simply to get *linear-time* behavior in the recursive version of Clarkson’s algorithm. Using this observation, Chazelle and Matoušek [CM96] obtained a deterministic algorithm with time-complexity $d^{O(d)}n$. This is currently the best time bound known for solving (45.1.1), and remains polynomial for $d = O(\log n / \log \log n)$.

45.6 LP-TYPE PROBLEMS

The randomized algorithms above by Clarkson and in [MSW96, Gär95] can be formulated in an abstract framework called *LP-type problems*. With an extra condition (involving VC-dimension of certain set-systems) this extends to the derandomization in [CM96]. In this way, the algorithms are applicable to a host of problems including smallest enclosing ball, polytope distance, smallest enclosing ellipsoid, largest ellipsoid in polytope, smallest ball intersecting a set of convex objects, angle-optimal placement in polygon, rectilinear 3-centers in the plane, spherical separability, width of thin point sets in the plane, and integer linear programming (see [MSW96, GW96] for descriptions of these problems and of the reductions needed). A different abstraction called *abstract objective functions* is described by Kalai in [Kal97], and for the even more general setting of *abstract optimization problems* see [Gär95].

For the definitions below, the reader should think of optimization problems in which we are given some set H of constraints and we want to *minimize* some given function under those constraints. For every subset G of H , let $w(G)$ denote the optimum value of this function when all constraints in G are satisfied. The function w is only given implicitly via some basic operations to be specified below. The goal is to compute an inclusion-minimal subset B_H of H with the same value as H (from which, in general, the value is easy to determine).

GLOSSARY

LP-type problem: A pair (H, w) , where H is a finite set and $w : 2^H \rightarrow \mathcal{W}$ for a linearly ordered set $(\mathcal{W}, \leq)$ with a minimal element $-\infty$, so that the monotonicity and locality axioms below are satisfied.

Monotonicity axiom: For any F, G with $F \subseteq G \subseteq H$, we have $w(F) \leq w(G)$.

Locality axiom: For any $F \subseteq G \subseteq H$ with $-\infty \neq w(F) = w(G)$ and for any $h \in H$, $w(G) < w(G \cup \{h\})$ implies $w(F) < w(F \cup \{h\})$.

Constraints of LP-type problem: Given an LP-type problem (H, w) , the elements of H are called constraints.

Basis: A set B of constraints is called a basis if $w(B') < w(B)$ for every proper subset of B .

Basis of set of constraints: Given a set G of constraints, a subset $B \subseteq G$ is called a basis of G if it is a basis and $w(B) = w(G)$ (i.e., an inclusion-minimal subset of G with equal w -value).

Combinatorial dimension: The maximum cardinality of any basis in an LP-type problem (H, w) , denoted by $\delta = \delta_{(H, w)}$.

Basis regularity: An LP-type problem (H, w) is basis-regular if, for every basis B with $|B| = \delta$ and for every constraint h , all bases of $B \cup \{h\}$ have exactly δ elements.

Violation test: Decides whether or not $w(B) < w(B \cup \{h\})$, for a basis B and a constraint h .

Basis computation: Delivers a basis of $B \cup \{h\}$, for a basis B and a constraint h .

A simple example of an LP-type problem is the smallest enclosing ball problem (this problem traces back to J.J. Sylvester [Syl57]): Let S be a finite set of points in $\mathbb{R}^d$, and for $G \subseteq S$, let $\rho(G)$ be the radius of the ball of smallest volume containing G (with $\rho(\emptyset) = -\infty$). Then (S, ρ) is an LP-type problem with combinatorial dimension at most $d + 1$. A violation test amounts to a test deciding whether a point lies in a given ball, while an efficient implementation of basis computations is not obvious (cf. [Gär95]).

Many more examples have been indicated above. As the name suggests, linear programming can be formulated as an LP-type problem, although some care is needed in the presence of degeneracies. Let us assume that we want to maximize the objective function $-x_d$ in (45.1.1), i.e., we are looking for a point in $\mathbb{R}^d$ of smallest x_d -coordinate. In the underlying LP-type problem, the set H of constraints is given by the halfspaces as defined by (45.1.2). For a subset G of these constraints, let $v(G)$ be the backwards lexicographically smallest point satisfying these constraints, with $v(G) := -\infty$ if G gives rise to an unbounded problem, and with $v(G) := \infty$ in case of infeasibility. We assume the backwards lexicographical ordering on $\mathbb{R}^d$ to be extended to $\mathbb{R}^d \cup \{-\infty, \infty\}$ by letting $-\infty$ and ∞ be the minimal and maximal element, resp. The resulting pair (H, v) is LP-type of combinatorial dimension at most $d + 1$. In fact, if the problem is feasible and bounded, then the LP-type problem is basis-regular of combinatorial dimension d . The violation test and basis computation (this amounts to a dual pivot step) are easy to implement.

Matoušek, Sharir, and Welzl [MSW96] showed that a basis-regular LP-type problem (H, w) of combinatorial dimension δ with n constraints can be solved (i.e.,

a basis of H can be determined) with an expected number of at most

$$\min\{e^{2\sqrt{\delta \ln((n-\delta)/\sqrt{\delta})} + O(\sqrt{\delta} \ln n)}, 2^{\delta+2}(n-\delta)\} \quad (45.6.1)$$

violations tests and basis computations, provided an initial basis B_0 with $|B_0| = \delta$ is available. (For linear programming one can easily generate such an initial basis by adding d symbolic constraints at “infinity”.) Then Gärtner [Gär95] was able to generalize this bound to all LP-type problems. Combining this with Clarkson’s methods, one gets a bound (cf. [GW96]) of

$$O(\delta n) + e^{O(\sqrt{\delta \log \delta})},$$

the best bound known up to now.

Matoušek [Mat94] provided a family of LP-type problems, for which the bound (45.6.1) is tight for the algorithm provided in [MSW96]. It is an open problem, though, whether the algorithm performs faster when applied to linear programming instances. In fact, Gärtner [Gär02] showed that the algorithm is quadratic for the instances in Matousek’s lower bound family which are realizable as linear programming problems as in (45.1.1).

Amenta [Ame94] considers the following extension of the abstract framework: Suppose we are given a family of LP-type problems (H, w_λ) , parameterized by a real parameter λ ; the underlying ordered value set $\mathcal{W}$ has a maximum element ∞ representing *infeasibility*. The goal is to find the smallest λ for which (H, w_λ) is feasible, i.e., $w_\lambda(H) < \infty$. [Ame94] provides conditions under which such a problem can be transformed into a single LP-type problem, and she gives bounds on the resulting combinatorial dimension. This work exhibits interesting relations between LP-type problems and Helly-type theorems (see also [Ame96]).

45.7 PARALLEL ALGORITHMS

GLOSSARY

PRAM: Parallel Random Access Machine. (See [Section 42.1](#) for more information on this and the next two terms.)

EREW: Exclusive Read Exclusive Write.

CRCW: Concurrent Read Concurrent Write.

P: The class of polynomial time problems.

NC: The class of problems that have poly-logarithmic parallel time algorithms running a polynomial number of processors.

P-complete problem: A problem in P whose membership in NC implies $P = NC$.

Expander: A graph in which, for every set of nodes, the set of the neighbors of the nodes is relatively large.

We will consider only PRAM algorithms. (See also [Section 42.2](#).)

The general linear programming problem has long been known to be P-complete, so there is little hope of very fast parallel algorithms. However, the situation is different in the case $d \ll n$, where the problem is in NC if d grows slowly enough.

First, we note that there is a straightforward parallel implementation of Megiddo's algorithm [Meg83] that runs in $O((\log n)^d)$ time on an EREW PRAM. However, this algorithm is rather inefficient in terms of processor utilization, since at the later stages, when there are few constraints remaining, most processors are idle. However, Deng [Den90] gave an "optimal" $O(n)$ work implementation in the plane running in $O(\log n)$ time on a CRCW PRAM with $O(n/\log n)$ processors. Deng's method does not seem to generalize to higher dimensions.

Alon and Megiddo [AM94] gave a *randomized* parallel version of Clarkson's algorithm which, with high probability, runs in constant time on a CREW PRAM in fixed dimension. Here the "constant" is a function of dimension only, and the probability of failure to meet the time bound is small for $n \gg d$.

Ajtai and Megiddo [AM96] attempted to improve the processor utilization in parallelizing Megiddo's algorithm for general d . They gave an intricate algorithm based on using an expander graph to select more nondisjoint pairs so as to utilize all the processors and obtain more rapid elimination. The resulting algorithm for (45.1.1) runs in $O((\log \log n)^d)$ time, but in a nonuniform model of parallel computation based on Valiant's comparison model. The model, which is stronger than the CRCW PRAM, requires $O(\log \log n)$ time median selection from n numbers using n processors, and employs an $O(\log \log n)$ time scheme for compacting the data after deletions, again based on a nonuniform use of expander graphs. A lower bound of $\Omega(\log n / \log \log n)$ time for median-finding on the CRCW PRAM follows from results of Beame and Håstad. Thus Ajtai and Megiddo's algorithm could not be implemented directly on the CRCW PRAM. Within Ajtai and Megiddo's model there is a lower bound $\Omega(\log \log n)$ for the case $d = 1$ implied by results of Valiant. This extends to the CRCW PRAM, and is the only lower bound known for solving (45.1.1) in this model.

Dyer [Dye95] gave a different parallelization of Megiddo's algorithm, which avoids the use of expanders. The method is based on forming groups of size $r \geq 2$, rather than simple pairs. As constraints are eliminated, the size of the groups is gradually increased to utilize the extra processors. Using this, Dyer [Dye95] establishes an $O(\log n (\log \log n)^{d-1})$ bound in the EREW model. It is easy to show that there is an $\Omega(\log n)$ lower bound for solving (45.1.1) on the EREW PRAM, even with $d = 1$. (See [KR90].) Thus improvements on Dyer's bound for the EREW model can only be made in the $\log \log n$ term. However, there was still an open question in the CRCW model, since exact median-finding and data compaction cannot be performed in time polynomial in $\log \log n$.

Goodrich [Goo93] solved these problems for the CRCW model by giving fast implementations of derandomization techniques similar to those outlined in Section 45.5. However, the randomized algorithm that underlies the method is not a parallelization of Clarkson's algorithm, but is similar to a parallelized version of that of Dyer and Frieze [DF89]. He achieves a work-optimal (i.e., $O(n)$ work) algorithm running in $O(\log \log n)^d$ time on the CRCW PRAM. The methods also imply a work-optimal EREW algorithm, but only with the same time bound as Dyer's. Neither Dyer nor Goodrich is explicit about the dependence on d of the execution time of their algorithms.

Independently of Goodrich's work, Sen [Sen95] has shown how to directly modify Dyer's algorithm to give a work-optimal algorithm with $O((\log \log n)^{d+1})$ execution time in the CRCW model. The "constant" in the running time is shown to be $2^{O(d^2)}$. To achieve this, he uses approximate median-finding and approximate data compaction operations, both of which can be done in time polynomial in $\log \log n$.

on the common CRCW PRAM. These additional techniques are, in fact, both examples of derandomized methods and similar to those Goodrich uses for the same purpose. Note that this places linear programming in NC provided $d = O(\sqrt{\log n})$. This is the best result known, although Goodrich's algorithm may give a better behavior once the "constant" has been explicitly evaluated. We may also observe that the Goodrich/Sen algorithms improve on Deng's result in $\mathbb{R}^2$.

There is still room for some improvements in this area, but there now seems to be a greater need for sharper lower bounds, particularly in the CRCW case.

45.8 RELATED ISSUES

GLOSSARY

Integer programming problem: A linear programming problem with the additional constraint that the solution must be integral.

k -violation linear programming: A problem as in 45.1.1, except that we want to maximize the linear objective function subject to all but at most k of the given linear constraints.

Average case analysis: Expected performance of an algorithm for random input (under certain distributions).

Smoothed analysis: Expected performance of an algorithm under small random perturbations of the input.

Linear programming is a problem of interest in its own right, but it is also representative of a class of geometric problems to which similar methods can be applied. Many of the references given below discuss closely related problems, and we have mentioned them in passing above.

An important related area is integer programming. Here the size of the numbers cannot be relegated to a secondary consideration. In general this problem is NP-hard, but in fixed dimension is polynomial-time solvable. See [Sch86] for further information. It may be noted that Clarkson's methods and the LP-type framework are applicable in this situation; some care with the interpretation of the primitive operations is in order, though.

We have considered only the solution of a single linear program. However, there are some situations where one might wish to solve a sequence of closely related linear programs. In this case, it may be worth the computational investment of building a data structure to facilitate fast solution of the linear programs. For results of this type see, for example, [Epp90, Mat93, Cha96, Cha98].

Finally there has been some work about optimization, where we are asked to satisfy all but at most k of the given constraints, see, e.g., [RW94, ESZ94, Mat95b, DLSS95, Cha99]. In particular, Matoušek [Mat95a] has investigated this question in the general setting of LP-type problems. Recently, Chan [Cha02] solved this problem in $\mathbb{R}^2$ with a randomized algorithm in expected time $O(n + k^2)$ (see this paper for the best bounds known for $d = 3, 4$).

A direction we did not touch upon here is *average analysis*, where we analyze a deterministic algorithm for random inputs [Bor87, Sma83]. Of course, the issue

here is to what extent the assumed input distribution is justified, even if the results relate to the measurements made in experiments. More recently, there has been an interesting new direction, where a simplex method is analyzed for small random perturbations of the input (smoothed analysis, [ST01]).

46 MATHEMATICAL PROGRAMMING

Michael J. Todd

INTRODUCTION

Mathematical programming is concerned with minimizing a real-valued function of several variables, which may be either discrete or continuous, subject to equality and/or inequality constraints on other functions of the variables. Optimality conditions and computational schemes for such problems frequently rely on geometrical properties of the set of feasible solutions or subsidiary geometrical constructions. Here we consider these aspects of general nonlinear optimization problems (Section 46.1), general convex programming (Section 46.2, where we discuss the ellipsoid method and its relatives), linear programming (Section 46.3, where we consider the simplex algorithm and more recent interior-point methods), integer and combinatorial optimization (Section 46.4), and special convex programming problems (Section 46.5). The treatment here focuses mainly on methods involving geometric ideas, especially those for which global complexity estimates are known.

46.1 GENERAL NONLINEAR PROGRAMMING

Consider the problem of choosing x to

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && g_i(x) \leq 0, \quad i = 1, \dots, m, \\ & && h_j(x) = 0, \quad j = 1, \dots, p, \end{aligned} \tag{P}$$

where f and all g_i 's and h_j 's are smooth functions on real n -dimensional Euclidean space $\mathbb{R}^n$ and x can vary over all $\mathbb{R}^n$. This is a **general nonlinear programming** problem.

Research on the general nonlinear programming problem seeks to characterize global or local minimizers by appropriate optimality conditions, and to compute or approximate a local minimizer or stationary point by some iterative method.

GLOSSARY

Objective function: The function f above.

Constraint functions: The functions g_i and h_j above.

Feasible point: Point in $\mathbb{R}^n$ satisfying all constraints.

Active constraints: All equality constraints and those inequality constraints holding with equality at a given feasible point.

Global minimizer: Feasible point with objective function value at most that of any other feasible point.

Local minimizer: Feasible point with objective function value at most that of any other sufficiently close feasible point.

Optimality conditions: Conditions that are necessary or sufficient, perhaps under regularity restrictions, for a given point to be a local or global minimizer.

Stationary point: Point satisfying optimality conditions.

Lagrangian function: Function $L(x, u, v) := f(x) + u^T g(x) + v^T h(x)$.

46.1.1 OPTIMALITY CONDITIONS

These are based on Taylor approximations of the objective and constraint functions. Let $\bar{x}$ be a feasible point. We seek conditions that are necessary or sufficient for $\bar{x}$ to be a local minimizer. The first-order **Karush-Kuhn-Tucker conditions**, *necessary* under a regularity condition (such as that the gradients of all constraints active at $\bar{x}$ are linearly independent), involve the Lagrangian function, but because of the presence of inequalities, are more general than the classical Lagrange conditions. They can be stated simply as follows: there exist multipliers $\bar{u}$, $\bar{v}$, such that

$$\begin{aligned}\nabla_x L(\bar{x}, \bar{u}, \bar{v}) &= 0, \\ \nabla_u L(\bar{x}, \bar{u}, \bar{v}) &\leq 0, \quad \bar{u} \geq 0, \quad \bar{u}^T \nabla_u L(\bar{x}, \bar{u}, \bar{v}) = 0, \\ \nabla_v L(\bar{x}, \bar{u}, \bar{v}) &= 0.\end{aligned}$$

THEOREM 46.1.1

Let $\bar{x}$ be a feasible point, and assume the regularity condition that the gradients of all constraints active at $\bar{x}$ are linearly independent. Then the Karush-Kuhn-Tucker conditions are necessary for $\bar{x}$ to be a local minimizer for (P).

Second-order conditions, involving the Hessian (second derivative matrix) of the Lagrangian, are also important because of the role of curvature in nonlinear optimization. For example:

THEOREM 46.1.2

Suppose that the first-order conditions above hold, and in addition that, for all nonzero directions d with $\nabla h_j(\bar{x})^T d = 0$ for all j , $\nabla g_i(\bar{x})^T d = 0$ for all i with $\bar{u}_i > 0$, and $\nabla g_i(\bar{x})^T d \leq 0$ for all other constraints g_i active at $\bar{x}$, $d^T \nabla_{xx}^2 L(\bar{x}, \bar{u}, \bar{v}) d > 0$. Then $\bar{x}$ is a local minimizer. (Thus these are sufficient conditions.)

These results can be found, for example, in [Chapter 12](#) of [NW99] or [Chapter 9](#) of [Fle87]. Note the following special case: For unconstrained problems, $\nabla f(\bar{x}) = 0$ is necessary for $\bar{x}$ to be a local minimizer, while this equality together with $\nabla^2 f(\bar{x})$ positive definite is sufficient.

46.1.2 ALGORITHMS

Methods to approximate stationary points or possibly local minimizers of general smooth nonlinear programming problems are often based on solving a sequence of simpler problems, using the final approximation or solution of the previous problem as a starting point for the new problem. Examples of simpler problems include un-

constrained minimization, using barrier, penalty, or (augmented) Lagrangian functions to incorporate the constraints, or a quadratic minimization subject to linear constraints, where the original nonlinear constraints are linearized and the Hessian of the quadratic objective approximates that of the Lagrangian of the original problem. (Such **quadratic programming** problems can be solved exactly when the objective function is convex, by extensions of methods for linear programming or other algorithms.) If the original problem is unconstrained, and we make a quadratic approximation to the function at each iteration, we recover Newton's method for optimization if the Hessian is exact, and various quasi-Newton methods if approximations are iterated.

Let us describe some typical examples of such algorithms. We state these in simplified form without worrying about important subjects like step size selection, termination criteria, or implementation details. We also omit *globalization* techniques, designed to force convergence to a stationary point or local minimizer from arbitrary starting points (not guaranteeing global minimizers, which is in general much harder!). The subscript k here refers to the iteration number, not a component.

NEWTON'S METHOD FOR UNCONSTRAINED MINIMIZATION

Given iterate x_k , calculate $\nabla f(x_k)$ and $H_k := \nabla^2 f(x_k)$. Stop if $\nabla f(x_k) = 0$ (success) or if H_k is not positive definite (failure). Otherwise, compute the direction d_k as the solution to $H_k d_k = -\nabla f(x_k)$: note that $x_k + d_k$ minimizes the Taylor approximation

$$f(x_k) + \nabla f(x_k)^T (x - x_k) + (1/2)(x - x_k)^T H_k (x - x_k).$$

Let $x_{k+1} := x_k + \alpha_k d_k$ for some step size α_k chosen so that $f(x_{k+1}) < f(x_k)$, and repeat.

BFGS METHOD FOR UNCONSTRAINED MINIMIZATION

This is a very popular quasi-Newton method. Instead of the Hessian matrix being calculated, a positive definite approximation to it is *updated* at each iteration using new information obtained about f . This method is named for Broyden, Fletcher, Goldfarb, and Shanno, who independently developed the update formula below. (More details on the BFGS and related methods can be found in [Chapter 9](#) of [DS96] or [Chapter 8](#) of [NW99].) Initially, choose H_0 , say, as some positive multiple of the identity matrix. At the k th iteration, proceed as above but with H_k the updated approximation. The step size α_k is chosen so that $f(x_{k+1}) < f(x_k)$ and so that, with $y_k := \nabla f(x_{k+1}) - \nabla f(x_k)$ and $s_k := x_{k+1} - x_k$, we have $y_k^T s_k > 0$. Then update H_k to

$$H_{k+1} := H_k - \frac{H_k s_k s_k^T H_k}{s_k^T H_k s_k} + \frac{y_k y_k^T}{y_k^T s_k}$$

(this formula maintains positive definiteness) and repeat. Note that we have $H_{k+1} s_k = y_k$, the so-called secant or quasi-Newton equation; clearly, if f is quadratic, its constant Hessian matrix satisfies this equation.

A SEQUENTIAL QUADRATIC PROGRAMMING METHOD FOR CONSTRAINED MINIMIZATION

Given the iterate x_k and estimates of the Lagrange multipliers u_k and v_k , evaluate the gradients of all functions and $\nabla_{xx}^2 L(x_k, u_k, v_k)$. Then solve the quadratic programming subproblem:

$$\begin{array}{llll} \min_d & \nabla f(x_k)^T d & + & (1/2)d^T \nabla_{xx}^2 L(x_k, u_k, v_k)d \\ & g_i(x_k) & + & \nabla g_i(x_k)^T d & \leq 0, & \text{all } i \\ & h_j(x_k) & + & \nabla h_j(x_k)^T d & = 0, & \text{all } j \end{array}$$

to get d_k . Let $x_{k+1} := x_k + \alpha_k d_k$ for some step size α_k chosen, for example, so that the penalty function

$$f(x) + \mu \sum_i \max\{g_i(x), 0\} + \nu \sum_j |h_j(x)|$$

is reduced in moving from x_k to x_{k+1} , for suitable positive μ and ν . Replace u_k and v_k by the Lagrange multipliers for the constraints in the quadratic programming problem above, and repeat. There are also quasi-Newton versions of this method.

CONVERGENCE

Some global, local, or rate of convergence results can be established for such methods, for example:

THEOREM 46.1.3

If Newton's method is started sufficiently close to a point x_* satisfying the second-order sufficient conditions to be a local minimizer of f , then the iterates will converge to x_* and the convergence will be quadratic: $\|x_{k+1} - x_*\|/\|x_k - x_*\|^2$ remains bounded.

(A similar result holds for the sequential quadratic programming method using an exact Hessian. See, e.g., [NW99]: Theorem 3.7 for the unconstrained and Theorem 18.4 for the constrained case.) For the quasi-Newton method, it is generally necessary to assume also that H_0 is sufficiently close to $\nabla^2 f(x_*)$, and the convergence is only superlinear: $\|x_{k+1} - x_*\|/\|x_k - x_*\|$ converges to zero. These are local convergence and rate of convergence results. For an example of a global convergence result, consider the unconstrained minimization problem. Then, assuming f is bounded below, if an algorithm of the form above has the angle between each search direction d_k and the direction of the negative gradient $-\nabla f(x_k)$ bounded away from 90° , and the step sizes are chosen appropriately, then $\nabla f(x_k)$ necessarily converges to zero, and so every limit point is a stationary point. However, no bounds on the total computation required for a prescribed precision are known in general (or to be expected lacking convexity). Vavasis [Vav91] describes what complexity results have been obtained for certain special nonconvex problems; for example, minimizing a general quadratic function subject to simple bound constraints is NP-hard, while minimizing such a function subject to lying in a ball is polynomially approximable.

46.2 CONVEX PROGRAMMING

Now we suppose that the functions f and all g_i 's are convex, and that all h_j 's are linear (affine). Then (P) is called a **convex programming** problem; it involves the minimization of a convex function over a convex set.

46.2.1 OPTIMALITY CONDITIONS

If all the functions involved are smooth, then the first-order conditions that are necessary (under a regularity condition) also turn out to be sufficient, not just for local but for global optimality. In other words, stationary points are global minimizers (see, e.g., Theorem 9.4.2 in [Fle87]):

THEOREM 46.2.1

Suppose $\bar{x}$ is feasible for the convex programming problem (P), and that there exist multipliers $\bar{u}$ and $\bar{v}$ such that the Karush-Kuhn-Tucker conditions hold. Then $\bar{x}$ is a global minimizer for (P).

There are also optimality conditions in the nonsmooth case, since convex functions admit subgradients (linear supports) even if they are not differentiable at a point. For a convex function k and a point $\bar{x}$,

$$\partial k(\bar{x}) := \{z \mid k(x) \geq k(\bar{x}) + z^T(x - \bar{x}) \text{ for all } x\}$$

is called the **subdifferential** of k at $\bar{x}$, and it is a nonempty compact convex set whose members are called **subgradients** of k at $\bar{x}$.

THEOREM 46.2.2

Consider the (modified) Karush-Kuhn-Tucker conditions at a point $\bar{x}$, where the first equation is replaced by

$$0 \in \partial_x L(\bar{x}, \bar{u}, \bar{v}).$$

These conditions are sufficient for $\bar{x}$ to be a global minimizer for (P). In the case that (P) satisfies the regularity condition that there is some feasible point $\hat{x}$ satisfying all inequality constraints strictly, these conditions are also necessary for $\bar{x}$ to be a local minimizer for (P).

See, e.g., Theorem 28.3 in [Roc70]. In addition, optimality conditions can be stated as saddle-point properties of the Lagrangian. Indeed, $(\bar{x}, \bar{u}, \bar{v})$ satisfies these conditions iff

$$L(x, \bar{u}, \bar{v}) \geq L(\bar{x}, \bar{u}, \bar{v}) \geq L(\bar{x}, u, v)$$

for any $x \in \mathbb{R}^n$, $u \in \mathbb{R}_+^m$, $v \in \mathbb{R}^p$. Whether the functions are smooth or not, local minimizers are always global minimizers. There is also a rich duality theory for convex programming, with many results mirroring those for linear programming. See [Roc70, RW98].

46.2.2 ALGORITHMS

As far as algorithms are concerned, in the smooth case one can again employ the general methods discussed above. Slightly stronger results are available about convergence; for example, for the unconstrained minimization of a convex function f , global convergence of the BFGS quasi-Newton method is assured for suitable step size rules, and it is no longer necessary to assume H_0 close to $\nabla^2 f(x_*)$ to obtain superlinear convergence. However, again no global estimates of the work required to attain a certain precision are known for such methods.

There are also methods designed for nonsmooth problems, such as subgradient and bundle methods. See, e.g., [Fle87, HL93a, HL93b].

LOCALIZER ALGORITHMS

On the other hand, a different class of methods for which such guarantees are available can be applied, even in the nonsmooth case. Various methods are appropriate in the case of smooth functions or the case of nonsmooth functions when the dimension n is high and the desired accuracy low. Here we will briefly describe methods for nonsmooth problems where n is small and high accuracy is required; these are based on very geometrical ideas involving *localizers*. While more general problems can be treated, suppose we wish to minimize a convex function f over the cube $G := \{x \in \mathbb{R}^n \mid \|x\|_\infty \leq 1\}$, where the variation of f over G is at most 1 (this is just a normalization condition).

GLOSSARY

ϵ -optimal point: $x \in G$ with $f(x) \leq \inf_G f + \epsilon$.

Localizer: Pair (H, z) , $H \subseteq \mathbb{R}^n$, $z \in G$, such that if $x \in G \setminus H$, $f(x) \geq f(z)$.

We mention three such methods here.

METHOD OF CENTRAL SECTIONS (MCS)

This algorithm, due to Levin [Lev65] and Newman [New65], generates a sequence $\{x_k\}$ of test points and a sequence $\{(Q_k, z_k)\}$ of localizers by the following rules. Choose $Q_0 := G$, $z_0 \in G$ arbitrary, and at the k th iteration, choose x_k as the center of gravity of Q_k and compute $f(x_k)$ and a subgradient g_k of f at x_k . If $g_k = 0$, x_k minimizes f ; in this case, stop. Otherwise, $Q_k^+ := \{x \in Q_k \mid g_k^T x \leq g_k^T x_k\}$ contains all minimizers of f over G . Set $Q_{k+1} := Q_k^+$ and let z_{k+1} be whichever of z_k and x_k has the lower function value. It is easy to see by induction that all (Q_k, z_k) 's are localizers. (For $n = 1$, this amounts to just the well-known bisection method.)

The key fact is that a substantial reduction in volume is obtained in successive localizers: $\text{vol}(Q_{k+1}) \leq (1 - 1/e)\text{vol}(Q_k)$. (Here e denotes the base of the natural logarithm.) From this it is not hard to see that an ϵ -optimal point will be found within $O(n \ln \frac{1}{\epsilon})$ iterations. This is optimal from a worst-case viewpoint—no algorithm can ask fewer questions of f (up to a constant factor) and guarantee ϵ -optimality. Unfortunately, it is not easy to find or approximate centers of gravity for general n , although Bertsimas and Vempala [BV01] provide a polynomial randomized algorithm.

ELLIPSOID METHOD (EM)

The (circumscribing) ellipsoid method due to Yudin-Nemirovskii [YN76] and Shor [Sho77] is similar, with the following variations: Q_0 is taken to be the minimum-volume ellipsoid containing G , and Q_{k+1} the minimum-volume ellipsoid containing the semiellipsoid Q_k^+ . The formulas for updating x_k and Q_k are then trivially implemented, thus removing the drawback of the MCS. However, the volume reduction is much less: $\text{vol}(Q_{k+1}) \approx (1 - [2(n+1)]^{-1})\text{vol}(Q_k)$, and this leads to a complexity bound of $O(n^2[\ln n + \ln \frac{1}{\epsilon}])$ iterations to get an ϵ -optimal point. An iteration of the ellipsoid method is shown in Figure 46.2.1.

FIGURE 46.2.1

An iteration of the ellipsoid method.

METHOD OF INSCRIBED ELLIPSOIDS (MIE)

This final method, due to Tarasov, Khachiyan, and Erlikh [TKE88], chooses the localizers Q_k as in the MCS, but at each iteration takes x_k as the center of (an approximation to) the maximum-volume ellipsoid E_k contained in Q_k . It can be shown that $\text{vol}(E_{k+1}) \leq (8/9)\text{vol}(E_k)$, which leads to an $O(n \ln \frac{1}{\epsilon})$ -iteration bound. After every $O(n \ln n)$ iterations, the polytope Q_k can be enlarged slightly to one with $O(n)$ facets, so that all Q_l 's can be restricted to only $O(n \ln n)$ facets, without changing the complexity. For these polytopes, x_k can be well approximated in $O(n^{3.5+\delta})$ arithmetic operations (see [KT93]), where δ is an arbitrarily small positive number whose presence compensates for various logarithmic factors.

One last remark: In the EM (because possibly $x_k \notin G$) or when (convex) constraints are present, x_k may not be feasible. In this case, g_k is chosen so that all feasible solutions satisfy $g_k^T x \leq g_k^T x_k$, and $z_{k+1} := z_k$.

Table 46.2.1 summarizes the complexities of all three methods (see, e.g., [TKE88, KT93]).

TABLE 46.2.1 Localizer algorithms for convex programming.

ALGORITHM	COMPLEXITY
MCS	$O(n \ln[1/\epsilon])$
EM	$O(n^2[\ln n + \ln(1/\epsilon)])$
MIE	$O(n \ln[1/\epsilon])$

These methods are not practical for large n , and may not be as efficient for small dimensions as other smooth methods, since they are based on a worst-case perspective. For more efficient methods that have global complexity estimates for certain classes of convex programming problems, see Section 46.5.

46.3 LINEAR PROGRAMMING

Now we discuss the case where all functions defining (P) are linear (affine). By performing simple manipulations, we can express any such problem in standard form, where the constraints take the form of m equations in n nonnegative variables:

$$\begin{aligned} \min \quad & c^T x \\ & Ax = b, \\ & x \geq 0. \end{aligned} \tag{LP}$$

Here A is $m \times n$, $b \in \mathbb{R}^m$, $c \in \mathbb{R}^n$, and the variable $x \in \mathbb{R}^n$.

Such problems are of great interest in a wide variety of areas, and their solution comprises a not insignificant fraction of all scientific computation. Problems with m of the order of 10^3 and n of the order of 10^4 are solved routinely, and larger instances can also be solved without too much difficulty in most cases. (Note the contrast with Chapter 45, where it is typically assumed that n is small.) In large-scale settings, the sparsity of the matrix A (typically it has at most 5–10 nonzero entries per column) is very important, and numerical methods must exploit sparse matrix technology.

46.3.1 DUALITY

Conditions for a feasible solution to be optimal in (LP) are best stated in terms of another linear programming problem, now involving n inequalities in m variables unrestricted in sign, constructed from the same data. This is the **dual** problem (we call (LP) the **primal**), and is

$$\begin{aligned} \max \quad & b^T y \\ & A^T y \leq c. \end{aligned} \tag{LD}$$

It is easy to see that $c^T x \geq b^T y$ for any feasible solutions x for (LP) and y for (LD) (this is called **weak duality**), so that if equality holds for $\bar{x}$ and $\bar{y}$ they must both be optimal. Indeed, the converse holds: a feasible point $\bar{x}$ is optimal in (LP) if and only if there is a $\bar{y}$ feasible in (LD) with $c^T \bar{x} = b^T \bar{y}$. This is **strong duality**. There is also a nice geometric way of looking at the optimal dual solution. Let us write $\bar{s}$ for the vector $c - A^T \bar{y}$ (we shall see more of this dual **slack vector** later). Then $c^T \bar{x} = b^T \bar{y}$ implies that $\bar{x}^T \bar{s} = 0$, and feasibility in the dual implies that $\bar{s} \geq 0$. Then the dual constraints $A^T \bar{y} + \bar{s} = c$ can be viewed as expressing the gradient of the objective function of the primal problem as a linear combination of the gradients of the constraints that are active at $\bar{x}$ (since $\bar{s}_j$ is nonzero only if $\bar{x}_j$ is zero), where we can take arbitrary multiples of the equality constraint gradients but only nonnegative multiples of the inequality constraint gradients.

Besides its use in proving optimality, the dual problem has important economic interpretations in many instances, and its solution provides crucial sensitivity infor-

mation about the effects of changes in the data on the solution and optimal value of the primal problem. In addition, it is much exploited in solution techniques for linear programming.

46.3.2 ALGORITHMS

Once again, algorithms for more general problems, i.e., from convex programming, can be applied to these more special problems. Indeed, the first polynomial-time algorithm for linear programming (for the case where all the data are integer-valued) was constructed by Khachiyan [Kha79] based on the ellipsoid method. This result has great theoretical significance (even more for combinatorial optimization, see below), but little practical importance, since the method is very inefficient even for small problems.

Efficient methods for solving (LP) rely on two geometrical ways of looking at its feasible region. This is a polyhedron, typically of dimension $d := n - m$, with at most n facets. The simplex method of Dantzig [Dan63] relies on the combinatorial properties of this polyhedron, in particular on its 1-skeleton, while interior-point methods originating from Karmarkar's projective algorithm [Kar84] (or the earlier method of Dikin [Dik67]) use a more analytic view relying on a Riemannian metric at points of the interior of the feasible region that reflects its local geometry. (There are also methods based on completely different geometric ideas, for example those of Welzl and coauthors (see, e.g., [GW96] and the references therein), and special methods appropriate for low-dimensional problems: see [Chapter 45](#).)

The differences among the various classes of methods are summarized in Table 46.3.1.

TABLE 46.3.1 Classes of linear programming methods.

METHOD	GEOMETRY	ITERATES	TERMINATION
Ellipsoid	convex	arbitrary points	in the limit
Simplex	combinatorial	vertices	finite
Interior-point	analytic	interior points	in the limit

The “efficiencies” of the methods are shown in Table 46.3.2 (incidentally, this shows the difference between practical and theoretical efficiency).

TABLE 46.3.2 Complexities of linear programming methods.

METHOD	WORST-CASE COMPLEXITY	EXPECTED COMPLEXITY	PRACTICAL
Ellipsoid	polynomial	polynomial	no
Simplex	exponential/super-polynomial?	polynomial	yes
Interior-point	polynomial	polynomial	yes

Articles on the practical efficiency of algorithms for large-scale linear programming problems may be found in [ORJ94].

46.3.3 SIMPLEX METHODS

Given a vertex of the feasible region, a variant of the simplex method proceeds from vertex to vertex along edges while improving the objective function, stopping either at an indication that the objective function is unbounded below or at an optimal solution. (In order to find an initial vertex, the same process is applied to an artificial problem.) The choice of a particular edge to follow is called a pivot rule, and leads to a particular variant. For example, we can choose the edge yielding the maximal decrease in the objective function per unit length (in the Euclidean norm) moved; this is the steepest-edge rule. Various rules can be shown to terminate finitely, even for degenerate problems when the “edge” followed has zero length and merely leads to a different representation of the same vertex (this may happen when the feasible region is not a simple polyhedron). However, no rule is currently known for which the number of steps taken is always bounded by a polynomial in the dimensions m and n or the input size (total number of bits to represent the data, assumed integer-valued). Indeed, for many rules, examples have shown the worst-case complexity to be exponential (see Amenta and Ziegler [AZ98]), although Kalai [Kal92] has described a randomized rule whose expected number of steps in the worst case is subexponential, though superpolynomial; see Section 45.2. Nevertheless, the simplex method using appropriate pivot rules works very well in practice, requiring only a small number of iterations (possibly $O(m \ln n)$) for typical problems. To explain this gap, some studies have shown that the expected number of steps for certain (deterministic) simplex variants, when applied to a random problem generated by a suitable probabilistic distribution, is polynomial; see Borgwardt [Bor86] and the references therein.

The number of steps taken by a simplex variant starting at an arbitrary vertex is clearly related to the *diameter* of the associated polyhedron of feasible solutions; this is the largest, over all pairs of vertices, of the smallest number of edges required to go from one to the other. The famous *Hirsch conjecture* states that this is at most $n - d$ for polytopes (bounded polyhedra) of dimension d with at most n facets. It is known to be true for $d \leq 3$ and $n - d \leq 5$, and for certain classes of polytopes arising in special applications, but the general case remains open; see [KK87]. A nice result [Nad89] shows that the conjecture is true for a polytope that is the convex hull of a set of $(0,1)$ -vectors, as arises in combinatorial optimization. Note that knowing that the diameter of a polytope is small does not immediately lead to an efficient simplex method for optimizing a linear function over that polytope.

46.3.4 INTERIOR-POINT METHODS

Algorithms for linear programming of this type generate a sequence of iterates for (LP) that satisfy all the equations and satisfy all the inequalities strictly (we call such points *strictly feasible*). At such an iterate, one can move in a direction of steepest descent restricted to the affine space $\{x \mid Ax = b\}$, but if the strictly feasible iterate is very close to the boundary of the feasible region, it is possible that only a very short step can be taken.

The first method of this kind, due to Dikin [Dik67], applied an affine transformation (or *scaling*) to move the current point to the vector e of ones. A steepest descent step was taken in the scaled space, and the resulting point was transformed

back to yield the next iterate. This very simple algorithm performs surprisingly well, but polynomial convergence has not been established. Dikin's paper was not well-known, but was rediscovered soon after Karmarkar's independent work [Kar84], which used a projective transformation and achieved a polynomial time bound (given in Table 46.3.3). The proof used an ingenious potential function, of the form

$$\phi(x, \zeta) := n \ln(c^T x - \zeta) - \sum_j \ln x_j,$$

with ζ a lower bound on the optimal value of (P), that is closely related to classical barrier functions used in nonlinear programming since the '50s (see, e.g., [Fle87]).

Instead of performing the transformations, we can view the search directions in the original space as given by steepest descent directions for a certain function with respect to a Riemannian metric. At the strictly feasible point x , the length of a displacement d_x is defined as $\|d_x\|_x := (d_x^T X^{-2} d_x)^{1/2}$, where X is the diagonal matrix containing the components of x . Thus the metric is defined by the matrix X^{-2} , which is the Hessian of the *barrier function*

$$F(x) := - \sum_j \ln x_j.$$

The Dikin, or affine-scaling, direction is the steepest direction for the objective function $c^T x$ in the null space of A with respect to this norm, whereas the Karmarkar, or projective-scaling, direction is a similar steepest descent direction for a certain linear combination of $c^T x$ and the barrier $F(x)$. This metric, and in the second case the presence of the barrier, steers the direction away from approaching the boundary of the feasible region too closely prematurely. We will not describe Karmarkar's algorithm in detail, since it is quite complicated and the method has been superseded by those in the next subsection.

46.3.5 PRIMAL-DUAL METHODS

Recent attention has focused on primal-dual methods, which iterate both primal and dual strictly feasible points. It is helpful to write the dual with explicit slack variables as

$$\max \quad \begin{array}{c} b^T y \\ A^T y + s \end{array} \geq 0. \quad (\text{LD})$$

GLOSSARY

Barrier function: Convex function defined on the relative interior of the feasible region, tending to infinity as the boundary is approached.

Interior point: Point satisfying all inequality constraints strictly.

Strictly feasible point: Interior point satisfying all constraints.

e : Vector of ones in $\mathbb{R}^n$.

X (resp. S): Diagonal matrix containing the components of x (resp. s).

Central path: Set of pairs of strictly feasible points x and (y, s) with $XS e = \mu e$ for some $\mu > 0$.

Neighborhoods of central path: Sets of strictly feasible pairs with $XS_e - \mu e$ suitably bounded.

Primal-dual potential function: $\rho \ln x^T s + F(x) + F(s)$ for $\rho \geq n + \sqrt{n}$, defined for strictly feasible pairs.

Noting that for feasible solutions we have

$$c^T x - b^T y = (A^T y + s)^T x - (Ax)^T y = x^T s \geq 0$$

(a short proof of weak duality), we see that optimality conditions for (LP) and (LD) can be written as

$$\begin{array}{rcll} A^T y & + & s & = & c & (s \geq 0), \\ Ax & & & = & b & (x \geq 0), \\ XS_e & & & = & 0. \end{array} \quad (\text{OC})$$

Indeed, the simplex method can be viewed as seeking to satisfy (OC) by maintaining all conditions except the nonnegativity of s at each iteration.

On the other hand, (OC) can be viewed as $m + 2n$ mildly nonlinear equations in $m + 2n$ variables, with nonnegativity restrictions as side constraints, and then Newton's method for nonlinear equations seems appropriate. If we start with strictly feasible solutions $\hat{x}$ and $(\hat{y}, \hat{s})$ ($\hat{x} > 0$ and $\hat{s} > 0$) and compute the Newton step for (OC), we can take a partial step to maintain strict feasibility for the next iterates (*damped* Newton step). Indeed, we can take a damped Newton step for a *perturbed* system with the zero right-hand side replaced by $\gamma \hat{\mu} e$, where $\hat{\mu} := \hat{x}^T \hat{s} / n$ is the current duality gap divided by n and $0 \leq \gamma \leq 1$, to encourage the iterates to remain positive while taking a large step.

This primal-dual framework appears to be rather far from the steepest descent view of primal-only interior-point methods. However, the direction for x can be seen to be a steepest descent direction for $c^T x + \gamma \hat{\mu} F(x)$ with respect to the norm $(d_x^T \hat{X}^{-1} \hat{S} d_x)^{1/2}$, rather than the expected $(d_x^T \hat{X}^{-2} d_x)^{1/2}$. Similarly, the directions for y and s are the steepest descent directions for $-b^T y + \gamma \hat{\mu} F(s)$ with respect to the norm (on just d_s) $(d_s^T \hat{S}^{-1} \hat{X} d_s)^{1/2}$, rather than the expected $(d_s^T \hat{S}^{-2} d_s)^{1/2}$. Note that these two norms are dual, as is appropriate since x and s lie in dual spaces (the duality gap is $x^T s = \langle s, x \rangle$), and that they are scalar multiples of the norms given by the Hessians of the barrier functions if $\hat{X} \hat{S} e = \hat{\mu} e$. (They can be viewed as the closest dual norms to the latter.)

Several algorithms are based on taking such damped perturbed Newton steps. We next describe a generic algorithm of this type.

A GENERIC PRIMAL-DUAL INTERIOR-POINT METHOD

Suppose we are given the strictly feasible points x_k and (y_k, s_k) at the k th iteration. Let $\mu_k := x_k^T s_k / n$ and choose $\gamma \in [0, 1]$. Solve for the directions d_x , d_y , and d_s from

$$\begin{array}{rcll} A^T d_y & + & d_s & = & 0, \\ A d_x & & & = & 0, \\ S_k d_x & + & X_k d_s & = & \gamma \mu_k e - X_k S_k e, \end{array}$$

where X_k and S_k denote the diagonal matrices corresponding to x_k and s_k . Then set $x_{k+1} := x_k + \alpha_P d_x$ and $(y_{k+1}, s_{k+1}) := (y_k, s_k) + \alpha_D (d_y, d_s)$, where the positive step sizes α_P and α_D are chosen so that the new iterates are strictly feasible.

A practical version of this method (which takes long steps to try to converge fast, but which lacks a polynomial bound) might choose $\gamma = 1/n$ and α_P and α_D as .999 of the maximum values that would maintain primal and dual feasibility, respectively.

Most theoretically attractive primal-dual methods try to stay close to the *central path*. For each $\mu > 0$, there is a unique pair x and (y, s) of strictly feasible solutions with $XS e = \mu e$, and the set of all these forms the central path, which leads (as $\mu \rightarrow 0$) to the set of optimal solutions. Some methods maintain $\|XS e/\mu - e\| \leq \beta$ with either the ℓ_2 - or ℓ_∞ -norm, and others only require $XS e \geq (1 - \beta)(x^T s/n)e$, for some $0 < \beta < 1$, for all iterates. When the ℓ_2 -neighborhood is used, we get a close path-following method, whereas the other restrictions yield loose path-following methods. For example, one can choose $\alpha_P = \alpha_D = 1$ and $\gamma \in [0, 1]$ as small as possible to maintain $\|XS e/\mu - e\|_2 \leq 1/4$ in the generic algorithm above. (One can show that $\gamma \leq 1 - 1/(4\sqrt{n})$ with this choice.) The first close path-following method was due to Renegar [Ren88] and operated in the dual space alone; this was also the first method with the improved complexity of $O(\sqrt{n} \ln \frac{1}{\epsilon})$ steps to attain ϵ -optimality. Also, primal-dual methods can be based on a primal-dual potential function and require no neighborhood. All the methods described in this subsection, with the exception of the affine-scaling method and the practical primal-dual algorithm outlined above, are polynomial. However, the methods with the better complexity bounds (see Table 46.3.3) seem not to be as useful practically, as they tend to force short steps.

INFEASIBLE-INTERIOR-POINT METHODS

Finally, as with the simplex method, initial feasible (here, strictly feasible) solutions are rarely known. However, a damped perturbed Newton step can also be taken from iterates $\hat{x}$ and $(\hat{y}, \hat{s})$ with $\hat{x} > 0$ and $\hat{s} > 0$ (*infeasible interior points*) even if the equations in (LP) and (LD) are violated. These infeasible-interior-point methods strive for feasibility and optimality at the same time, and are the basis for most interior-point codes. Polynomial bounds have recently been obtained (see below). Another approach [YTM94] applies a “feasible” method to an artificial homogeneous self-dual problem and either generates optimal solutions or proves primal or dual infeasibility in the limit.

COMPLEXITY OF INTERIOR-POINT METHODS

The types of algorithms and their iteration complexities to obtain ϵ -optimality given suitable starting points are given in Table 46.3.3: see, e.g., [Wri96, Ye97]. Note that all except the last two assume that a feasible solution is at hand.

All these methods require $O(n^3)$ arithmetical operations at each iteration (although an acceleration trick can reduce this to $O(n^{2.5})$ operations on average for some methods), assuming dense linear algebra is used. To get the complexity of solving exactly a linear programming problem with integer data of length L , replace $(1/\epsilon)$ in Table 46.3.3 by L ; we then get polynomial complexity. Roughly, from an ϵ -optimal solution with $\epsilon = 2^{-O(L)}$ we can obtain an exact solution.

TABLE 46.3.3 Complexities of interior-point methods.

ALGORITHM		COMPLEXITY
Primal	affine-scaling	—
	projective-scaling	$O\left(n \ln(1/\epsilon)\right)$
Primal-dual	close path-following	$O\left(\sqrt{n} \ln(1/\epsilon)\right)$
	loose path-following	$O\left(n \ln(1/\epsilon)\right)$
	potential-reduction	$O\left(\sqrt{n} \ln(1/\epsilon)\right)$
	infeasible-interior-point	$O\left(n \ln(1/\epsilon)\right)$
	homogeneous self-dual	$O\left(\sqrt{n} \ln(1/\epsilon)\right)$

46.4 INTEGER AND COMBINATORIAL OPTIMIZATION

Now suppose we wish to optimize a linear function subject to linear constraints and the requirement that the variables be integer. Such a problem is called an integer (linear) programming problem. For simplicity, we assume that all variables must be 0 or 1. Then the problem can be formulated as:

$$\begin{array}{rcll} \max & c^T x & & \\ & Ax \leq b, & & \\ 0 \leq & x \leq e, & & \\ & x & \text{integer.} & \end{array} \tag{IP}$$

(Recall that e denotes the vector of ones.) Clearly, such problems (sometimes with only some of the variables required to be integer) arise from applications like those leading to linear programming instances—for example, production of certain items (e.g., aircraft carriers) is essentially discrete. But it is important to realize the modeling possibilities of (0,1) variables: they can be used to represent either-or situations, such as whether to build a new factory, invest in a new product, etc., or to model such nonconvexities as setup costs and minimum batch sizes.

There are also inherently combinatorial problems that can be represented in the form (IP). Consider for example the notorious *traveling salesman problem* [LLRS85], which arises in routing and sequencing applications. Here it is desired to visit each of n cities exactly once, starting and finishing at the same city, at minimum cost. By introducing variables x_{ij} , $1 \leq i < j \leq n$, equal to 1 if the salesman goes directly from city i to city j or vice versa, we can model the problem as minimizing a linear function over a finite (but large!) set of (0,1)-vectors of length $n(n-1)/2$. It is not hard to see that this can be written in the form (IP) by introducing appropriate constraints. Indeed, this can be done in several ways.

46.4.1 OPTIMALITY CONDITIONS AND DUALITY

Solving integer programming problems is NP-hard in general, although it is polynomial when the dimension is fixed and for certain special problems (see [Len83, Sch86, GLS88]). One reason for the difficulty is that it is far from trivial to check whether a given feasible solution is optimal. Very often, a heuristic method or

routine within an algorithm will produce a very good or optimal solution quickly, but proving that it is (near-)optimal is very time-consuming.

The main tool for establishing the quality of a feasible solution for (IP) is linear programming. Note that the optimal value of (IP) is bounded above by that of its *linear programming relaxation*

$$\begin{array}{ll} \max & c^T x \\ & Ax \leq b, \\ 0 \leq & x \leq e. \end{array} \quad (\text{LR})$$

There are some problems (mostly network-flow-related) for which the linear programming relaxation has only integer vertices. Thus solving (LR) by, say, the simplex method will solve (IP). If this is not the case, then the optimal value of (LR) (or of its linear programming dual) provides information about the quality of a given feasible solution of (IP), and its optimal solution may help to locate a good integer solution. In any case, it is clear that a “tight” formulation (so that (LR) is “closer” to (IP)), and the *integrality gap*—the gap between their optimal values—is smaller) will be very helpful in (approximately) solving (IP).

There are also specialized duals for integer programming involving subadditive functions, but they do not seem to be as useful computationally.

46.4.2 ALGORITHMS

Certain integer or combinatorial optimization problems (for example, network flow problems, see [CCPS98]) can be solved very efficiently. This can be done either using the simplex method (as indicated above, for some such problems it suffices to solve the linear programming relaxation, and in some cases a polynomial bound on the number of iterations has been proved) or specialized combinatorial methods (e.g., for certain graph, network, and matroid problems), but these usually have little geometric content. For harder problems two general approaches are possible.

BRANCH-AND-BOUND

The first is an implicit enumeration scheme. Suppose we solve the linear programming relaxation (LR). If the solution is integer, we are done; otherwise, we obtain a bound on the optimal value, and by choosing a variable whose optimal value is fractional, we construct two other problems, in one of which the variable is restricted to be 0 and in the other, 1. If we continued branching in this way, we would eventually reach a tree with 2^n leaves, with each corresponding to a particular (0,1) assignment for all the variables. Two things may allow us to construct only a very much smaller enumeration tree. First, if the optimal solution for the relaxation at some node (corresponding to a partial assignment of the variables) is integer, we need not perform any more branching from this node. If this solution is the best seen so far, we record it. Second, if the linear programming relaxation at a node is either infeasible or has optimal value below that of some known integer solution (obtained by a heuristic or from examination of other parts of the tree), the node need not be considered further. If neither of these cases holds, we choose a fractional variable and branch as above, thus creating two new nodes. Since we keep track of the best integer solution found, when all nodes have been considered, the current best solution solves (IP), or, if there is none, (IP) is infeasible. Note that

the efficiency of this technique depends on the tightness of the formulation, since this helps both to generate integer solutions to linear programming relaxations and to give good bounds allowing nodes to be rejected as above.

CUTTING-PLANE METHODS

The other approach tries to generate ever tighter linear programming relaxations. Note that if we could optimize the objective function over the convex hull C of the finitely many feasible solutions of (IP), we would obtain the optimal solution directly. Since this convex hull is a polytope (such a polytope is called a **(0,1)-polytope**), it can be expressed as the solution set to a set of linear inequalities, so that there is *some* linear programming relaxation that allows the integer programming problem to be solved using linear programming methods. The problem is that we do not know all of these inequalities, and even if we could describe them completely (as we can, say, for the matching problem in a nonbipartite graph) there might be exponentially many. Thus we would like to generate them “on the fly.”

One algorithm that does not require all the inequalities to be available explicitly is the ellipsoid method. Indeed, there is a precise sense in which, if we can determine in polynomial time whether a given point is within the convex hull C and, if not, produce a separating hyperplane, then we can optimize over C in polynomial time using the ellipsoid method, and vice versa; see [GLS88]. Of course, this is not a practical method, but it has significant theoretical consequences in combinatorial optimization (showing that some problems are polynomially solvable and, conversely, that others are NP-hard), and gives a strong indication that similar constraint-generation methods using efficient linear programming methods can be practically useful for many problems. We need to be able to reoptimize a linear programming problem easily after slight modifications (addition of constraints, fixing of variables), and for this simplex methods seem preferable at the present time to interior-point algorithms. We also need a way to generate a “good” set of constraints to add when we discover that our current linear programming relaxation is not tight enough. These constraints should be valid for all feasible solutions to (IP), but violated by the optimal solution of the current relaxation, so they are called *cutting planes*.

This approach to the study of combinatorial problems is called:

POLYHEDRAL COMBINATORICS

Given a collection of subsets of some finite ground set (e.g., each subset could be the set of edges of a Hamiltonian circuit of a given graph), one can consider the corresponding collection of their (0,1) incidence vectors, and the convex hull C of these vectors. This is a (0,1)-polytope. Questions about the combinatorial system can then be reduced to questions about the resulting polytope; in particular, optimizing over the set of subsets often becomes a linear programming problem over C . It is therefore of interest to obtain complete or partial descriptions of the linear inequalities defining C . These can then be used in developing special algorithms or within the context of the cutting-plane methods above. Thus much recent research has been devoted to finding deep valid inequalities or, if possible, facets of C for practically interesting problems, and also to developing separation techniques to identify a member of a class of facets that is violated by a given point. A very

interesting recent result testifies to the complexity of the convex hull of feasible solutions for at least one class of hard problems: Billera and Sarangarajan [BS96] show that *any* $(0,1)$ -polytope is a traveling salesman polytope. Another indication of the complexity of such facet descriptions is the following. For the case of 8 cities, the traveling salesman polytope has been completely described [CJR91]—it has 194,187 facets! No such description is known for the case of 9 cities. Recall that $(0,1)$ -polytopes have small diameter—they satisfy the Hirsch conjecture. Unfortunately this is of little comfort when we cannot give a complete facet description of them; moreover, they are often very degenerate, so the simplex method might take many pivot steps going nowhere. Further discussion and references on polyhedral combinatorics can be found in Chapter 7 of this Handbook.

REMARKS

The two techniques above can be combined, so that cutting planes are added as long as one can be found, and then enumeration resorted to if necessary. If possible, the inequalities found at one node of the tree should also be valid for other nodes in the tree, so we always have tight relaxations. Using these ideas, very large combinatorial and integer optimization problems have been solved. We note that recently a traveling salesman problem with 15,112 cities was solved to optimality by Applegate, Bixby, Chvátal, and Cook: see <http://www.math.princeton.edu/tsp/d15sol/index.html>.

46.5 SPECIAL CONVEX PROGRAMMING PROBLEMS

In Section 46.2, we described the ellipsoid method and its relatives, but noted that they are not practical for large (or even medium-sized) convex programming problems. On the other hand, Section 46.3 gave methods that are efficient even for very large linear programming problems. Here we address the possibility of solving efficiently large convex optimization problems falling into nice classes, using methods with global complexity estimates.

The first such class is that of (convex) quadratic programming problems. As we noted in Section 46.1, these arise as subproblems in methods for general smooth nonlinear programming; they are also important in their own right, with applications in portfolio analysis and constrained data-fitting. The optimality conditions for such problems are very similar to those for linear programming: another linear term is added to one of the sets of linear equations in (OC). Thus it is not too surprising that extensions of linear programming methods, of both the simplex and interior-point persuasions, have been devised for quadratic programming. The complexity of the latter kinds of algorithm is the same as for linear programming. There are also direct methods for quadratic programming, described in [Fle87, GMW81, NW99].

46.5.1 INTERIOR-POINT METHODS FOR NONLINEAR PROGRAMMING

There has recently been great interest in extending interior-point methods to certain classes of convex programming problems, maintaining a polynomial complexity

bound. The most extensive work has been done by Nesterov and Nemirovskii, and appears in their book [NN94]; see also [BTN01, Ren01].

Any convex programming problem can be rewritten, by adding one or two variables, in the form of either

$$\min\{c^T x \mid x \in G\}$$

or

$$\min\{c^T x \mid Ax = b, x \in K\},$$

where G and K are closed convex sets in $\mathbb{R}^n$ with nonempty interiors, and K is a cone. The second formulation, said to be in conical form, is clearly closely related to the standard form linear programming problem (LP), and allows a nice statement of the dual as

$$\max\{b^T y \mid A^T y + s = c, s \in K^*\},$$

where K^* is the dual cone $\{s \in \mathbb{R}^n \mid x^T s \geq 0 \text{ for all } x \in K\}$. Weak duality is immediate, while strong duality holds if, for example, there are feasible solutions to both problems with x and s in the interiors of their respective cones.

GLOSSARY

Self-concordant barrier: Barrier function satisfying certain smoothness conditions allowing efficient interior-point methods.

Self-scaled barrier: Self-concordant barrier satisfying further conditions allowing greater freedom in efficient methods.

Semidefinite programming: Convex optimization with constraints that certain symmetric matrices be positive semidefinite.

Symmetric cones: Self-dual homogeneous cones.

The view of interior-point methods given in Section 46.3 leads us to consider steepest descent steps for a strictly feasible point (in $\text{int } G$ or $\{x \in \text{int } K \mid Ax = b\}$) with respect to the norm defined by the Hessian of a barrier function for the set G or K . Nesterov and Nemirovskii devise path-following and potential-reduction methods with polynomial complexity for the problems above as long as a barrier function F for G or K can be found satisfying certain key properties. These properties, roughly convexity and Lipschitz continuity of F and its second derivative with respect to the norm defined by the second derivative itself, define the set of *self-concordant barriers*. An attractive feature of these functions is that Newton's method performs well (in a precise sense) when applied to their minimization, not just locally but also globally. One of the Lipschitz constants, the *parameter* ν of the barrier, takes the place of the number of linear inequalities n in linear programming in complexity bounds. Thus the number of iterations of their algorithms to attain ϵ -optimality is $O(\nu \ln \frac{1}{\epsilon})$ or $O(\sqrt{\nu} \ln \frac{1}{\epsilon})$.

To develop symmetric primal-dual methods like those used in interior-point codes for LP, we need to consider the problem in conical form and require a further condition on the barrier: it should be *self-scaled* [NT97]. We will not give the precise definition here, but we note that one of its consequences is that, for every $x \in \text{int } K$ and $s \in \text{int } K^*$, there is a unique $w \in \text{int } K$ with $F''(w)x = s$. Then the

generic primal-dual interior-point method is exactly as in the linear programming case, except that the last equation defining the directions becomes

$$F''(w_k)d_x + d_s = -s_k - \gamma\mu_k F'(x_k),$$

where $F''(w_k)x_k = s_k$.

It turns out that a cone admits a self-scaled barrier exactly when it is symmetric, i.e., self-dual (isomorphic to its dual) and homogeneous (there is an automorphism of the cone taking any point of its interior into any other). Such cones have been studied in depth since the 1960s. This connection was made by Güler [Gül96].

Barriers of these types have strong geometric consequences. For example, the ball of radius 1 centered at a strictly feasible point and defined by the norm based on the Hessian of a self-concordant barrier at that point lies completely within G or K . Moreover, if such a barrier for G has a minimizer x^* (the *analytic center* of G), then G not only contains the ball of radius 1 centered at x^* with respect to this norm, but is also contained in the ball of radius $1 + 3\nu$, where ν is the parameter of the barrier. For self-scaled barriers, we can find even larger inscribed sets, corresponding to ℓ_∞ -balls. The fact that G or K can be thus “well-fitted” by simple convex sets gives an indication of the reason that efficient algorithms can be found to optimize over them.

Because of the general theory it is obviously desirable to construct self-concordant or self-scaled barriers for convex sets and cones that can be used to model important optimization problems. Here is a list of some special cases:

1. Quadratic constraints: Let $g_i, i = 1, \dots, m$, be convex quadratic functions (note that these include linear functions). Then

$$F(x) := - \sum_{i=1}^m \ln[-g_i(x)]$$

is a self-concordant barrier with parameter m for

$$G := \{x \mid g_i(x) \leq 0, i = 1, \dots, m\}.$$

2. Second-order, or Lorentz, or “ice-cream” cone: The function

$$F(x) := -\ln(x_0^2 - \sum_{j=1}^n x_j^2)$$

is a self-concordant (and self-scaled) barrier with parameter 2 for the cone

$$K := \{x \in \mathbb{R}^{n+1} \mid x_0 \geq (\sum_{j=1}^n x_j^2)^{1/2}\}.$$

3. Symmetric positive semidefinite matrices: The function

$$F(X) := -\ln \det X$$

is a self-concordant (and self-scaled) barrier with parameter n for the cone K of symmetric positive semidefinite matrices of order n .

This last example is particularly interesting, because several important applications (including obtaining bounds in hard combinatorial optimization or control theory problems, and eigenvalue optimization) can be modeled as optimizing a linear function over the cone of symmetric positive semidefinite matrices, subject to linear constraints; such problems are the subject of semidefinite programming.

46.6 SOURCES AND RELATED MATERIAL

BOOKS AND SURVEYS

Besides the references cited above, the reader can consult the following sources for more background and further citations of the literature. In general, the chapters in [NRT89] provide state-of-the-art surveys of various fields of mathematical programming as of 1989. For nonlinear programming, see also [Fle87, GMW81, HL93a, HL93b, NW99, Vav91]. The book [NY83] contains almost all you want to know about localizer algorithms and the (informational) complexity of convex programming, although it predates the MIE (discussed in [NN94]); see also [BGT81]. For linear programming, the classic texts are [Dan63, Chv83, Sch86]; more recent surveys on path-following methods and potential-reduction algorithms are [Gon92, Tod96], and the books [BTN01, Ren01, Van96, Wri96, Ye97] are recommended. For combinatorial optimization, see [CCPS98] and consult the chapters on optimization, convex polytopes, and polyhedral combinatorics in [GGL95]. The application of interior-point methods to convex programming is discussed in [BTN01, dH93, NN94, Ren01]. Semidefinite programming and more general conic programming problems are covered in [WSV00].

47 ALGORITHMIC MOTION PLANNING

Micha Sharir

INTRODUCTION

Motion planning is a fundamental problem in robotics. It comes in a variety of forms, but the simplest version is as follows. We are given a robot system B , which may consist of several rigid objects attached to each other through various joints, hinges, and links, or moving independently, and a 2D or 3D environment V cluttered with obstacles. We assume that the shape and location of the obstacles and the shape of B are known to the planning system. Given an initial placement Z_1 and a final placement Z_2 of B , we wish to determine whether there exists a collision-avoiding motion of B from Z_1 to Z_2 , and, if so, to plan such a motion. In this simplified and purely geometric setup, we ignore issues such as incomplete information, nonholonomic constraints, control issues related to inaccuracies in sensing and motion, nonstationary obstacles, optimality of the planned motion, and so on.

Since the early 1980s, motion planning has been an intensive area of study in robotics and computational geometry. In this chapter we will focus on *algorithmic motion planning*, emphasizing theoretical algorithmic analysis of the problem and seeking worst-case asymptotic bounds, and only mention briefly practical heuristic approaches to the problem. The majority of this chapter is devoted to the simplified version of motion planning, as stated above. Section 47.1 presents general techniques and lower bounds. Section 47.2 considers efficient solutions to a variety of specific moving systems with a small number of degrees of freedom. These efficient solutions exploit various sophisticated methods in computational and combinatorial geometry related to arrangements of curves and surfaces ([Chapter 24](#)). Section 47.3 then briefly discusses various extensions of the motion planning problem, incorporating uncertainty, moving obstacles, etc. We conclude in Section 47.4 with a brief review of Davenport-Schinzel sequences, a combinatorial structure that plays an important role in many motion planning and other geometric algorithms.

47.1 GENERAL TECHNIQUES AND LOWER BOUNDS

GLOSSARY

Some of the terms defined here are also defined in [Chapter 48](#).

Robot B : A mechanical system consisting of one or more rigid bodies, possibly connected by various joints and hinges.

Physical space (workspace): The 2D or 3D environment in which the robot

moves.

Placement: The portion of physical space occupied by the robot at some instant.

Degrees of freedom k : The number of real parameters that determine the robot B 's placements. Each placement can be represented as a point in $\mathbb{R}^k$.

Free placement: A placement at which the robot is disjoint from the obstacles.

Semifree placement: A placement at which the robot does not meet the interior of any obstacle (but may be in contact with some obstacles).

Configuration space $\mathcal{C}$: A portion of k -space (where k is the number of degrees of freedom of B) that represents all possible robot placements; the coordinates of any point in this space specify the corresponding placement.

Expanded obstacle / $\mathcal{C}$ -obstacle / forbidden region: For an obstacle O , this is the portion O^* of configuration space consisting of placements at which the robot intersects (collides with) O .

Free configuration space $\mathcal{F}$: The subset of configuration space consisting of free placements of the robot: $\mathcal{F} = \mathcal{C} \setminus \bigcup_O O^*$. (In the literature, this usually also includes semifree placements. In that case, $\mathcal{F}$ is the complement of the union of the interiors of the expanded obstacles.)

Contact surface: For an obstacle feature a (corner, edge, face, etc.) and for a feature b of the robot, this is the locus in $\mathcal{C}$ of placements at which a and b are in contact with each other. In most applications, these surfaces are semialgebraic sets of constant description complexity (see definitions below).

Collision-free motion of B : A path contained in $\mathcal{F}$. Any two placements of B that can be reached from each other via a collision-free path must lie in the same (arcwise-)connected component of $\mathcal{F}$.

Arrangement $\mathcal{A}(\Sigma)$: The decomposition of k -space into cells of various dimensions, induced by a collection Σ of surfaces in $\mathbb{R}^k$. Each cell is a maximal connected portion of the intersection of some fixed subcollection of surfaces that does not meet any other surface. See [Chapter 24](#). Since a collision-free motion should not cross any contact surface, $\mathcal{F}$ is the union of some of the cells of $\mathcal{A}(\Sigma)$, where Σ is the collection of contact surfaces.

Semialgebraic set: A subset of $\mathbb{R}^k$ defined by a Boolean combination of polynomial equalities and inequalities in the k coordinates. See [Section 33.2](#).

Constant description complexity: Said of a semialgebraic set if it is defined by a constant number of polynomial equalities and inequalities of constant maximum degree (where the number of variables is also assumed to be constant).

Example. Let B be a rigid polygon with k edges, moving in a planar polygonal environment V with n edges. The system has three degrees of freedom, (x, y, θ) , where (x, y) are the coordinates of some reference point on B , and θ is the orientation of B . Each contact surface is the locus of placements where some vertex of B touches some edge of V , or some edge of B touches some vertex of V . There are $2kn$ contact surfaces, and if we replace θ by $\tan \frac{\theta}{2}$, then each contact surface becomes a portion of some algebraic surface of degree at most 4, bounded by a constant number of algebraic arcs, each of degree at most 2.

47.1.1 GENERAL SOLUTIONS

GLOSSARY

Cylindrical algebraic decomposition of $\mathcal{F}$: A recursive decomposition of $\mathcal{C}$ into cylindrical-like cells originally proposed by Collins [Col75]. Over each cell of the decomposition, each of the polynomials involved in the definition of $\mathcal{F}$ has a fixed sign (positive, negative, or zero), implying that $\mathcal{F}$ is the union of some of the cells of this decomposition. See [Section 33.5](#) for further details.

Connectivity graph: A graph whose nodes are the (free) cells of a decomposition of $\mathcal{F}$ and whose arcs connect pairs of adjacent cells.

Roadmap $\mathcal{R}$: A network of one-dimensional curves within $\mathcal{F}$, having the properties that (i) it *preserves the connectivity* of $\mathcal{F}$, in the sense that the portion of $\mathcal{R}$ within each connected component of $\mathcal{F}$ is (nonempty and) connected; and (ii) it is *reachable*, in the sense that there is a simple procedure to move from any free placement of the robot to a placement on $\mathcal{R}$; we denote the mapping resulting from this procedure by $\phi_{\mathcal{R}}$.

Retraction of $\mathcal{F}$ onto $\mathcal{R}$: A continuous mapping of $\mathcal{F}$ onto $\mathcal{R}$ that is the identity on $\mathcal{R}$. The roadmap mapping $\phi_{\mathcal{R}}$ is usually a retraction. When this is the case, we note that for any path ψ within $\mathcal{F}$, represented as a continuous mapping $\psi : [0, 1] \mapsto \mathcal{F}$, $\phi_{\mathcal{R}} \circ \psi$ is a path within $\mathcal{R}$, and, concatenating to it the motions from $\psi(0)$ and $\psi(1)$ to $\mathcal{R}$, we see that there is a collision-free motion of B between two placements Z_1, Z_2 iff there is a path within $\mathcal{R}$ between $\phi_{\mathcal{R}}(Z_1)$ and $\phi_{\mathcal{R}}(Z_2)$.

Silhouette: The set of critical points of a mapping; see [Section 33.6](#).

CELL DECOMPOSITION

$\mathcal{F}$ is a semialgebraic set in $\mathbb{R}^k$. Applying Collins's cylindrical algebraic decomposition results in a collection of cells whose total complexity is $O((nd)^{3^k})$, where d is the maximum algebraic degree of the polynomials defining the contact surfaces; the decomposition can be constructed within a similar time bound. If the coordinate axes are generic, then we can also compute all pairs of cells of $\mathcal{F}$ that are *adjacent* to each other (i.e., cells whose closures (within $\mathcal{F}$) overlap), and store this information in the form of a connectivity graph. It is then easy to search for a collision-free path through this graph, if one exists, between the (cell containing the) initial robot placement and the (cell containing the) final placement. This leads to a doubly-exponential general solution for the motion planning problem:

THEOREM 47.1.1 *Cylindrical Cell Decomposition* [SS83]

Any motion planning problem, with k degrees of freedom, for which the contact surfaces are defined by a total of n polynomials of maximum degree d , can be solved by Collins's cylindrical algebraic decomposition, in randomized expected time $O((nd)^{3^k})$.

(The randomization is needed only to choose a generic direction for the coordinate axes.)

ROADMAPS

A more recent and improved solution is given in [Can87, BPR00] based on the notion of a **roadmap** $\mathcal{R}$, a network of one-dimensional curves within (the closure of) $\mathcal{F}$, having properties defined in the glossary above. Once such a roadmap $\mathcal{R}$ has been constructed, any motion planning instance reduces to path searching within $\mathcal{R}$, which is easy to do. $\mathcal{R}$ is constructed recursively, as follows. One projects $\mathcal{F}$ onto some generic 2-plane, and computes the silhouette of $\mathcal{F}$ under this projection. Next, the critical values of the projection of the silhouette on some line are found, and a roadmap is constructed recursively within each slice of $\mathcal{F}$ at each of these critical values. The resulting “sub-roadmaps” are then merged with the silhouette, to obtain the desired $\mathcal{R}$.

The original algorithm of Canny relies heavily on the polynomials defining $\mathcal{F}$ being in general position, and on the availability of a generic plane of projection. This algorithm runs in $n^k(\log n)d^{O(k^4)}$ deterministic time, and in $n^k(\log n)d^{O(k^2)}$ expected randomized time. Recent work [BPR00] addresses and overcomes the general position issue, and produces a roadmap for any semialgebraic set; the running time of this solution is $n^{k+1}d^{O(k^2)}$.

If we ignore the dependence on the degree d , the algorithm of Canny is close to optimal in the worst case, assuming that some representation of the entire $\mathcal{F}$ has to be output, since there are easy examples where the free configuration space consists of $\Omega(n^k)$ connected components.

THEOREM 47.1.2 *Roadmap Algorithm* [Can87]

Any motion planning problem, as in the preceding theorem, in general position can be solved by the roadmap technique in $n^k(\log n)d^{O(k^4)}$ deterministic time, and in $n^k(\log n)d^{O(k^2)}$ expected randomized time.

47.1.2 LOWER BOUNDS

The upper bounds for both general solutions are (at least) exponential in k (but are polynomial in the other parameters when k is fixed). This raises the issue of calibrating the complexity of the problem when k can be arbitrarily large.

THEOREM 47.1.3 *Lower Bounds*

The motion planning problem, with arbitrarily many degrees of freedom, is PSPACE-hard for the instances of: (a) coordinated motion of many rectangular boxes along a rectangular floor [HSS84]; (b) motion planning of a planar mechanical linkage with many links [HJW84]; and (c) motion planning for a multi-arm robot in a 3-dimensional polyhedral environment [Rei87].

All these results can also be found in the collection [HSS87]. There are also many NP-hardness results for other systems; see, e.g., [HJW85].

Facing these findings, we can either approach the general problem with heuristic and approximate schemes, or attack specific problems with small values of k , with the goal of obtaining solutions better than those yielded by the general techniques. We will mostly survey here the latter approach, and mention toward the end what has been achieved by the first approach.

47.2 MOTION PLANNING WITH A SMALL NUMBER OF DEGREES OF FREEDOM

In this main section of the chapter, we review solutions to a variety of specific motion planning problems, most of which have 2 or 3 degrees of freedom. Exploiting the special structure of these problems leads to solutions that are more efficient than the general methods described above.

GLOSSARY

Jordan arc/curve: The image of the closed unit interval under a continuous bijective mapping into the plane. A closed Jordan curve is the image of the unit circle under a similar mapping, and an unbounded Jordan curve is an image of the open unit interval (or of the entire real line) that separates the plane.

Randomized algorithm: An algorithm that applies internal randomization (“coin-flips”). We consider here algorithms that always terminate, and produce the correct output, but whose running time is a random variable that depends on the internal coin-flips. We will state upper bounds on the expectation of the running time (the *randomized expected time*) of such an algorithm, which hold for any input. See [Chapter 40](#).

Minkowski sum: For two planar (or spatial) sets A and B , their Minkowski sum, or pointwise vector addition, is the set $A \oplus B = \{x + y \mid x \in A, y \in B\}$.

General position: The input to a geometric problem is said to be in general position if no nontrivial algebraic identity with integer coefficients holds among the parameters that specify the input (assuming the input is not overspecified). For example: no three input points should be collinear, no four points cocircular, no three lines concurrent, etc.

Convex distance function: A convex region B that contains the origin in its interior induces a convex distance function d_B defined by

$$d_B(p, q) = \min \{ \lambda \mid q \in p \oplus \lambda B \}.$$

If B is centrally symmetric with respect to the origin then d_B is a metric whose unit ball is B .

B -Voronoi diagram: For a set S of sites, and a convex region B as above, the B -Voronoi diagram $\text{Vor}_B(S)$ of S is a decomposition of space into Voronoi cells $V(s)$, for $s \in S$, such that

$$V(s) = \{p \mid d_B(p, s) \leq d_B(p, s') \text{ for all } s' \in S\}.$$

Here $d_B(p, s) = \min_{q \in s} d_B(p, q)$.

$\alpha(n)$: The extremely slowly-growing inverse Ackermann function; see Section 47.4.

Contact segment: The locus of (not necessarily free) placements of a polygon B translating in a planar polygonal workspace, at each of which either some specific vertex of B touches some specific obstacle edge, or vice-versa.

Contact curve: A generalization of “contact segment” to the locus of (not necessarily free) placements of a more general robot system B , assuming that B has only two degrees of freedom, where some specific feature of B makes contact with some specific obstacle feature.

47.2.1 TWO DEGREES OF FREEDOM

A TRANSLATING POLYGON IN 2D

This is a system with two degrees of freedom (translations in the x and y directions).

A CONVEX POLYGON

Suppose first the translating polygon B is a *convex* k -gon, and there are m convex polygonal obstacles, $A_1, \dots, A_m$, with pairwise disjoint interiors, having a total of n edges. The region of configuration space where B collides with A_i is the *Minkowski sum*

$$K_i = A_i \oplus (-B) = \{x - y \mid x \in A_i, y \in B\}.$$

The free configuration space is the complement of $\bigcup_{i=1}^m K_i$. Assuming general position, one can show:

THEOREM 47.2.1 [KLPS86]

- (a) Each K_i is a convex polygon, with $n_i + k$ edges, where n_i is the number of edges of A_i .
- (b) For each $i \neq j$, the boundaries of K_i and K_j intersect in at most two points. (This also holds when the A_i 's and B are not polygons.)
- (c) Given a collection of planar regions $K_1, \dots, K_m$, each enclosed by a closed Jordan curve, such that any pair of the bounding curves intersects at most twice, then the boundary of the union $\bigcup_{i=1}^m K_i$ consists of at most $6m - 12$ maximal connected portions of the boundaries of the K_i 's, provided $m \geq 3$, and this bound is tight in the worst case.

These properties, combined with several algorithmic techniques [KLPS86, MMP⁺91, dBDS95], imply:

THEOREM 47.2.2

- (a) The free configuration space for a translating convex polygon, as above, is a polygonal region with at most $6m - 12$ convex vertices and $N = \sum_{i=1}^m (n_i + k) = n + km$ nonconvex vertices.
- (b) $\mathcal{F}$ can be computed in deterministic time $O(N \log^2 n)$, or in randomized expected time $O(N \log n)$.

If the robot is translating in a convex room with n walls, then the complexity of the free space is $O(n)$ and it can be computed in $O(n + k)$ time.

AN ARBITRARY POLYGON

Suppose next that B is an arbitrary polygonal region with k edges. Let A be the union of all obstacles, which is another polygonal region with n edges. As above, the free configuration space is the complement of the Minkowski sum

$$K = A \oplus (-B) = \{x - y \mid x \in A, y \in B\}.$$

K is again a polygonal region, but, in this case, its maximum possible complexity is $\Theta(k^2 n^2)$ (see, e.g., [AFH02]), so computing it might be considerably more expensive than in the convex case. Efficient practical algorithms for the exact computation of Minkowski sums in this case (together with their implementation) are described in [AFH02].

A single face suffices. If the initial placement Z of B is given, then we do not have to compute the entire (complement of) K ; it suffices to compute the connected component f of the complement of K that contains Z , because no other placement is reachable from Z via a collision-free motion.

Let Σ be the collection of all contact segments; there are $2kn$ such segments. The desired component f is the face of $\mathcal{A}(\Sigma)$ that contains Z . Using the theory of *Davenport-Schinz sequences* (Section 47.4), one can show that the maximum possible combinatorial complexity of a single face in a two-dimensional arrangement of N segments is $\Theta(N\alpha(N))$. A more careful analysis [HCA⁺95], combined with the algorithmic techniques of [CEG⁺93, GSS89], shows:

THEOREM 47.2.3

- (a) *The maximum combinatorial complexity of a single face in the arrangement of contact segments for the case of an arbitrary translating polygon is $\Theta(kn\alpha(k))$ (this improvement is significant only when $k \ll n$).*
- (b) *Such a face can be computed in deterministic time $O(kn\alpha(k)\log^2 n)$ [GSS89], or in randomized expected time $O(kn\alpha(k)\log n)$ [CEG⁺93].*

VORONOI DIAGRAMS

Another approach to motion planning for a translating *convex* object B , is via generalized *Voronoi diagrams* (see [Chapter 23](#)), based on the convex distance function $d_B(p, q)$. This function effectively places B centered at p and expands it until it hits q . The scaling factor at this moment is the d_B -distance from p to q (if B is a unit disk, d_B is the Euclidean distance). d_B satisfies the triangle inequality, and is thus “almost” a metric, except that it is not symmetric in general; it is symmetric iff B is centrally symmetric with respect to the point of reference.

Using this distance function d_B , a *B-Voronoi diagram* $\text{Vor}_B(\mathcal{S})$ of $\mathcal{S}$ may be defined for a set $\mathcal{S}$ of m pairwise disjoint obstacles. See [LS87a, Yap87a].

THEOREM 47.2.4

Assuming that each of B and the obstacles in $\mathcal{S}$ has constant description complexity, and that they are in general position, the B-Voronoi diagram has $O(m)$ complexity, and can be computed in $O(m \log m)$ time (in an appropriate model of computation). If B and the obstacles are convex polygons, as above, then the complexity of $\text{Vor}_B(\mathcal{S})$ is $O(N)$ and it can be computed in time $O(N \log m)$.

One can show that if Z_1 and Z_2 are two free placements of B , then there exists a collision-free motion from Z_1 to Z_2 if and only if there exists a collision-free motion of B where its center moves only along the edges of $\text{Vor}_B(\mathcal{S})$, between two corresponding placements W_1, W_2 , where W_i , for $i = 1, 2$, is the placement obtained by pushing B from the placement Z_i away from its d_B -nearest obstacle, until it becomes equally nearest to two or more obstacles (so that its center lies on an edge of $\text{Vor}_B(\mathcal{S})$).

Thus motion planning of B reduces to a path-searching in the one-dimensional network of edges of $\text{Vor}_B(\mathcal{S})$. This technique is called the *retraction technique*, and can be regarded as a special case of the general roadmap algorithm. The resulting motions have “high clearance,” and so are safer than arbitrary motions, because they stay equally nearest to at least two obstacles.

THEOREM 47.2.5

The motion planning problem for a convex object B translating amidst m convex and pairwise disjoint obstacles can be solved in $O(m \log m)$ time, by constructing and searching in the B -Voronoi diagram of the obstacles, assuming that B and the obstacles have constant description complexity each. If B and the obstacles are convex polygons, then the same technique yields an $O(N \log m)$ solution, where $N = n + km$ is as above.

THE GENERAL MOTION PLANNING PROBLEM WITH TWO DEGREES OF FREEDOM

If B is any system with two degrees of freedom, its configuration space is 2D, and, for simplicity, let us think of it as the plane (spaces that are topologically more complex can be decomposed into a constant number of “planar” patches). We construct a collection Σ of contact curves, which, under reasonable assumptions concerning B and the obstacles, are each an algebraic Jordan arc or curve of some fixed maximum degree b . In particular, each pair of contact curves will intersect in at most some constant number, $s \leq b^2$, of points.

As above, it suffices to compute the single face of $\mathcal{A}(\Sigma)$ that contains the initial placement of B . The theory of Davenport-Schinzel sequences implies that the complexity of such a face is $O(\lambda_{s+2}(n))$, where $\lambda_{s+2}(n)$ is the maximum length of an $(n, s+2)$ -Davenport-Schinzel sequence (Section 47.4), which is slightly super-linear in n when s is fixed.

The face in question can be computed in deterministic time $O(\lambda_{s+2}(n) \log^2 n)$, using a fairly involved divide-and-conquer technique based on line-sweeping; see [GSS89] and Section 24.5. (Some slight improvements in the running time have been subsequently obtained.) Using randomized incremental (or divide-and-conquer) techniques, the face can be computed in randomized expected $O(\lambda_{s+2}(n) \log n)$ time [CEG⁺93, SA95].

THEOREM 47.2.6 *see* [GSS89, CEG⁺93, dBDS95]

Under the above assumptions, the general motion planning problem for systems with two degrees of freedom can be solved in deterministic time $O(\lambda_{s+2}(n) \log^2 n)$, or in $O(\lambda_{s+2}(n) \log n)$ randomized expected time.

47.2.2 THREE DEGREES OF FREEDOM

A ROD IN A PLANAR POLYGONAL ENVIRONMENT

We next pass to systems with three degrees of freedom. Perhaps the simplest instance of such a system is the case of a line segment B (“rod,” “ladder,” “pipe”) moving (translating and rotating) in a planar polygonal environment with n edges. The maximum combinatorial complexity of the free configuration space $\mathcal{F}$ of B is $\Theta(n^2)$ (recall that the naive bound for systems with three degrees of freedom is $O(n^3)$). A cell-decomposition representation of $\mathcal{F}$ can be constructed in (deterministic) $O(n^2 \log n)$ time [LS87b]. Several alternative near-quadratic algorithms have also been developed, including one based on constructing a Voronoi diagram in $\mathcal{F}$ [OSY87]. A worst-case optimal algorithm, with running time $O(n^2)$, has been given in [Veg90].

An $\Omega(n^2)$ lower bound for this problem has been established in [KO88]. It exhibits a polygonal environment with n edges and two free placements of B that are reachable from each other. However, any free motion between them requires $\Omega(n^2)$ “elementary moves,” that is, the specification of any such motion requires $\Omega(n^2)$ complexity. This is a fairly strong lower bound, since it does not rely on lower bounding the complexity of the free configuration space (or of a single connected component thereof); after all, it is not clear why a motion planning algorithm should have to produce a full description of the whole free space (or of a single component).

THEOREM 47.2.7

Motion planning for a rod moving in a polygonal environment bounded by n edges can be performed in $O(n^2)$ time. There are instances where any collision-free motion of the rod between two specified placements requires $\Omega(n^2)$ “elementary moves.”

A CONVEX POLYGON IN A PLANAR POLYGONAL ENVIRONMENT

Here B is a convex k -gon, free to move (translate and rotate) in an arbitrary polygonal environment bounded by n edges. The free configuration space is 3D, and there are at most $2kn$ contact surfaces, of maximum degree 4. The naive bound on the complexity of $\mathcal{F}$ is $O((kn)^3)$ (attained if B is nonconvex), but, using Davenport-Schinzle sequences, one can show that the complexity of $\mathcal{F}$ is only $O(kn\lambda_6(kn))$. Geometrically, a vertex of $\mathcal{F}$ is a semifree placement of B at which it makes simultaneously three obstacle contacts. The above bound implies that the number of such *critical placements* is only slightly super-quadratic (and not cubic) in kn .

Computing $\mathcal{F}$ in time close to this bound has proven more difficult, and only recently has a complete solution, running in $O(kn\lambda_6(kn) \log kn)$ time and constructing the entire $\mathcal{F}$, been attained [AAS99]. Previous solutions that were either incomplete with the same time bound or complete and somewhat more expensive are given in [KS90, HS96, KST97].

Another approach was given in [CK93]. It computes the Delaunay triangulation of the obstacles under the distance function d_B , when the orientation of B is fixed, and then traces the discrete combinatorial changes in the diagram as the orientation

varies. The number of changes was shown to be $O(k^4 n \lambda_3(n))$. Using this structure, the algorithm of [CK93] produces a high-clearance motion of B between any two specified placements, in time $O(k^4 n \lambda_3(n) \log n)$.

Since all these algorithms are fairly complicated, one might consider in practice an alternative approximate scheme, proposed in [AFK⁺92]. This scheme, originally formulated for a rectangle, discretizes the orientation of B , solves the translational motion planning for B at each of the discrete orientations, and finds those placements of B at which it can rotate (without translating) between two successive orientations. This scheme works very well in practice.

THEOREM 47.2.8

Motion planning for a k -sided convex polygon, translating and rotating in a planar polygonal environment bounded by n edges, can be performed in $O(kn\lambda_6(kn) \log kn)$ or $O(k^4 n \lambda_3(n) \log n)$ time.

EXTREMAL PLACEMENTS

A related problem is to find the largest free placement of B in the given polygonal environment. This has applications in manufacturing, where one wants to cut out copies of B that are as large as possible from a sheet of some material.

If only translations are allowed, the B -Voronoi diagram can be used to find the largest free homothetic copy of B . If general rigid motions are allowed, the technique of [CK93] computes the largest free similar copy of B in time $O(k^4 n \lambda_3(n) \log n)$. An alternative technique is given in [AAS98], with randomized expected running time $O(kn\lambda_6(kn) \log^4 kn)$. Both bounds are nearly quadratic in n . See also earlier work on this problem in [ST94].

Finally, we mention the special case where the polygonal environment is the interior of a convex n -gon. This is simpler to analyze. The number of free critical placements of (similar copies of) B , at which B makes simultaneously four obstacle contacts, is $O(kn^2)$ [AAS98], and they can all be computed in $O(kn^2 \log n)$ time. If only translations are allowed, this problem can easily be expressed as a linear program, and can be solved in $O(n + k)$ time [ST94].

THEOREM 47.2.9

The largest similar placement of a k -sided convex polygon in a planar polygonal environment bounded by n edges can be computed in randomized expected time $O(kn\lambda_6(kn) \log^4 kn)$ or in deterministic time $O(k^4 n \lambda_3(n) \log n)$. When the environment is the interior of an n -sided convex polygon, the running time improves to $O(kn^2 \log n)$, and to $O(n + k)$ if only translations are allowed.

A NONCONVEX POLYGON

Next we consider the case where B is an arbitrary polygonal region (not necessarily connected), translating and rotating in a polygonal environment bounded by n edges, as above. Here one can show that the maximum complexity of $\mathcal{F}$ is $\Theta((kn)^3)$. Using standard techniques, $\mathcal{F}$ can be constructed in $\Theta((kn)^3 \log kn)$ time, and algorithms with this running time bound have been implemented; see, e.g., [ABF89]. However, as in the purely translational case, it suffices to construct the connected component of $\mathcal{F}$ containing the initial placement of B . The general result, stated

below, for systems with three degrees of freedom, implies that the complexity of such a component is only near-quadratic in kn . A special-purpose algorithm that computes the component in time $O((kn)^{2+\epsilon})$ is given in [HS96]. A more general algorithm with a similar running time bound is reported below. An earlier work considered the case where B is an L-shaped object moving amid n point obstacles [HOS92]. Motion planning can be performed in this case in time $O(n^2 \log^2 n)$.

THEOREM 47.2.10

Motion planning for an arbitrary k -sided polygon, translating and rotating in a planar polygonal environment bounded by n edges, can be performed in time $O((kn)^{2+\epsilon})$, for any $\epsilon > 0$. If the polygon is L-shaped and the obstacles are points, the running time improves to $O(n^2 \log^2 n)$.

A TRANSLATING POLYTOPE IN A 3D POLYHEDRAL ENVIRONMENT

Another interesting motion planning problem with three degrees of freedom involves a polytope B , with a total of k vertices, edges, and facets, translating amidst polyhedral obstacles in $\mathbb{R}^3$, with a total of n vertices, edges, and faces. The contact surfaces in this case are planar polygons, composed of a total of $O(kn)$ triangles in 3-space.

Without additional assumptions, the complexity of $\mathcal{F}$ can be $\Theta((kn)^3)$ in the worst case. However, the complexity of a single component is only $O((kn)^2 \log kn)$. Such a component can be constructed in $O((kn)^{2+\epsilon})$ time, for any $\epsilon > 0$ [AS94].

If B is a convex polytope, and the obstacles consist of m convex polyhedra, with pairwise disjoint interiors and with a total of n faces, the complexity of the entire $\mathcal{F}$ is $O(kmn \log m)$ and it can be constructed in $O(kmn \log^2 m)$ time [AS97]. (Note that, in analogy with the two-dimensional case, $\mathcal{F}$ is the complement of the union of the Minkowski sums $A_i \oplus (-B)$, where A_i are the given obstacles. The above-cited bound is about the complexity and construction of such a union.) An earlier study [HY98] considered the case where B is a box, and obtained an $O(n^2 \alpha(n))$ bound for the complexity of $\mathcal{F}$.

THEOREM 47.2.11

Translational motion planning for an arbitrary polytope with k facets, in an arbitrary 3D polyhedral environment bounded by n facets, can be performed in time $O((kn)^{2+\epsilon})$, for any $\epsilon > 0$. If B is a convex polytope, and there are m convex pairwise disjoint obstacles with a total of n facets, then the motion planning can be performed in $O(kmn \log^2 m)$ time.

A BALL IN A 3D POLYHEDRAL ENVIRONMENT

Let B be a ball moving in 3D amidst polyhedral obstacles with a total of n vertices, edges, and faces. The complexity of the entire $\mathcal{F}$ is $O(n^{2+\epsilon})$, for any $\epsilon > 0$ [AS00a]. Note that, for the special case of line obstacles, the expanded obstacles are congruent (infinite) cylinders, and $\mathcal{F}$ is the complement of their union.

THEOREM 47.2.12

Motion planning for a ball in an arbitrary 3D polyhedral environment bounded by n facets can be performed in time $O(n^{2+\epsilon})$, for any $\epsilon > 0$.

3D B -VORONOI DIAGRAMS

A more powerful approach to translational motion planning in three dimensions is via B -Voronoi diagrams, defined in three dimensions in full analogy to the two-dimensional case mentioned above. The goal is to establish a near-quadratic bound for the complexity of such a diagram. This would yield near-quadratic algorithms for planning the motion of the moving body B , for planning a high-clearance motion, and for finding largest homothetic free placements of B . The analysis of B -Voronoi diagrams is considerably more difficult in 3-space, and there are only a few instances where a near-quadratic complexity bound is known. One instance is for the case where B is a translating convex polytope with $O(1)$ facets in a 3D polyhedral environment [KS02b]; the complexity of the diagram in this case is $O(n^{2+\epsilon})$. If the obstacles are lines or line segments, the complexity is $O(n^2 \alpha(n) \log n)$ [CKS⁺98, KS02b].

The case where B is a ball appears to be more challenging. Even for the special case where the obstacles are lines, no near-quadratic bounds are known. However, if the obstacles are n lines with a constant number of orientations, the B -diagram has complexity $O(n^{2+\epsilon})$ [KS02a].

THE GENERAL MOTION PLANNING PROBLEM WITH THREE DEGREES OF FREEDOM

The last several instances were special cases of the general motion planning problem with three degrees of freedom. In abstract terms, we have a collection Σ of N contact surfaces in $\mathbb{R}^3$, where these surfaces are assumed to be (patches of) algebraic surfaces of constant maximum degree. The free configuration space consists of some cells of the arrangement $\mathcal{A}(\Sigma)$, and a single connected component of $\mathcal{F}$ is just a single cell in that arrangement.

Inspecting the preceding cases, a unifying observation is that while the maximum complexity of the entire $\mathcal{F}$ can be $\Theta(N^3)$, the complexity of a single component is invariably only near-quadratic in N . This was recently shown in [HS95a] to hold in general: the combinatorial complexity of a single cell of $\mathcal{A}(\Sigma)$ is $O(N^{2+\epsilon})$, for any $\epsilon > 0$, where the constant of proportionality depends on ϵ and on the maximum degree of the surfaces; cf. Section 24.5.

A general-purpose algorithm for computing a single cell in such an arrangement was recently given in [SS97]. It runs in randomized expected time $O(N^{2+\epsilon})$, for any $\epsilon > 0$, and is based on *vertical decompositions* in such arrangements (see Section 24.3.2).

THEOREM 47.2.13

An arbitrary motion planning problem with three degrees of freedom, involving N contact surface patches, each of constant description complexity, can be solved in time $O(N^{2+\epsilon})$, for any $\epsilon > 0$.

47.2.3 OTHER PROBLEMS WITH FEW DEGREES OF FREEDOM

MORE DEGREES OF FREEDOM

The general motion planning problem for systems with d degrees of freedom, for $d \geq 4$, calls for estimating the complexity of a single cell in the d -dimensional arrangement of the appropriate contact surfaces, and for efficient algorithms for constructing such a cell. A recent result [Bas03] shows that the complexity of such a cell in a d -dimensional arrangement of n surfaces of constant description complexity is $O(n^{d-1+\epsilon})$, for any $\epsilon > 0$, where the constant of proportionality depends on d , ϵ , and the maximum degree of the polynomials defining the surfaces.

In contrast, computing such a cell within a comparable time bound remains an open problem.

COORDINATED MOTION PLANNING

Another class of motion planning problems involves coordinated motion planning of several independently moving systems. Conceptually, this situation can be handled as just another special case of the general problem: Consider all the moving objects as a single system, with $k = \sum_{i=1}^t k_i$ degrees of freedom, where t is the number of moving objects, and k_i is the number of degrees of freedom of the i th object. However, k will generally be too large, and the problem then will be more difficult to tackle.

A better approach is as follows [SS91]. Let $B_1, \dots, B_t$ be the given independent objects. For each $i = 1, \dots, t$, construct the free configuration space $\mathcal{F}^{(i)}$ for B_i alone (ignoring the presence of all other moving objects). The actual free configuration space $\mathcal{F}$ is a subset of $\prod_{i=1}^t \mathcal{F}^{(i)}$. Suppose we have managed to decompose each $\mathcal{F}^{(i)}$ into subcells of constant description complexity. Then $\mathcal{F}$ is a subset of the union of Cartesian products of the form $c_1 \times c_2 \times \dots \times c_t$, where c_i is a subcell of $\mathcal{F}^{(i)}$.

We next compute the portion of $\mathcal{F}$ within each such product. Each such subproblem can be intuitively interpreted as the coordinated motion planning of our objects, where each moves within a small portion of space, amidst only a constant number of nearby obstacles; so these subproblems are much easier to solve. Moreover, in typical cases, for most products $P = c_1 \times c_2 \times \dots \times c_t$ the problem is trivial, because P represents situations where the moving objects are far from one another, and so cannot interact at all, meaning that $\mathcal{F} \cap P = P$. The number of subproblems that really need to be solved will be relatively small.

The connectivity graph that represents $\mathcal{F}$ is also relatively easy to construct. Its nodes are the connected components of the intersections of $\mathcal{F}$ with each of the above cell products P , and two nodes are connected to each other if they are adjacent in the overall $\mathcal{F}$. In many typical cases, determining this adjacency is easy.

As an example, one can apply this technique to the coordinated motion planning of k disks moving in a planar polygonal environment bounded by n edges, to get a solution with $O(n^k)$ running time [SS91]. Since this problem has $2k$ degrees of freedom, this is a significant improvement over the bound $O(n^{2k} \log n)$ yielded by Canny's general algorithm.

See [ABS⁺99] for another treatment of coordinated motion planning, for two or three general independently moving robots, where algorithms that are also faster than Canny’s general technique are developed.

A ROD IN A 3D POLYHEDRAL ENVIRONMENT

This problem has five degrees of freedom (three of translation and two of rotation). Recent work shows that the complexity of $\mathcal{F}$ is only $O(n^3\lambda_4(n))$ [Kol].

TABLE 47.2.1 Summary of motion planning algorithms.

SYSTEM	MOTION	ENVIRONMENT	df	RUNNING TIME
Convex k -gon	translation	planar polygonal	2	$O(N \log m)$
Arbitrary k -gon	translation	planar polygonal	2	$O(kn \log^2 n)$
General			2	$O(\lambda_{s+2}(n) \log^2 n)$
Line segment	trans & rot	planar polygonal	3	$O(n^2 \log n)$
Convex k -gon	trans & rot	planar polygonal	3	$O(k^4 n \lambda_3(n) \log n)$ $O(kn \lambda_6(kn) \log n)$
Arbitrary k -gon	trans & rot	planar polygonal	3	$O((kn)^{2+\epsilon})$
Convex polytope	translation	3D polyhedral	3	$O(kmn \log^2 m)$
Arbitrary polytope	translation	3D polyhedral	3	$O((kn)^{2+\epsilon})$
Ball		3D polyhedral	3	$O(n^{2+\epsilon})$
General			3	$O(N^{2+\epsilon})$

MOTION PLANNING AND ARRANGEMENTS

As can be seen from the preceding subsections, motion planning is closely related to the study of arrangements of surfaces in higher dimensions. Motion planning has motivated many problems in arrangements, such as the problem of bounding the complexity of, and designing efficient algorithms for, computing a single cell in an arrangement of n low-degree algebraic surface patches in d dimensions, the problem of computing the union of geometric objects (the expanded obstacles), and the problem of decomposing higher-dimensional arrangements into subcells of constant description complexity. These problems are only partially solved and present major challenges in the study of arrangements. See [Chapter 24](#) and [SA95] for further details.

SUMMARY

Some of the above results are summarized in Table 47.2.1. For each specific system, only one or two algorithms are listed.

47.3 VARIANTS OF THE MOTION PLANNING PROBLEM

We now briefly review several variants of the basic motion planning problem, in which additional constraints are imposed on the problem. Further material on many of these problems can be found in [Chapter 48](#).

OPTIMAL MOTION PLANNING

The preceding section described techniques for determining the existence of a collision-free motion between two given placements of some moving system. It paid no attention to the optimality of the motion, which is an important consideration in practice. There are several problems involved in optimal motion planning. First, optimality is a notion that can be defined in many ways, each of which leads to different algorithmic considerations. Second, optimal motion planning is usually much harder than motion planning per se.

SHORTEST PATHS

The simplest case is when the moving system B is a single point. In this case the cost of the motion is simply the length of the path traversed by the point (normally, we use the Euclidean distance, but other metrics have been considered as well). We thus face the problem of computing *shortest paths* amidst obstacles in a 2D or 3D environment.

The planar case. Let V be a closed planar polygonal environment bounded by n edges, and let s (the “source”) be a point in V . For any other point $t \in V$, let $\pi(s, t)$ denote the (Euclidean) shortest path from s to t within V . Finding $\pi(s, t)$ for any t is facilitated by construction of the *shortest path map* $SPM(s, V)$ from s in V , a decomposition of V into regions detailed in [Chapter 27](#). A recent result [HS99] computes $SPM(s, V)$ in optimal $O(n \log n)$ time.

The same problem may be considered in other metrics. For example, it is easier to give an $O(n \log n)$ algorithm for the shortest path problem under the L_1 or L_∞ metric. See [Section 27.3](#).

The three-dimensional case. Let V be a closed polyhedral environment bounded by a total of n faces, edges, and vertices. Again, given two points $s, t \in V$, we wish to compute the shortest path $\pi(s, t)$ within V from s to t . Here $\pi(s, t)$ is a polygonal path, bending at *edges* (sometimes also at vertices) of V . To compute $\pi(s, t)$, we need to solve two subproblems: to find the sequence of edges (and vertices) of V visited by $\pi(s, t)$ (the *shortest-path sequence* from s to t), and to compute the actual points of contact of $\pi(s, t)$ with these edges. These points obey the rule that the incoming angle of $\pi(s, t)$ with an edge is equal to the outgoing angle. Hence, given the shortest-path sequence of length m , we need to solve a system of m quartic equations in m variables in order to find the contact points. This can be solved either approximately, using an iterative scheme, or exactly, using techniques of computational real algebraic geometry; the latter method requires exponential time. Even the first, more “combinatorial,” problem of computing the shortest-path sequence is NP-hard [CR87], so the general shortest-path problem is certainly much harder in three dimensions.

Many special cases of this problem, with more efficient solutions, have been studied, of which we mention the problem of computing shortest paths on a convex polytope (see [MMP87] for an exact $O(n^2 \log n)$ algorithm, which has been subsequently improved to $O(n^2)$ [CH96], and [AHSV97] for an approximate linear-time solution), and on a polyhedral terrain [MMP87, VA01, LMS97]. See also [Section 27.5](#).

VARIOUS OPTIMAL MOTION PLANNING PROBLEMS

Suppose next that the moving system B is a rigid body free only to translate in two or three dimensions. Then the notion of optimality is still well defined—it is the total distance traversed by (any reference point attached to) B . One can then apply the same techniques as above, after replacing the obstacles by their expanded versions. For example, if B is a convex polygon in the plane, and the obstacles are m pairwise openly-disjoint convex polygons $A_1, \dots, A_m$, then we form the Minkowski sums $K_i = A_i \oplus (-B)$, for $i = 1, \dots, m$, and compute a shortest path in the complement of their union. Since the K_i 's may overlap, we first need to compute their union, as above. A similar approach can be used in planning shortest motion of a polyhedron translating amidst polyhedra in 3-space, etc.

If B admits more complex motions, then the notion of optimality begins to be fuzzy. For example, consider the case of a line segment (“rod”) translating and rotating in a planar polygonal environment. One could measure the cost of a motion by the total distance traveled by a designated endpoint (or the centerpoint) of B , or by a weighted average between such a distance and the total turning angle of B , etc. A version of this problem has recently been shown to be NP-hard [AKY96]. See [Section 27.3](#).

The notion of optimality gets even more complicated when one introduces kinematic constraints on the motion of B . It is then often challenging even without obstacles; see [Section 48.5.4](#).

PRACTICAL APPROACHES TO MOTION PLANNING

When the number of degrees of freedom is even moderately large, exact and complete solutions of the motion planning problem are very inefficient in practice, so one seeks heuristic or other incomplete but practical solutions. Several such techniques have been developed.

Potential field. The first heuristic regards the robot as moving in a potential field induced by the obstacles and by the target placement, where the obstacles act as repulsive barriers, and the target as a strongly attracting source. By letting the robot follow the gradient of such a potential field, we obtain a motion that avoids the obstacles and that can be expected to reach the goal. An attractive feature of this technique is that planning and executing the desired motion are done in a single stage. Another important feature is the generality of the approach; it can easily be applied to systems with many degrees of freedom.

This technique, however, may lead to a motion where the robot gets stuck at a local minimum of the potential field, leaving no guarantee that the goal will be reached. To overcome this problem, several solutions have been proposed. One is to try to escape from such a “potential well” by making a few small random moves, in the hope that one of them will put the robot in a position from which the field leads it away from this well. Another approach is to use the potential field only for subproblems where the initial and final placements are close to each other, so the chance to get stuck at a local minimum is small.

Probabilistic roadmaps. In the past decade, this method has picked up momentum, and has become the method of choice in many practical motion planning systems [BKL⁺97, KSLO96]. The general approach is to generate many random

free placements throughout the workspace, and to apply any “local” simple-minded planner to plan a motion between pairs of these placements; one may use for this purpose the potential field approach, or simply attempt to connect the two placements by a straight segment in configuration space. If the configuration space is sufficiently densely sampled, enough local free paths will be generated, and they will form a roadmap, in the sense of Section 47.1.1, which can then be used to perform motion planning between any pair of input placements. This technique has been applied to the difficult problem of protein folding with some success [SA01].

A significant problem that arises is how to sample well the free configuration space; informally, the goal is to detect all “tight” passages within $\mathcal{F}$, which will be missed unless some placements are generated near them. See [ABD⁺98, BKL⁺97, HLM99, KSLO96, KL01] and Section 48.4 for more details concerning this technique, its extensions and variants.

Fat obstacles. Another technique exploits the fact that, in typical layouts, the obstacles can be expected to be “fat” (this has several definitions; intuitively, they do not have long and skinny parts). Also, the obstacles tend not to be too clustered, in the sense that each placement of the robot can interact with only a constant number of obstacles. These facts tend to make the problem easier to solve in such so-called *realistic* input scenes. See [vdS⁺93] for the case of fat obstacles, [vdS⁺98] for the case of environments with low obstacle density, and [BKO⁺02] for two other models of realistic input scenes.

EXPLORATORY MOTION PLANNING

If the environment in which the robot moves is not known to the system a priori, but the system is equipped with sensory devices, motion planning assumes a more “exploratory” character. If only tactile (or proximity) sensing is available, then a plausible strategy might be to move along a straight line (in physical or configuration space) directly to the target position, and when an obstacle is reached, to follow its boundary until the original straight line of motion is reached again. This technique has been developed and refined for arbitrary systems with two degrees of freedom (see, e.g., [LS87]). It can be shown that this strategy provably reaches the goal, if at all possible, with a reasonable bound on the length of the motion. This technique has been implemented on several real and simulated systems, and has applications to maze-searching problems.

One attempt to extend this technique to a system with three degrees of freedom is given in [CY91]. This technique computes within $\mathcal{F}$ a certain one-dimensional skeleton (roadmap) $\mathcal{R}$ which captures the connectivity of $\mathcal{F}$. The twist here is that $\mathcal{F}$ is not known in advance, so the construction of $\mathcal{R}$ has to be done in an incremental, exploratory manner. This exploration can be implemented in a controlled manner that does not require too many “probing” steps, and which enables the system to recognize when the construction of $\mathcal{R}$ has been completed (if the goal has not been reached beforehand).

If vision is also available, then other possibilities need to be considered, e.g., the system can obtain partial information about its environment by viewing it from the present placement, and then “explore” it to gain progressively more information until the desired motion can be fully planned. Results that involve such *model-building* tasks can be found in [GMR97, ZF96] and Section 48.7.

TIME-VARYING ENVIRONMENTS

Interesting generalizations of the motion planning problem arise when some of the obstacles in the robot's environment are assumed to be moving along known trajectories. In this case the robot's goal will be to "dodge" the moving obstacles while moving to its target placement. In this "dynamic" motion planning problem, it is reasonable to assume some limit on the robot's velocity and/or acceleration. Two studies of this problem are [SM88, RS94]. They show that the problem of avoiding moving obstacles is substantially harder than the corresponding static problem. By using time-related configuration changes to encode Turing machine states, they show that the problem is PSPACE-hard even for systems with a small and fixed number of degrees of freedom. However, polynomial-time algorithms are available in a few particularly simple special cases. Another variant of this problem involves movable obstacles, which the robot B can, say, push aside to clear its passage. Again, it can be shown that the general problem of this kind is PSPACE-hard, some special instances are NP-hard, and polynomial-time algorithms are available in certain other special cases [Wil91, DZ99].

COMPLIANT MOTION PLANNING

In realistic situations, the moving system has only approximate knowledge of the geometry of the obstacles and/or of its current position and velocity, and it has an inherent amount of error in controlling its motion. The objective is to devise a strategy that will guarantee that the system reaches its goal, where such a strategy usually proceeds through a sequence of free motions (until an obstacle is hit) intermixed with *compliant motions* (sliding along surfaces of contacted obstacles) until it can be ascertained that the goal has been reached.

A standard approach to this problem is through the construction of pre-images (or back projections) [LPMT84]. Specific algorithms that solve various special cases of the problem can be found in [Bri89, Don90, FHS96]. See [Section 48.5.3](#).

NONHOLONOMIC MOTION PLANNING

Another realistic constraint on the possible motions of a given system is kinematic (or *kinodynamic*). For example, the moving object B might be constrained not to exceed certain velocity or acceleration thresholds, or has only limited steering capability. Even without any obstacles, such problems are usually quite hard, and the presence of (stationary or moving) obstacles makes them extremely complicated to solve. These so-called *nonholonomic motion planning* problems are usually handled using tools from control theory. A relatively simple special case is that of a car-like robot in a planar workspace, with a bound on the radius of curvature of its motion. Issues like reachability between two given placements (even in the absence of obstacles) raise interesting geometric considerations, where one of the goals is to identify canonical motions that always suffice to get to any reachable placement. See [Lat91, LC92, Lau98] for several books that cover this topic, and [Section 48.5.2](#). Kinodynamic motion planning is treated in [CDRX88, CRR91], and bounded-curvature motion planning is treated in [AW01, RW98].

GENERAL TASK AND ASSEMBLY PLANNING

In task planning problems, the system is given a complex task to perform, such as assembling a part from several components or restructuring its workcell into a new layout, but the precise sequence of substeps needed to attain the final goal is not specified and must be inferred by the system.

Suppose we want to manufacture a product consisting of several parts. Let S be the set of parts in their final assembled form. The first question is whether the product can be disassembled by translating in some fixed direction one part after the other, so that no collision occurs. An order of the parts that satisfies this property is called a **depth order**. It need not always exist, but when it does, the product can be assembled by translating the constituent parts one after another, in the reverse of the depth order, to their target positions. Products that can be assembled in this manner are called **stack products** [WL94]. The simplicity of the assembly process makes stack products attractive to manufacture. Computing a depth order in a given direction (or deciding that no such order exists) can be done in $O(m^{4/3+\epsilon})$ time, for any $\epsilon > 0$, for a set of polygons in 3-space with m vertices in total [dBOS94]. Faster algorithms are known for the special cases of axis-parallel polygons, c -oriented polygons, and “fat” objects.

Many products, however, are not stack products, that is, a single direction in which the parts must be moved is not sufficient to assemble the product. One solution is to search for an assembly sequence that allows a subcollection of parts to be moved as a rigid body in *some* direction. This can be accomplished in polynomial time, though the running time is rather high in the worst case: it may require $\Omega(m^4)$ time for a collection of m tetrahedra in 3-space [WL94]. A more modest, but considerably more efficient, solution allows each disassembly step to proceed in one of a few given directions [ABHS96]. It has running time $O(m^{4/3+\epsilon})$, for any $\epsilon > 0$.

A general approach to assembly planning, based on the concept of a *nondirectional blocking graph* [WL94], is proposed in [HLW00]. It is called the *motion space approach*, where the motion space plays a role parallel to configuration space in motion planning. Every point in the motion space represents a possible (dis)assembly sequence motion, all having the same number of degrees of freedom. The motion space is decomposed into an arrangement of cells where in each cell the blocking relations among the parts are invariant, namely, for a every pair of parts P, Q , P will either hit Q for all the possible motions of a cell, or avoid it. It thus suffices to check one specific motion sequence from each cell, leading to a finite complete solution. specific motion

See [Section 48.3](#) and [dML91] for further details on assembly sequencing, and [Chapter 55](#) for related problems.

ON-LINE MOTION PLANNING

Consider the problem of a point robot moving through a planar environment filled with polygonal obstacles, where the robot has no a priori information about the obstacles that lie ahead. One models this situation by assuming that the robot knows the location of the target position and of its own absolute position, but that it only acquires knowledge about the obstacles as it contacts them. The goal is to

minimize the distance that the robot travels. See also the discussion on exploratory motion planning above.

Because the robot must make decisions without knowing what lies ahead, it is natural to use the *competitive ratio* to evaluate the performance of a strategy. In particular, one would like to minimize the ratio between the distance traveled by the robot and the length of the shortest start-to-target path in that scene. The competitive ratio is the worst-case ratio achieved over all scenes having a given source-target distance. A special case of interest is when all obstacles are axis-parallel rectangles of width at least 1 located in the infinite Euclidean plane. Natural greedy strategies yield a competitive ratio of $\Theta(n)$, where n is the Euclidean source-target distance. More sophisticated algorithms obtain competitive ratios of $\Theta(\sqrt{n})$ [BRS97]. Randomized algorithms can do much better [BBF⁺96]. Through the use of randomization, one can translate the case of arbitrary convex obstacles [BRS97] to rectilinearly-aligned rectangles, at the cost of some increase in the competitive ratio. If the scene is not on an infinite plane but rather within some finite rectangular “warehouse,” and the start location is one of the warehouse corners, then the competitive ratio drops to $\log n$ [BBFY94].

COLLISION DETECTION

Although not a motion planning problem per se, collision detection is a closely related problem in robotics [LG98]. It arises, for example, when one tries to use some heuristic approach to motion planning, where the planned path is not guaranteed a priori to be collision-free. In such cases, one wishes to test whether collisions occur during the proposed motion. Several methods have been developed, including: (a) Keeping track of the closest pair of features between two objects, at least one of which is moving, and updating the closest pair, either at discrete time steps, or using *kinetic data structures* (Chapter 50). (b) Using a hierarchical representation of more complex moving systems, by means of bounding boxes or spheres, and testing for collision recursively through the hierarchical representation (see, e.g., [LGLM00] and references therein). See Chapter 35 for more details.

IMPLEMENTATION OF COMPLETE SOLUTIONS

Previously, complete solutions have barely been implemented, mainly due to lack of the nontrivial infrastructure that is needed for such tasks. With the recent advancement in the laying out of such infrastructure, and in particular with tools now available in the software libraries LEDA [MN99] and CGAL [CGAL] (cf. Chapter 65), implementing complete solutions to motion planning has become feasible. A summary of progress and prospects in this domain can be found in [Hal02].

47.4 DAVENPORT-SCHINZEL SEQUENCES

Davenport-Schinzel sequences are interesting and powerful combinatorial structures that arise in the analysis and calculation of the lower or upper envelope of collections of functions, and therefore have applications in many geometric problems, including numerous motion planning problems, which can be reduced to the calculation of such an envelope. A recent comprehensive survey of Davenport-Schinzel sequences and their geometric applications can be found in [SA95].

An (n, s) **Davenport-Schinzel sequence**, where n and s are positive integers, is a sequence $U = (u_1, \dots, u_m)$ composed of n symbols with the properties:

- (i) No two adjacent elements of U are equal: $u_i \neq u_{i+1}$ for $i = 1, \dots, m-1$.
- (ii) U does not contain as a subsequence any alternation of length $s+2$ between two distinct symbols: there do not exist $s+2$ indices $i_1 < i_2 < \dots < i_{s+2}$ so that $u_{i_1} = u_{i_3} = u_{i_5} = \dots = a$ and $u_{i_2} = u_{i_4} = u_{i_6} = \dots = b$, for two distinct symbols a and b .

Thus, for example, an $(n, 3)$ sequence is not allowed to contain any subsequence of the form $(a \dots b \dots a \dots b \dots a)$. Let $\lambda_s(n)$ denote the maximum possible length of an (n, s) Davenport-Schinzel sequence.

The importance of Davenport-Schinzel sequences lies in their relationship to the combinatorial structure of the lower (or upper) envelope of a collection of functions (Section 24.2). Specifically, for any collection of n real-valued continuous functions $f_1, \dots, f_n$ defined on the real line, having the property that each pair of them intersect in at most s points, one can show that the sequence of function indices i in the order in which these functions attain their lower envelope (i.e., their pointwise minimum $f = \min_i f_i$) from left to right is an (n, s) Davenport-Schinzel sequence. Conversely, any (n, s) Davenport-Schinzel sequence can be realized in this way for an appropriate collection of n continuous univariate functions, each pair of which intersect in at most s points.

The crucial and surprising property of Davenport-Schinzel sequences is that, for a fixed s , the maximal length $\lambda_s(n)$ is nearly linear in n , although for $s \geq 3$ it is slightly super-linear. Specifically, one has

$$\begin{aligned}
 \lambda_1(n) &= n \\
 \lambda_2(n) &= 2n - 1 \\
 \lambda_3(n) &= \Theta(n\alpha(n)) \\
 \lambda_4(n) &= \Theta(n \cdot 2^{\alpha(n)}) \\
 \lambda_{2s}(n) &\leq n \cdot 2^{\alpha(n)^{s-1} + C_{2s}(n)} \\
 \lambda_{2s+1}(n) &\leq n \cdot 2^{\alpha(n)^{s-1} \log \alpha(n) + C_{2s+1}(n)} \\
 \lambda_{2s}(n) &= \Omega\left(n \cdot 2^{\frac{1}{(s-1)!} \alpha(n)^{s-1} + C'_{2s}(n)}\right),
 \end{aligned}$$

where $\alpha(n)$ is the inverse of Ackermann's function, and where $C_r(n)$, $C'_r(n)$ are asymptotically smaller than the leading terms in the respective exponents. Ackermann's function $A(n)$ grows extremely quickly, with $A(4)$ an exponential "tower" of 65636 2's. Thus $\alpha(n) \leq 4$ for all practical values of n . See [SA95].

If one considers the lower envelope of n continuous, but only partially defined, functions, then the complexity of the envelope is at most $\lambda_{s+2}(n)$, where s is the maximum number of intersections between any pair of functions [SA95]. Thus for a collection of n line segments (for which $s = 1$), the lower envelope consists of at most $O(n\alpha(n))$ subsegments. A surprising result is that this bound is tight in the worst case: there are collections of n segments, for arbitrarily large n , whose lower envelope does consist of $\Omega(n\alpha(n))$ subsegments. This is perhaps the most natural example of a combinatorial structure defined in terms of n simple objects, whose complexity involves the inverse Ackermann's function; see [SA95, WS88].

Algorithms. The lower envelope of n given total or partial continuous functions, each pair of which intersect in at most s points, can be computed by a simple divide-and-conquer technique that runs (in an appropriate model of computation) in time $O(\lambda_s(n) \log n)$ or $O(\lambda_{s+2}(n) \log n)$ (depending on whether the functions are totally or partially defined). A refined technique (see [Her89]) reduces the time for partially-defined functions to $O(\lambda_{s+1}(n) \log n)$. Thus, in the case of segments, the algorithm computes their lower envelope in optimal $O(n \log n)$ time. More complex combinatorial and algorithmic applications of Davenport-Schinzel sequences (such as the complexity and construction of a single face in a planar arrangement) are mentioned throughout this chapter. Extensions to higher-dimensional instances, which arise naturally in many motion planning problems, are described in the book [SA95] and in the survey articles [AS00b, AS00c].

47.5 SOURCES AND RELATED MATERIAL

SURVEYS

The results not given an explicit reference above, and additional material on motion planning and related problems may be traced in these surveys:

[Lat91]: A book devoted to robot motion planning.

[HSS87]: A collection of early papers on motion planning.

[SA95]: A book on Davenport-Schinzel sequences and their geometric applications; contains a section on motion planning.

[HS95b]: A recent review on arrangements and their applications to motion planning.

[SS88, SS90, Sha89, Sha95, AY90]: Several survey papers on algorithmic motion planning.

[AS00b, AS00c]: Recent surveys on Davenport-Schinzel sequences and on higher-dimensional arrangements.

48 ROBOTICS

Dan Halperin, Lydia E. Kavraki, and Jean-Claude Latombe

INTRODUCTION

Robotics is concerned with the generation of computer-controlled motions of physical objects in a wide variety of settings. Because physical objects define spatial distributions in 3-space, geometric representations and computations play an important role in robotics. As a result the field is a significant source of practical problems for computational geometry. There are substantial differences, however, in the ways researchers in robotics and in computational geometry address related problems. Robotics researchers are primarily interested in developing methods that work well in practice and can be combined into integrated systems. They often pay less attention than researchers in computational geometry to the underlying combinatorial and complexity issues (the focus of [Chapter 47](#)). This difference in approach will become clear in the present chapter.

In Section 48.1 we survey basic definitions and problems in robot kinematics. Part manipulation is discussed in Section 48.2 with emphasis on part grasping, fixturing, and feeding. In Section 48.3 we present algorithms for assembly sequencing. The basic path planning problem is the topic of Section 48.4. Extensions of this problem, in particular nonholonomic motion planning, are discussed in Section 48.5. We briefly survey additional topics in two sections that follow: data structures for representing moving objects in Section 48.6, and sensing and localization in Section 48.7.

GLOSSARY

Workspace W : A subset of 2D or 3D physical space: $W \subset \mathbb{R}^k$ ($k = 2$ or 3).

Body: Rigid physical object modeled as a compact manifold with boundary $B \subset \mathbb{R}^k$ ($k = 2$ or 3). B 's boundary is assumed piecewise-smooth. We will use the terms “body,” “physical object,” and “part” interchangeably.

Robot: A collection of bodies capable of generating their own motions.

Configuration: Any mathematical specification of the position and orientation of every body composing a robot, relative to a fixed coordinate system. The configuration of a single body is also called a *placement* or a *pose*.

Configuration space $\mathcal{C}$: Set of all configurations of a robot. For almost any robot, this set is a smooth manifold. We will always denote the configuration space of a robot by $\mathcal{C}$ and its dimension by m . Given a robot A , we will let $A(\mathbf{q})$ denote the subset of the workspace occupied by A at configuration $\mathbf{q}$.

Number of degrees of freedom: The dimension m of $\mathcal{C}$. In the following we will abbreviate “degree of freedom” by *dof*.

48.1 KINEMATICS

Many robots consist of multiple bodies connected by joints, which may be either actuated or passive. The spatial relations among these bodies and the space of their feasible motions is an important area of study in robotics; cf. Section 59.4.1.

GLOSSARY

Linkage: A collection of bodies, called *links*, in which some pairs of links are connected by *joints*. The graph whose nodes (resp. edges) represent links (resp. joints) is connected.

Prismatic joint: A joint between two links that allows one link to translate along a line attached to the other.

Revolute joint: A joint between two links that allows one link to rotate about a line attached to the other.

Joint parameter: A real parameter associated with a prismatic or revolute joint whose value uniquely determines the relative position or orientation of the two links connected by that joint.

Robot arm: Serial linkage such that the first link, called the *base*, is fixed in space. The last link is called the *end-effector*.

There are other types of joints besides the prismatic and revolute joints considered in this chapter. Most of them can be reduced to independent prismatic and/or revolute joints. For example, a *telescopic joint* is equivalent to collinear prismatic joints connecting links that penetrate one another. We also note that some industrial robot arms contain closed mechanical loops. For many computational purposes, however, they can be considered as serial linkages, as we assume here.

NUMBER OF DEGREES OF FREEDOM OF A LINKAGE

Let L be an arbitrary linkage with n_{link} links and n_{joint} joints, with each joint either prismatic or revolute. The number of dofs of L , denoted by n_{dof} , is the number of joints in L that can move independently with the others complying, and is given by the Grübler formula [Rot94]:

$$n_{dof} \geq n_0(n_{link} - 1) - (n_0 - 1)n_{joint} ,$$

where $n_0 = 3$ if the linkage is planar, and $n_0 = 6$ if the linkage is in 3-space. In general, this formula holds with equality. The strict “greater-than” is needed only for mechanisms with special proportions or alignments.

If L is a serial linkage, we have $n_{link} = n_{joint} + 1$. So $n_{dof} = n_{joint}$. If L consists of a single closed loop, we have $n_{link} = n_{joint}$. So $n_{dof} = n_{joint} - n_0$; thus, one degree of freedom requires 4 joints in 2-space and 7 joints in 3-space. If L consists of multiple loops, the Grübler formula yields $n_{dof} = n_{joint} - n_0\ell$, where ℓ is the number of independent loops.

FORWARD AND INVERSE KINEMATICS

The number of dofs of a robot arm is equal to its number of joints. The determination of the placement of the end-effector from the joint parameters is called the *direct kinematics problem*. In order for the last link's placement to span a 6-space, the arm must have at least 6 joints. (See Figure 59.4.1.)

The determination of the values of the arm's joint parameters from the last link's placement is called the *inverse kinematics problem*. For a 6-joint arm this problem has at most 16 distinct solutions (except for some singularities). In other words, at most 16 distinct legal placements of the arm's links achieve the same specified placement of the end-effector. If the arm has two prismatic joints, then the maximum drops to 8. If it has three prismatic joints, it drops to 2. Any time three consecutive revolute joints have intersecting or parallel axes, the number is at most 8 (see [Rot94]).

OPEN PROBLEM

Given a workspace W , find the optimal design of a robot arm that can reach everywhere in W without collision. Several variants of this problem are solved in [Kol95]. However the 3D case is largely open. An extension of this problem also asks for a design of the layout of the workspace so that a certain task can be completed efficiently. (Additional reachability problems for planar robot arms and their solutions are presented in [O'R98, Section 8.6].)

48.2 PART MANIPULATION

Part manipulation is one of the most frequently performed operations in industrial robotics: parts are grasped from conveyor belts, they are oriented prior to feeding assembly workcells, and they are immobilized for machining operations.

GLOSSARY

Wrench: A pair $[\mathbf{f}, \mathbf{p} \times \mathbf{f}]$, where $\mathbf{p}$ denotes a point in the boundary of a body B , represented by its coordinate vector in a frame attached to B , $\mathbf{f}$ designates a force applied to B at $\mathbf{p}$, and $\times$ is the vector cross-product. If $\mathbf{f}$ is a unit vector, the wrench is said to be a *unit* wrench.

Finger: A tool that can apply a wrench.

Grasp: A set of unit wrenches $\mathbf{w}_i = [\mathbf{f}_i, \mathbf{p}_i \times \mathbf{f}_i]$, $i = 1, \dots, p$, defined on a body B , each created by a finger in contact with the boundary, ∂B , of B . For each $\mathbf{w}_i$, if the contact is frictionless, $\mathbf{f}_i$ is normal to ∂B at $\mathbf{p}_i$; otherwise, it can span the friction cone defined by the Coulomb law.

Force-closure grasp: A grasp $\{\mathbf{w}_i\}_{i=1,\dots,p}$ such that, for any arbitrary wrench $\mathbf{w}$, there exists a set of real values $\{f_1, \dots, f_p\}$ achieving $\sum_{i=1}^p f_i \mathbf{w}_i = -\mathbf{w}$. In other words, a force-closure grasp can resist any external wrenches applied to B . If contacts are nonsticky, we require that $f_i \geq 0$ for all $i = 1, \dots, p$, and the

grasp is called **positive**. In this section we only consider positive grasps.

Form-closure grasp: A positive force-closure grasp in which all finger-body contacts are frictionless.

48.2.1 GRASPING

Grasp analysis and synthesis has been an active research area over the last decade and has contributed to the development of robotic hands and grasping mechanisms.

SIZE OF A FORM/FORCE CLOSURE GRASP

The following results are shown in [MNP90, MSS87]:

- Bodies with rotational symmetry (e.g., disks in 2-space, spheres and cylinders in 3-space) admit no form-closure grasps.
- All other bodies admit a form-closure grasp with at most four fingers in 2-space and twelve fingers in 3-space.
- All polyhedral bodies have a form-closure grasp with seven fingers.
- With frictional finger-body contacts, all bodies admit a force-closure grasp that consists of three fingers in 2-space and four fingers in 3-space.

TESTING FOR FORM/FORCE CLOSURE

A necessary and sufficient condition for force closure in 2-space (resp. 3-space) is that the finger wrenches span three (resp. six) dimensions and that a strictly positive linear combination of them be zero. Said otherwise, the null wrench (the origin) should lie in the interior of the convex hull H of the finger wrenches [MSS87]. This condition provides an effective test for deciding in constant time whether a given grasp achieves force closure. A related quantitative measure of the quality of a grasp (one among several metrics proposed) is the radius of the maximum ball centered at the origin and contained in the convex hull H [KMY92].

SYNTHESIZING FORM/FORCE CLOSURE GRASPS

Most research has concentrated on computing grasps with two to four nonsticky fingers. Optimization techniques and elementary Euclidean geometry are used in [MNP90] to derive an algorithm computing a single force-closure grasp of a polygonal or polyhedral part. This algorithm is linear in the part complexity. Other linear-time techniques using results from combinatorial geometry (Steinitz's theorem) are presented in [MSS87, Mis95]. Optimal force-closure grasps are synthesized in [FC92] by maximizing the set of external wrenches that can be balanced by the contact wrenches.

Finding the maximal regions on a body where fingers can be positioned independently while achieving force closure makes it possible to accommodate errors in finger placement. Geometric algorithms for constructing such regions are proposed in [Ngu88] for grasping polygons with two fingers (with friction) and four fingers (without friction), and for grasping polyhedra with three fingers (with frictional contact capable of generating torques) and seven fingers (without friction).

Curved obstacles have also been studied [PSS⁺97]. The latter paper contains a good overview of work on the effect of curvature at contact points on grasp planning.

DEXTRIOUS GRASPING

Reorienting a part by moving fingers on the part's surface is often considered to lie in the broader realm of grasping. Finger gait algorithms and nonholonomic rolling contacts (Section 48.5.2) for fingertips have been explored.

48.2.2 FIXTURING

Most manufacturing operations require fixtures to hold parts. To avoid the custom design of fixtures for each part, modular reconfigurable fixtures are often used. A typical modular fixture consists of a workholding surface, usually a plane, that has a lattice of holes where locators, clamps, and edge fixtures can be placed. Locators are simple round pins, while clamps apply pressure on the part.

Contacts between fixture elements and parts are generally assumed to be frictionless. In modular fixturing, contact locations are restricted by the lattice of holes, and form closure cannot always be achieved. In particular, when three locators and one clamp are used on a workholding plane, there exist polygons of arbitrary size for which no fixture design can be achieved [ZG95]. But if parts are restricted to be rectilinear, a fixture can always be found as long as all edges have length at least four lattice units [Mis91]. Algorithms for computing all placements of (frictionless) point fingers that put a polygonal part in form closure and all placements of point fingers that achieve “2nd-order immobility” [RB98] of a polygonal part are presented in [vSWO00].

When the fixturing kit consists of a latticed workholding plane, three locators, and one clamp, the algorithm in [BG96] finds all possible placements of a given part on the workholding surface where form closure can be achieved, along with the corresponding positions of the locators and the clamp. The algorithm in [ORSW95] computes the form-closure fixtures of input polygonal parts using a kit containing one edge fixture, one locator, and one clamp.

An algorithm for fixturing an assembly of parts that are not rigidly fastened together is proposed in [Mat95]. A large number of fixturing contacts are first scattered at random on the external boundary of the assembly. Redundant contacts are then pruned until the stability of the assembly is no longer guaranteed.

48.2.3 PART FEEDING

Part feeders account for a large fraction of the cost of a robotic assembly workcell. A typical feeder must bring parts at subsecond rates with high reliability. The problem of part-feeder design is formalized in [Nat89] in terms of a set of functions—called *transfer functions*—which map configurations to configurations. The goal is then to find a composition of these functions that maps each configuration to a unique final configuration (or a small set of final configurations). Given k transfer functions and n possible configurations, the shortest composition that will result in the smallest number of final configurations can be found in $O(kn^4)$ [Nat89]. If the transfer functions are all monotone, the complexity is reduced to $O(kn^2)$ [Epp90].

Part feeding often relies on *nonprehensile manipulation*. Nonprehensile

manipulation exploits task mechanics to achieve a goal state without grasping and frequently allows accomplishing complex feeding tasks with few dofs. It may also enable a robot to move parts that are too large or heavy to be grasped and lifted.

Pushing is one form of nonprehensile manipulation. Work on pushing originated in [Mas82] where a simple rule is established to qualitatively determine the motion of a pushed object. This rule makes use of the position of the center of friction of the object on the supporting surface. Given a part we can compute its *push* transfer function. The push function, $p_\alpha : S_1 \rightarrow S_1$, when given an orientation θ returns the orientation of the part $p_\alpha(\theta)$ after it has been pushed from direction α by a fence orthogonal to the push direction. With a sequence of different push operations it is possible to uniquely orient a part. The push function has been used in several nonprehensile manipulation algorithms:

- A planning algorithm for a robot that tilts a tray containing a planar part of known shape to orient it to a desired orientation [EM88]. This algorithm was extended to the polyhedral case in [EMV93].
- An algorithm to compute the design of a sequence of curved fences along a conveyor belt to reorient a given polygonal part [WGPB96]. See also [BGO⁺98].
- An algorithm that computes a sequence of motions of a single articulated fence on a conveyor belt that achieves a goal orientation of an object [AHLM00].

A frictionless parallel-jaw gripper was used in [Gol93] to orient polygonal parts. For any part P having an n -sided convex hull, there exists a sequence of $2n - 1$ squeezes achieving a single orientation of P (up to symmetries of the convex hull). This sequence is computed in $O(n^2)$ time [CI95]. The result has been generalized to planar parts having a piecewise algebraic convex hull [RG95]. It was shown [vSGO00] that one could design plans whose length depends on a parameter that describes the part's shape (called *geometric eccentricity* in [vSGO00]) rather than on the description of the combinatorial complexity of the part. For the parallel-jaw gripper we can define the *squeeze* transfer function. In [MGEF02] another transfer function is defined: the *roll* function. With this function a part is rolled between the jaws by making one jaw slide in the tangential direction. Using a combination of squeeze and roll primitives a polygonal part can be oriented without changing the orientation of the gripper.

Distributed manipulation systems provide another form of nonprehensile manipulation. These systems induce motions on objects through the application of many external forces. The part-orienting algorithm for the parallel-jaw gripper has been adapted for arrays of microelectromechanical actuators which—due to their tiny size—can generate almost continuous fields [BDM99]. Algorithms that position and orient parts based on identifying a finite number (depending on the number of vertices of the part) of distinct equilibrium configurations were also given in [BDM99]. Subsequent work showed that using a carefully selected actuators field, it is possible to position and orient parts in two stable equilibrium configurations [Kav97]. Finally, a long standing conjecture was proved, namely that there exists a field that can uniquely position and orient parts in a single step [BDKL00]. In fact, two different such fields were fully analyzed in [LK01b, SK01]. On the macroscopic scale it was shown that in-plane vibration can be used for closed-loop manipulation of objects using vision systems for feedback [RMC00], that arrays of controllable airjets can manipulate paper [YB00], and that foot-sized discrete actuator arrays can handle heavier objects under various manipulation strategies [LMC01].

OPEN PROBLEMS

A major open practical problem is to predict feeder throughputs to evaluate alternative feeder designs, given the geometry of the parts to be manipulated. In relation to this problem, simulation algorithms have been proposed recently to predict the pose of a part dropped on a horizontal surface [MZG⁺96], and on arbitrary surfaces [ME02b]. In distributed manipulation, an open problem is to analyze the effect of discrete arrays of actuators on the positioning and orientation of parts [LMC01, LK01b].

48.3 ASSEMBLY SEQUENCING

Most mechanical products consist of multiple parts. The goal of assembly sequencing is to compute both an order in which parts can be assembled and the corresponding required movements of the parts.

GLOSSARY

Assembly: Collection of bodies in some given relative placements.

Subassembly: Subset of the bodies composing an assembly A in their relative positions and orientations in A .

Separated subassemblies: Subassemblies that are arbitrarily far apart from one another.

Hand: A tool that can hold an arbitrary number of bodies in fixed relative placements.

Assembly operation: A motion that merges s pairwise-separated subassemblies ($s \geq 2$) into a new subassembly; each subassembly moves as a single body. No overlapping between bodies is allowed during the operation. The parameter s is called the **number of hands of the operation**. We call the reverse of an assembly operation **assembly partitioning**.

Assembly sequence: A total ordering on assembly operations that merge the separated parts composing an assembly into this assembly. The maximum, over all the operations in the sequence, of the number of hands required by an operation is called the **number of hands of the sequence**.

Monotone assembly sequence: A sequence in which no operation brings a body to an intermediate placement (relative to other bodies), before another operation transfers it to its final placement. See [Figure 48.3.1](#).

NUMBER OF HANDS IN ASSEMBLY

Every assembly of convex polygons in the plane has a two-handed assembly sequence of translations. In the worst case, s hands are necessary and sufficient for assemblies of s star-shaped polygons/polyhedra [Nat88].

There exists an assembly of six tetrahedra without a two-handed assembly sequence of translations, but with a three-handed sequence of translations. Every

FIGURE 48.3.1

Both assemblies below admit two-handed sequences with translational motions only. While (a) accepts such a monotone sequence, (b) does not. To disassemble (b) the triangle must be translated to an intermediate position [HW95]. If general motions are accepted, there exists a monotone two-handed sequence for (b). A monotone three-handed sequence with translations only is also possible.

assembly of five or fewer convex polyhedra admits a two-handed assembly sequence of translations. There exists an assembly of thirty convex polyhedra that cannot be assembled with two hands [SS94].

COMPLEXITY OF ASSEMBLY SEQUENCING

When arbitrary sequences are allowed, assembly sequencing is PSPACE-hard. The problem remains PSPACE-hard even when the bodies are polygons, each with a constant number of vertices [Nat88].

When only two-handed monotone sequences are permitted, deciding if an assembly A can be partitioned into two subassemblies S and $A \setminus S$ such that they can be separated by an arbitrary motion is NP-complete [WKL⁺95]. The problem remains NP-complete when both S and $A \setminus S$ are required to be connected and motions are restricted to translations [KK95].

MONOTONE TWO-HANDED ASSEMBLY SEQUENCING

A popular approach to assembly sequencing is disassembly sequencing [HS91]. A sequence that separates an assembly into its individual components is first generated and next reversed. Most existing assembly sequencers can only generate two-handed monotone sequences. Such a sequence is computed by partitioning the assembly and, recursively, the resulting subassemblies into two separated subassemblies.

The **nondirectional blocking graph** (NDBG) is proposed in [WL95] to represent all the blocking relations in an assembly. It is a subdivision of the space of all allowable motions of separation into a finite number of cells such that within each cell the set of blocking relations between all pairs of parts remains fixed. Within each cell this set is represented in the form of a directed graph, called the directional blocking graph (DBG). The NDBG is the collection of the DBGs over all the cells in the subdivision.

We illustrate this approach for polyhedral assemblies when the allowable motions are infinite translations. The partitioning of an assembly consisting of polyhedral parts into two subassemblies is performed as follows. For an ordered pair of parts P_i, P_j , the 3-vector $\vec{d}$ is a **blocking direction** if translating P_i to infinity in

direction $\vec{d}$ will cause P_i to collide with P_j . For each ordered pair of parts, the set of blocking directions is constructed on the unit sphere $\mathcal{S}^2$ by drawing the boundary arcs of the union of the blocking directions (each arc is a portion of a great circle). The resulting collection of arcs partitions $\mathcal{S}^2$ into maximal regions such that the blocking relation among the parts is the same for any direction inside such a region.

Next, the blocking graph is computed for one such maximal region. The algorithm then moves to an adjacent region and updates the DBG by the blocking relations that change at the boundary between the regions, and so on. After each time the construction of a DBG is completed, this graph is checked for strong connectivity in time linear in its number of edges. The algorithm stops the first time it encounters a DBG that is not strongly connected and it outputs the two subassemblies of the partitioning. The overall sequencing algorithm continues recursively with the resulting subassemblies. If all the DBG's that are produced during a partitioning step are strongly connected, the algorithm reports that the assembly does not admit a two-handed monotone assembly sequence with infinite translations.

Polynomial-time algorithms are proposed in [WL95] to compute and exploit NDBG's for restricted families of motions. In particular, the case of partitioning a polyhedral assembly by a single translation to infinity is analyzed in detail, and it is shown that partitioning an assembly of m polyhedra with a total of v vertices takes $O(m^2v^4)$ time. Another case studied in [WL95] is where the separating motions are infinitesimal rigid motions. Then partitioning the polyhedral assembly takes $O(mc^5)$ time, where m is the number of pairs of parts in contact and c is the number of independent point-plane contact constraints. (This result is improved in [GHH⁺98] by using the concept of maximally covered cells; see [Section 24.6.](#)) Using these algorithms, every feasible disassembly sequence can be generated in polynomial time.

In [WL95], NDBG's are defined only for simple families of separating motions (infinitesimal rigid motions and infinite translations). An extension, called the ***interference diagram***, is proposed in [WKL⁺95] for more complex motions. In the worst case, however, this diagram yields a partitioning algorithm that is exponential in the number of surfaces describing the assembly. When each separating motion is restricted to be a short sequence of concatenated translations (for example, a finite translation followed by an infinite translation), rather efficient partitioning algorithms are available [HW95]. A unified and general framework for assembly planning, based on the NDBG, called the *motion space approach* is presented in [HLW00].

OPEN PROBLEM

The complexity of the NDBG grows exponentially with the number of parameters that control the allowable motions, making this approach highly time consuming for assembly sequencing with compound motions. For the case of infinitesimal rigid motion it has been observed that only a (relatively small) subset of the NDBG needs to be constructed [GHH⁺98]. Are there additional types of motion where similar gains can be made? Are there situations where the full NDBG (or a structure of comparable size) must be constructed?

48.4 PATH PLANNING

Motion planning is aimed at providing robots with the capability of deciding automatically which motions to execute in order to achieve goals specified by spatial arrangements of physical objects. It arises in a variety of forms. The simplest form—the *basic path planning problem*—requires finding a geometric collision-free path for a single robot in a known static workspace. The path is represented by an arc connecting two points in the robot’s configuration space [LP83]. This arc must not intersect a forbidden region, the *C-obstacle region*, which is the image of the workspace obstacles. Other motion planning problems require dealing with moving obstacles, multiple robots, movable objects, uncertainty, etc.

In this section we consider basic path planning. In the next one we review other motion planning problems. Most of our presentation focuses on practical methods. See [Chapter 47](#) for a more extensive review of theoretical motion planning.

GLOSSARY

Path: A continuous map $\tau : [0, 1] \rightarrow \mathcal{C}$.

Obstacle: A workspace $W \subset \mathbb{R}^k$ is often defined by a set of obstacles B_i , $i = 1, \dots, q$, such that $W = \mathbb{R}^k \setminus \bigcup_1^q B_i$.

C-obstacle: Given an obstacle B_i , the subset $CB_i \subseteq \mathcal{C}$ such that, for any $\mathbf{q} \in CB_i$, $A(\mathbf{q})$ intersects B_i .

C-obstacle region: The union $CB = \bigcup_i CB_i$ plus the configurations that violate the mechanical limits of the robot’s joints.

Free space: The complement of the *C-obstacle region* in $\mathcal{C}$, $\mathcal{F} = \mathcal{C} \setminus CB$.

Free path: A path in free space.

Semifree path: A path in the complement of the union of the interior of *C-obstacles*.

Basic path planning problem: Compute a free or semifree path between two input configurations.

Path planning query: Given two points in configuration space find a (semi)free path between them. The term is often used in connection with algorithms that preprocess the configuration space in preparation for many queries.

Complete algorithm: A motion planning algorithm is complete if it is guaranteed to find a (semi)free path between two given configurations whenever such a path exists, and report that there is no (semi)free path otherwise. Complete algorithms are sometimes referred to as *exact* algorithms. There are weaker variants of completeness, for example, *probabilistic completeness*.

COMPLETE ALGORITHMS

Basic path planning for a 3D linkage made of polyhedral links is PSPACE-hard (Theorem 47.1.3c). The proof provides strong evidence that any complete algorithm will require exponential time in the number of dofs. This result remains true in more

specific cases, e.g., when the robot is a planar arm in which all joints are revolute (Theorem 47.1.3b). However, it no longer holds in some very simple settings; for instance, planning the path of a planar arm within an empty circle is in P [HJW85].

Two kinds of complete planners have been proposed: general ones, which apply to virtually any robot with an arbitrary number of dofs, and specific ones, which apply to a restricted family of robots usually having a fixed small number of dofs. The general “roadmap” algorithm in [Can88] is singly-exponential in the dimension of $\mathcal{C}$ and polynomial in both the number of polynomial constraints defining the free space and their maximal degree (Theorem 47.1.2). Specific algorithms have been developed mainly for robots with 2 or 3 dofs. For a k -sided polygonal robot moving freely in a polygonal workspace, the algorithm in [HS96] takes $O((kn)^{2+\epsilon})$ time, where n is the total number of edges of the workspace (Theorem 47.2.10).

PROBABILISTIC ALGORITHMS

The complexity of path planning for robots with many dofs (more than 4 or 5) has led to the development of computational schemes that attempt to trade off completeness against time. One such scheme, *probabilistic planning* [BKL⁺97], avoids computing an explicit geometric representation of the free space. Instead, it uses an efficient procedure to compute distances between bodies in the workspace. It samples the configuration space by selecting a large number of configurations at random and retaining only the free configurations as *milestones*. It then checks if each pair of milestones can be connected by a collision-free straight path in configuration space. This computation yields the graph (V, E) , called a *probabilistic roadmap*, where V is the set of milestones and E is the set of pairs of milestones that have been connected.

Various strategies can be applied to sample the configuration space. The strategy in [KŠLO96] proceeds as sketched above. Once a roadmap has been precomputed, it is used to process an arbitrary number of path planning queries. Other sampling strategies [BL91, HLM99] assume that the initial and goal configurations are given, and incrementally build a roadmap until these two configurations are connected.

The results reported in [KLMR98, HLM99] bound the number of milestones generated by probabilistic-roadmap planners, under the assumption that the free space $\mathcal{F}$ satisfies some geometric properties. One such property, called **expansiveness**, measures the difficulty caused by the presence of “narrow passages.” Let S be a subset of $\mathcal{F}$. The *lookout* of S is the set of all points in S that see a significant fraction of the volume of $\mathcal{F} \setminus S$ (the complement of S in $\mathcal{F}$). The lookout of S is “large” if its volume is a significant fraction of the volume of S . $\mathcal{F}$ is said to be expansive if its subsets have large lookouts. If $\mathcal{F}$ is expansive, the probability that a probabilistic-roadmap planner fails to find a free path between two given configurations, while one exists, goes to 0 exponentially in the number of milestones.

Recent research has focused on designing efficient sampling and connection strategies. For instance, the Gaussian sampling strategy produces a greater density of milestones near the boundary of the free space $\mathcal{F}$, whose connectivity is usually more difficult to capture by a roadmap than wide-open areas of $\mathcal{F}$ [BOvS99]. Different methods to create milestones near the boundary of $\mathcal{F}$ were obtained in [ABD⁺98]. A lazy-evaluation of the roadmap has been suggested in [BK00, SL02] while visibility has been exploited in [SL01]. Sampling and connection strategies

are reviewed in [SL02]. While some planners are better geared toward searching the whole $\mathcal{F}$ (e.g., [KŠLO96]), others focus on answering single queries very efficiently (e.g., [BK00, SL02, LK01c]).

Probabilistic-roadmap techniques have also been used to compute collision-free trajectories taking dynamic constraints (e.g., bounded torques of actuators) into account [HKLR01, LK01c], and to plan manipulation and locomotion paths of humanoid robots under stability constraints [KNK⁺01]. The techniques have also been used for planning for nonholonomic systems [ŠO97, HKLR01] (see also Section 48.5.2).

Applications of probabilistic planning include the maintenance of aircraft engines, the riveting of aircraft fuselages, design automation (by ensuring correctness and maintainability of products from their CAD models), the programming of automotive assembly lines, the generation of aggressive maneuvers for autonomous helicopters, the generation of reconfiguration strategies for modular robots, the generation of motions in contact, and computer animation. Recent work has applied randomized path planning techniques to planning for flexible objects [LK01a] and to the computation of protein folding pathways and molecular motion [ADS02, ABG⁺02].

HEURISTIC ALGORITHMS

Several heuristic techniques have been proposed to speed up path planning. Some of them work well in practice, but they usually offer no performance guarantee.

Heuristic algorithms often search a regular grid defined over the configuration space and generate a path as a sequence of adjacent grid points [Don87]. The search can be guided by a *potential field*, a function over the free space that has a global minimum at the goal configuration. This function may be constructed as the sum of an attractive and a repulsive field [Kha86]. The attractive field has a single minimum at the goal and grows to infinity as the distance to the goal increases. The repulsive field is null at all configurations where the distance between the robot and the obstacles is greater than some predefined value, and grows to infinity as the robot gets closer to an obstacle. Evaluating the repulsive field requires an efficient distance computation algorithm. The search is usually done by following the steepest descent of the potential function. Several techniques deal with local minima [BL91]. Potentials free of local minima have been proposed [RK92], but their computation is likely to be at least as expensive as path planning.

One may also construct grids at variable resolution. Hierarchical space decomposition techniques such as octrees and boxtrees have been used to that purpose [BH95]. At any decomposition level, each grid cell is labeled EMPTY, FULL, or MIXED depending on whether it lies entirely in the free space, lies in the C -obstacle region, or overlaps both. Only the MIXED cells are decomposed further, until a search algorithm finds a sequence of adjacent FREE cells connecting the initial and goal configurations.

DISTANCE COMPUTATION

The efficient computation of distances between two bodies is a crucial element of many path planners. Various algorithms have been proposed to compute distances

between two convex bodies. A numerical descent technique is described in [GJK88] to compute the distance between two convex polyhedra; experience indicates that it runs in approximately linear time in the total complexity of the polyhedra. See [Chapters 34](#) and [37](#) for related techniques.

In robotics applications one often needs to compute the minimum distance between two sets of bodies, one representing the robot, the other the obstacles. The cost of computing the distance between every pair of bodies can be prohibitive. Simple bounding volumes, often coupled with hierarchical decomposition techniques, have been used to reduce computation time [Qui94, GLM96]. When motion is involved, incremental distance computation has been suggested for tracking the closest points on a pair of convex polyhedra [LC91]. It takes advantage of the fact that the closest features (faces, edges, vertices) change infrequently as the polyhedra move along finely discretized paths. See [Chapter 35](#).

OPEN PROBLEMS

1. Design algorithms for probabilistic-roadmap planners capable of efficiently sampling milestones in narrow passages of the free space.
2. Implement effective complete solutions, namely exact algorithmic solutions that run reasonably fast. The CGAL library ([Chapter 65](#)) of geometric algorithms provides infrastructure for such development [Hal02]. For example, an exact solver for translational motion planning in the plane has already been developed on top of CGAL [Fla00].
3. Design algorithms to compute distance between rigid and continuously deformable objects (e.g., power cables).

48.5 OTHER MOTION PLANNING PROBLEMS

There are many useful extensions of the basic path planning problem. Several are surveyed in [Chapter 47](#), e.g., shortest paths, coordinated motion planning (multi-robot case), time-varying workspaces (moving obstacles), and exploratory motion planning. Below we focus on the following extensions: manipulation planning, nonholonomic robots, uncertainty, and optimal planning.

GLOSSARY

Movable object: Body that can be grasped and moved by a robot.

Manipulation planning: Motion planning with movable objects.

Trajectory: Path parameterized by time.

Tangent space: Given a smooth manifold M and a point $p \in M$, the vector space $T_p(M)$ spanned by the tangents at p to all smooth curves passing through p and contained in M . The tangent space has the same dimension as M .

Nonholonomic robot: Robot whose permissible velocities at every configuration $\mathbf{q}$ span a subset $\Omega(\mathbf{q})$ of the tangent space $T_{\mathbf{q}}(\mathcal{C})$ of lower dimension. Ω is called the *set of controls* of the robot.

Feasible path: A piecewise differentiable path of a nonholonomic robot whose tangent at every point belongs to the robot's set of controls, i.e., satisfies the nonholonomic velocity constraints.

Locally controllable robot: A nonholonomic robot is locally controllable if for every configuration $\mathbf{q}_0$ and any configuration $\mathbf{q}_1$ in a neighborhood U of $\mathbf{q}_0$, there exists a feasible path connecting $\mathbf{q}_0$ to $\mathbf{q}_1$ which is entirely contained in U .

Uncertainty in control and sensing: Distributions of control and position sensing errors over multiple executions.

Landmark: Workspace feature that the robot may reliably sense and use to precisely localize itself. The region of configuration space from which the robot can sense a landmark is called a *landmark area*.

Kinodynamic planning: Find a minimal-time trajectory between two given configurations of a robot, given the robot's dynamic equation of motion.

48.5.1 MANIPULATION PLANNING

Many robot tasks consist of achieving arrangements of physical objects. Such objects, called movable objects, cannot move autonomously; they must be grasped by a robot. Planning with movable objects is called manipulation planning.

In [Wil91] the robot A and the movable object M are both convex polygons in a polygonal workspace. The goal is to bring A and M to specified positions. A can only translate. To grasp M , A must have one of its edges that exactly coincides with an edge of M . While A grasps M , they move together as one rigid object. An exact cell decomposition algorithm is given that runs in $O(n^2)$ time after $O(n^3 \log^2 n)$ preprocessing, where n is the total number of edges in the workspace, the robot, and the movable object. An extension of this problem allowing an infinite set of grasps is solved by an exact cell decomposition algorithm in [ALS95].

Heuristic algorithms have also been proposed. The planner in [KL94] first plans the path of the movable object M . During that phase, it verifies only that for every configuration taken by M there exists at least one collision-free configuration of the robot where it can hold M . In the second phase, the planner determines the points along the path of M where the robot must change grasps. It then computes the paths where the robot moves alone (transit paths) to (re)grasp M . The paths of the robot when it carries M (transfer paths) are obtained through inverse kinematics. This planner is not complete, but it has solved complex tasks in practice. Probabilistic roadmap methods have also been used for manipulation planning [NK00]. Finally, of special interest are the efforts on planning for closed kinematic chains using probabilistic methods, manipulation that frequently leads to closed chains formed by two manipulators and the manipulated object [CSL02].

48.5.2 NONHOLONOMIC ROBOTS

The trajectories of a nonholonomic robot are constrained by $p \geq 1$ nonintegrable scalar equality constraints:

$$G(\mathbf{q}(t), \dot{\mathbf{q}}(t)) = (G^1(\mathbf{q}(t), \dot{\mathbf{q}}(t)), \dots, G^p(\mathbf{q}(t), \dot{\mathbf{q}}(t))) = (0, \dots, 0),$$

where $\dot{\mathbf{q}}(t) \in T_{\mathbf{q}(t)}(\mathcal{C})$ designates the velocity vector along the trajectory $\mathbf{q}(t)$. At every $\mathbf{q}$, the function $G_{\mathbf{q}} = G(\mathbf{q}, \cdot)$ maps the tangent space $T_{\mathbf{q}}(\mathcal{C})$ into $\mathbb{R}^p$. If $G_{\mathbf{q}}$ is smooth and its Jacobian has full rank (two conditions that are often satisfied), the constraint $G_{\mathbf{q}}(\dot{\mathbf{q}}) = (0, \dots, 0)$ constrains $\dot{\mathbf{q}}$ to be in a linear subspace of $T_{\mathbf{q}}(\mathcal{C})$ of dimension $m - p$. The nonholonomic robot may also be subject to scalar inequality constraints of the form $H^j(\mathbf{q}, \dot{\mathbf{q}}) > 0$. The subset of $T_{\mathbf{q}}(\mathcal{C})$ that satisfies all the constraints on $\dot{\mathbf{q}}$ is called the set $\Omega(\mathbf{q})$ of controls at $\mathbf{q}$. A feasible path is a piecewise differentiable path whose tangent lies everywhere in the control set.

A car-like robot is a classical example of a nonholonomic robot. It is constrained by one equality constraint (the linear velocity points along the car's main axis). Limits on the steering angle impose two inequality constraints. Other nonholonomic robots include tractor-trailers, airplanes, and satellites.

Given an arbitrary subset $U \subset \mathcal{C}$, the configuration $\mathbf{q}_1 \in U$ is said to be *U-accessible* from $\mathbf{q}_0 \in U$ if there exists a piecewise constant control $\dot{\mathbf{q}}(t)$ in the control set whose integral is a trajectory joining $\mathbf{q}_0$ to $\mathbf{q}_1$ that lies fully in U . Let $A_U(\mathbf{q}_0)$ be the set of configurations *U-accessible* from $\mathbf{q}_0$. The robot is said to be **locally controllable** at $\mathbf{q}_0$ iff for every neighborhood U of $\mathbf{q}_0$, $A_U(\mathbf{q}_0)$ is also a neighborhood of $\mathbf{q}_0$. It is locally controllable iff this is true for all $\mathbf{q}_0 \in \mathcal{C}$. Car-like robots and tractor-trailers that can go forward and backward are locally controllable [BL93].

Let X and Y be two smooth vector fields on $\mathcal{C}$. The Lie bracket of X and Y , denoted by $[X, Y]$, is the smooth vector field on $\mathcal{C}$ defined by $[X, Y] = dY \cdot X - dX \cdot Y$, where dX and dY , respectively, denote the $m \times m$ matrices of the partial derivatives of the components of X and Y w.r.t. the configuration coordinates in a chart placed on $\mathcal{C}$. To get a better intuition of the Lie bracket, imagine a trajectory starting at an arbitrary configuration $\mathbf{q}_s$ and obtained by concatenating four subtrajectories: the first is the integral curve of X during time δt ; the second, third, and fourth are the integral curves of Y , $-X$, and $-Y$, respectively, each during the same δt . Let $\mathbf{q}_f$ be the final configuration reached. A Taylor expansion yields:

$$\lim_{\delta t \rightarrow 0} \frac{\mathbf{q}_f - \mathbf{q}_s}{\delta t^2} = [X, Y].$$

Hence, if $[X, Y]$ is not a linear combination of X and Y , the above trajectory allows the robot to move away from $\mathbf{q}_s$ in a direction that is not contained in the vector subspace defined by $X(\mathbf{q}_s)$ and $Y(\mathbf{q}_s)$. But the motion along this new direction is an order of magnitude slower than along any direction $\alpha X(\mathbf{q}_s) + \beta Y(\mathbf{q}_s)$.

The **control Lie algebra** associated with the control set Ω , denoted by $L(\Omega)$, is the space of all linear combinations of vector fields in Ω closed by the Lie bracket operation. The following result derives from the Controllability Rank Condition Theorem [BL93]:

A robot is locally controllable if, for every $\mathbf{q} \in \mathcal{C}$, $\Omega(\mathbf{q})$ is symmetric with respect to the origin of $T_{\mathbf{q}}(\mathcal{C})$ and the set $\{X(\mathbf{q}) \mid X \in L(\Omega(\mathbf{q}))\}$ has dimension m .

The minimal length of the Lie brackets required to construct $L(\Omega)$, when these brackets are expressed with vectors in Ω , is called the *degree of nonholonomy* of the robot. The degree of nonholonomy of a car-like robot is 2. Except at some singular configurations, the degree of nonholonomy of a tractor towing a chain of s trailers is $2 + s$ [LR96]. Intuitively, the higher the degree of nonholonomy, the more complex (and the slower) the robot's maneuvers to perform some motions.

PLANNING FOR CONTROLLABLE ROBOTS

Let A be a locally controllable nonholonomic robot. A necessary and sufficient condition for the existence of a feasible free path of A between two given configurations is that they lie in the same connected component of the *open* free space. Indeed, local controllability guarantees that a possibly nonfeasible path can be decomposed into a finite number of subpaths, each short enough to be replaced by a feasible free subpath. Hence, deciding if there exists a free path for a locally controllable nonholonomic robot has the same complexity as deciding if there exists a path for the holonomic robot having the same geometry.

Transforming a nonfeasible free path τ into a feasible one can be done by recursively decomposing τ into subpaths. The recursion halts at every subpath that can be replaced by a feasible free subpath. Specific substitution rules (e.g., Reeds and Shepp curves) have been defined for car-like robots [LJTM94]. The complexity of transforming a nonfeasible free path τ into a feasible one is of the form $O(\epsilon^d)$, where ϵ is the smallest clearance between the robot and the obstacles along τ and d is the degree of nonholonomy of the robot (see [LJTM94] for the case $d = 2$).

The algorithm in [BL93] directly constructs a nonholonomic path for a car-like or a tractor-trailer robot by searching a tree obtained by concatenating short feasible paths, starting at the robot's initial configuration. The planner is *asymptotically complete*, i.e., it is guaranteed to find a path if one exists, provided that the lengths of the short feasible paths are small enough. It can also find paths that minimize the number of cusps (changes of sign of the linear velocity).

PLANNING FOR NONCONTROLLABLE ROBOTS

Path planning for nonholonomic robots that are not locally controllable is much less understood. Research has almost exclusively focused on car-like robots that can only move forward. Results include:

- No obstacles: A complete synthesis of the shortest, no-cusp path for a point moving with a lower-bounded turning radius [SL93].
- Polygonal obstacles: An algorithm to decide whether there exists such a path between two configurations; it runs in time exponential in obstacle complexity [FW88].
- Convex obstacles: The algorithm in [ART95] computes a path in polynomial time under the assumptions that all obstacles are convex and their boundaries have a curvature radius greater than the minimum turning radius of the point.
- Other polynomial algorithms (e.g., [BL93]) require some sort of discretization and are only asymptotically complete.

OPEN PROBLEM

Establish a nontrivial lower bound on the complexity of planning for a nonholonomic robot that is not locally controllable.

48.5.3 UNCERTAINTY

In practice, robots deviate from planned paths due to errors in control and position sensing. A motion planning problem with uncertainty can be formulated as follows:

Input. The inputs are the initial region $I \subset \mathcal{C}$, in which the robot is known to be prior to moving, the goal region $G \subset \mathcal{C}$, in which it should terminate its motion, and the uncertainty in control and sensing. Uncertainty is specified in the form of regions. For instance, the uncertainty in position sensing is the set of actual robot configurations that are possible given the sensor readings.

Output. The output is a series of motion commands, if one exists, whose execution enables the robot to reach G from I . Each command is a velocity vector $\mathbf{v}$ and a termination condition T . The vector $\mathbf{v}$ specifies the desired behavior of the robot over time (with or without compliance). The condition T is a Boolean function of the sensor readings and time which causes the motion to stop as soon as it becomes true. A plan may contain conditional branchings.

This problem is NEXPTIME-hard for a point robot moving in 3-space among polyhedral obstacles [CR87].

PREIMAGE OF A GOAL

Given a goal G and a command $(\mathbf{v}, T)$, a preimage of G is any region $P \subset \mathcal{C}$ such that executing the command from anywhere in P makes the robot reach and stop in G [LPMT84]. One way to compute a (nonmaximal) preimage is to restrict the termination condition so that it recognizes G independently of the region from which the motion started [Erd86]. For example, one may shrink G to a subset K , called the **kernel** of G , such that whenever the robot is in K , all robot configurations consistent with the current sensor readings are in G . A preimage is then computed as the region from which the robot commanded along $\mathbf{v}$ is guaranteed to reach K . This region is called the **backprojection** of K for $\mathbf{v}$. This preimage computation has been well studied in a polygonal configuration space with G a polygon [Lat91].

ONE-STEP PLANNING

In a polygonal configuration space, the kernel of a polygonal goal is either independent of the selected $\mathbf{v}$ or changes at a number of critical orientations of $\mathbf{v}$ that is linear in the workspace complexity [Lat91]. Moreover, the backprojection of a polygonal region K , when the orientation of $\mathbf{v}$ varies, changes topology only at a quadratic number of critical directions. Its intersection with a polygonal initial region I of constant complexity also changes qualitatively at few directions of $\mathbf{v}$. Checking the containment of I by the backprojection at each such direction yields a one-step motion plan, if one exists, in amortized time $O(n^2 \log n)$, where n are the edges in $\mathcal{C}$ [Bri95]. In [dBGH⁺95] the computational complexity of solving certain one-step planning problems is expressed also in terms of the size of the control error.

MULTI-STEP PLANNING

For multi-step planning, algebraic approaches that check the satisfiability of a first-order semialgebraic formula have been proposed. In [Can89] it is assumed that all possible trajectories have an algebraic description. The approach there is based on a two-player game interpretation of planning, where the robot is one player and nature the other. Each step of a plan contributes three quantifiers: one existential quantifier applies to the direction of motion, and corresponds to choosing this direction; another existential quantifier applies to time, and corresponds to choosing when to terminate the motion; one universal quantifier applies to the sensor readings and represents the unknown action of nature. The formula representing an r -step plan thus contains r quantifier alternations; checking its satisfiability takes doubly-exponential time in r , which is itself polynomial in the total complexity of the robot and the workspace.

LANDMARK-BASED PLANNING

Often a workspace contains features that can be reliably sensed and used to precisely localize the robot. Each such landmark feature induces a region in configuration space called the *landmark area* from which the robot can sense the corresponding feature.

The planner described in [LL95] considers a point robot among n circular obstacles and $O(n)$ circular landmark areas. It assumes perfect position sensing and motion control in landmark areas. Outside these areas, it assumes that the robot has no position sensing whatsoever and that directional errors in control are bounded by the angle θ . Given circular initial and goal regions I and G (with G intersecting at least one landmark area), the planner constructs a motion plan that enables the robot to move from landmark area to landmark area until it reaches the goal. It proceeds backward by computing the preimages of the landmark regions intersecting G , the preimages of the landmark regions intersected by these preimages, and so on, until a preimage contains I . The planner runs in $O(n^4 \log n)$ time; it is complete and generates plans that minimize the number of steps to be executed in the worst case.

48.5.4 OPTIMAL PLANNING

There has been considerable research on finding shortest paths (see [Chapter 27](#)), but minimal Euclidean length may not be the most suitable criterion in practice. One is often more interested in minimizing execution time, which requires dealing with the robot's dynamics.

OPTIMAL-TIME CONTROL PLANNING

The input is a (geometric) free path τ parameterized by $s \in [0, L]$, the distance traveled from the starting configuration. The problem is to find the time parametrization $s(t)$ that minimizes travel time along τ , while satisfying actuator limits.

The equation of motion of a robot arm with m dofs can be written as $M(\mathbf{q})\ddot{\mathbf{q}} + V(\dot{\mathbf{q}}, \mathbf{q}) + G(\mathbf{q}) = \Gamma$, where $\mathbf{q}$, $\dot{\mathbf{q}}$, and $\ddot{\mathbf{q}}$, respectively, denote the robot's configuration, velocity, and acceleration [Cra89]. M is the $m \times m$ inertia matrix of the robot, V the m -vector (quadratic in $\dot{\mathbf{q}}$) of centrifugal and Coriolis forces, and G the m -vector of gravity forces. Γ is the m -vector of the torques applied by the

joint actuators.

Using the fact that the robot follows τ , this equation can be rewritten in the form: $\mathbf{m}\ddot{s} + \mathbf{v}\dot{s}^2 + \mathbf{g} = \Gamma$, where $\mathbf{m}$, $\mathbf{v}$, and $\mathbf{g}$ are derived from M , V , and G , respectively. Minimum-time control planning becomes a two-point boundary value problem: Find $s(t)$ that minimizes $t_f = \int_0^L ds/\dot{s}$, subject to $\Gamma = \mathbf{m}\ddot{s} + \mathbf{v}\dot{s}^2 + \mathbf{g}$, $\Gamma_{min} \leq \Gamma \leq \Gamma_{max}$, $s(0) = 0$, $s(t_f) = L$, and $\dot{s}(0) = \dot{s}(L) = 0$. Numerical techniques solve this problem by finely discretizing the path τ [BDG85].

MINIMAL-TIME TRAJECTORY PLANNING

Finding a minimal-time trajectory, called *kinodynamic motion planning*, is much more difficult. One approach is to first plan a geometric path and then iteratively deform this path to reduce travel time [SD91]. Each iteration requires checking the new path for collision and recomputing the optimal-time control. No bound has been established on the running time of this approach or the goodness of its outcome. Kinodynamic planning is NP-hard for a point robot under Newtonian mechanics in 3-space [DX95]. The approximation algorithm in [DXCR93] computes a trajectory ϵ -close to optimal in time polynomial in both $1/\epsilon$ and the workspace complexity.

Other optimality questions concern the layout of a robotic cell and in particular the optimal placement of robots inside the cell. Such problems bear resemblance to *facility location* problems; see, for example, an efficient solution to the problem of placing two robot arms in order to minimize the maximal horizontal stretch of an arm for a given collection of workpoints that the robots must reach [HSG02].

48.6 DATA STRUCTURES FOR MOVING OBJECTS

Robotics requires efficient algorithms to compute motions and/or to update properties of bodies as they move (e.g., distances to obstacles). Several data structures have been specifically proposed to represent moving bodies. The related study of *kinetic data structures* is described in [Chapter 50](#).

NONDIRECTIONAL DATA STRUCTURES

These data structures partition the space of possible motions into an arrangement of cells such that a given property remains satisfied over each cell. They are typically computed in a preprocessing step to speed up the treatment of subsequent queries.

For example, in the context of assembly sequencing (Section 48.3), a property of interest is how the parts in an assembly block one another for a certain family of motions. It yields the concepts of a nondirectional blocking graph and an interference diagram. In motion planning with uncertainty (Section 48.5.3), a similar concept is the nondirectional backprojection/preimage of a goal [Bri95, LL95]. As the direction of motion varies, the topology of a preimage changes only at critical values which define an arrangement of cells in the motion space. This arrangement, along with a preimage computed in each cell, forms the ***nondirectional preimage***.

A related concept is used in [Gol93] to construct the possible orientations of a polygonal body after it has been squeezed by a parallel-jaw gripper (Section 48.2.3).

DYNAMIC MAINTENANCE OF KINEMATIC STRUCTURES

Several prototypes of highly flexible robots have been designed and constructed in recent years. Since the number of dofs in these new designs is far larger than in more traditional robots, they raise new algorithmic issues. Similar issues arise in computer simulation of large kinematic structures outside robotics, e.g., in molecular biology and in graphic animation of digital actors.

A basic problem in this domain can be phrased as follows. Given a linkage with many dofs, how can we efficiently maintain a data structure that allows us to quickly answer intersection (or range) queries as the bodies move. Several models for dynamic maintenance of such linkages are proposed in [HLM97], together with efficient maintenance algorithms. Tight results are given on the worst-case, amortized, and randomized complexity of this data structure problem. For the off-line version of the problem, NP-hardness is established and efficient approximation algorithms are provided.

Another basic problem is to efficiently detect collisions (cf. Chapter 35) of a kinematic chain with itself (“self collisions”), motivated primarily by Monte Carlo simulation of conformational change of polymers. Two variants of the problem have been addressed: (i) single joint, continuous motion—detecting self-collision while continuously modifying one degree of freedom of the chain [ST00]. This variant was shown to defy preprocessing that would lead to efficient query answering [SEO03]. (ii) Several joints, discrete modification—changing a small number of degrees of freedom and testing statically for self-collision at the new configuration [LSHL02]. A data structure that combines bounding volume hierarchy and a hierarchy of transformations over the links of the chain was shown to perform very well in practice, with guaranteed theoretical resource bounds.

48.7 SENSING

Sensing allows a robot to acquire information about its workspace and to localize itself. A wide variety of sensors are available and provide raw data of different types, such as time of flight, light intensity, color, or force. Preprocessing these data yield more directly usable information, e.g., geometric information, which can then be exploited to perform such tasks as model construction, object identification, and robot localization. Vision sensors are the most widely used sensors. Many textbooks focus on the role of geometry in computer vision, e.g., [Gri90]. Touch and force sensors are important to detect and characterize contacts among objects, for instance in manipulation tasks. Sensing is a wide domain of research with many subareas and challenging problems. Here we mention only a few selected topics.

MODEL BUILDING

Consider a mobile robot in an unknown workspace W . A first task for this robot is likely to be the construction of a geometric model (also called a map) of W . This requires the robot to perform a series of sensing operations at different locations. Each operation yields a partial model. The robot must patch together the succes-

sively obtained partial models to eventually form a complete map of the workspace. This problem is complicated by the fact that the robot has imperfect control and cannot accurately keep track of its position in a fixed coordinate system. See, e.g., [ZF96].

Recently model building has led to two families of methods, SLAM and NBV. In SLAM (for *Simultaneous Localization and Sensing*), probability distributions are computed and combined to best localize the robot(s) with respect to the partial map built so far and to patch this map with newly acquired data [DWDG00]. In NBV (for *Next Best View*), geometric visibility algorithms are used to compute where the robot should move next in order to acquire the “best” new data [GBL02b].

ROBOT LOCALIZATION

A robot often has to localize itself relative to its workspace W . A model of W is given and localization is done by matching sensory inputs against this model to infer the transform that defines the robot configuration. This problem usually arises for mobile robots. Other types of robots, such as robot arms, often have absolute references (e.g., mechanical stops) and internal sensors (e.g., joint encoders) that provide configurations more directly. Mobile robots have wheel encoders allowing dead-reckoning, but the absence of absolute reference on the one hand and slipping on the ground on the other hand usually necessitate sensor-based localization. GPS (Global Positioning System) has recently become a more widely available alternative, but it does not work in all environments.

Two kinds of sensor-based localization problems can be distinguished, *static* and *dynamic*. In the static problem, the robot is placed at an arbitrary unknown configuration and the problem is to compute this configuration. In the dynamic problem, the robot moves continuously and must regularly update its configuration. The second problem consists of refining an available estimate of the current configuration; here the computation must be done in real time. The static problem is usually more complex, but computation time is less restricted. A preprocessing approach to the static localization problem for a point robot equipped with a 360° range sensor is discussed in Section 47.3. Practical techniques for localization are also available, e.g., [TA96]. Probabilistic methods (particle filtering) have also been successfully applied to the dynamic localization problem for one or several robots [FBKT00]. Localization using wireless Ethernet has been explored in [LBM⁺02].

PURSUIT-EVASION

The problem here is for a team of robots (called pursuers) equipped with visual sensors to find a moving target in an environment of given geometry. The solution is a set of coordinated paths such that one pursuer is eventually guaranteed to see the target. In a polygonal environment with n edges and h holes, it has been shown that the minimum number of pursuers needed is $\Omega(\sqrt{h} + \log n)$ and $O(h + \log n)$. If $h = 0$, it is $\Theta(\log n)$. Computing the actual minimum number of pursuers is NP-hard. See [SY92, GLL⁺99, LSS02].

ADDITIONAL ISSUES IN SENSING

Sensor placement is the problem of computing the set of placements from which a sensor (or guard) can monitor a region within a given workspace [Bri95]. Another problem is to choose a minimal set of sensors and their placement so as to completely cover a given region. This induces a family of art-gallery type problems (see [Section 28.1](#)) that vary according to the type of data that the sensors provide. For the case of visual sensors with realistic physical constraints, a practical randomized solution has been proposed that produces a good approximation of the minimal necessary number of guards [GBL02a]. In the case where each point sees a sizable fraction of the gallery, bounds on the number of guards are given in [Val98, Val99]. Interestingly, the latter results were motivated by questions in randomized motion planning [KLMR98].

There has been considerable interest in recognizing and reconstructing shapes of objects using simple sensors. So-called *probes*, described in [Chapter 29](#), provide a convenient abstraction for the case where the robot takes a discrete number of measurements. There is also work on combining shape reconstruction with manipulation; see e.g., [BMP99, ME02a]. *Matching* and *aspect graphs* (Section 28.6.3) are two related topics that have been well studied, mainly in computer vision.

48.8 SOURCES AND RELATED MATERIAL

Craig's book [Cra89] provides an introduction to robot arm kinematics, dynamics, and control. For advanced kinematics see the book by Bottema and Roth [BR79]. Robot motion planning and its variants are discussed in Latombe's book [Lat91]. This book takes an algorithmic approach to a variety of advanced issues in robotics (not restricted to robot arms). The mechanics of robotic manipulation is covered in Mason's book [Mas01].

The proceedings series of the *International Symposium on Robotics Research* gives state-of-the-art presentations of robotics in general (e.g., [GH96] and subsequent volumes). The proceedings of the *Workshop on Algorithmic Foundations of Robotics* (WAFR)—see [GHLW95] and subsequent volumes—emphasize algorithmic issues in robotics.

Several computational geometry books contain sections on robotics or motion planning [O'R98, SA95, dBvK⁺00].

49 COMPUTER GRAPHICS

David Dobkin and Seth Teller

INTRODUCTION

Computer graphics is often cited as a prime application area for the techniques of computational geometry. The histories of the two fields have a great deal of overlap, with similar methods (e.g., sweep-line and area subdivision algorithms) arising independently in each. Both fields have often focused on similar problems, although with different computational models. For example, hidden surface removal (visible surface identification) is a fundamental problem in both fields. At the same time, as the fields have matured, they have brought different requirements to similar problems. Here, we aim to highlight both similarities and differences between the fields.

Computational geometry is fundamentally concerned with the efficient quantitative representation and manipulation of ideal geometric entities to produce exact results. Computer graphics shares these goals, in part. However, graphics practitioners also model the interaction of objects with light and with each other, and the media through which these effects propagate. Moreover, graphics researchers and practitioners: (1) typically use finite precision (rather than exact) representations for geometry; (2) rarely formulate closed-form solutions to problems, instead employing sampling strategies and numerical methods; (3) often design into their algorithms explicit tradeoffs between running time and solution quality; (4) often analyze algorithm performance by defining as primitive operations those that have been implemented in hardware and (5) implement most algorithms they propose.

49.1 RELATIONSHIP TO COMPUTATIONAL GEOMETRY

In this section we elaborate these five contacts and contrasts.

GEOMETRY VS. RADIOMETRY AND PSYCHOPHYSICS

One fundamental computational process in graphics is *rendering*: the synthesis of realistic images of physical objects. This is done through the application of a simulation process to quantitative models of light, materials, and transmission media to predict (i.e., *synthesize*) appearance. Of course, this process must account for the shapes of and spatial relationships among objects and the viewer, as must computational geometric algorithms. In graphics, however, objects are imbued further with material properties, such as *reflectance* (in its simplest form, color), *refractive index*, *opacity*, and (for light sources) *emissivity*. Moreover, physically justifiable graphics algorithms must model *radiometry*: quantitative representations of light sources and the electromagnetic radiation they emit (with associated attributes of intensity, wavelength, polarization, phase, etc.), and the psychophysical aspects of the human visual system. Thus rendering is a kind of radiometrically

and psychophysically “weighted” counterpart to computational geometry problems involving interactions among objects.

CONTINUOUS IDEAL VS. DISCRETE REPRESENTATIONS

Computational geometry is largely concerned with ideal objects (points, lines, circles, spheres, hyperplanes, polyhedra), continuous representations (effectively infinite precision arithmetic), and exact combinatorial and algebraic results. Graphics algorithms (and their implementations) model such objects as well, but do so in a discrete, finite-precision computational model. For example, most graphics algorithms use a floating-point or fixed-point coordinate representation. Thus, one can think of many computer graphics computations as occurring on a (2D or 3D) sample grid. However, a practical difficulty is that the grid spacing is not constant, causing certain geometric predicates (e.g., sidedness) to change under simple transformations such as scaling or translation (see [Chapter 41](#)).

An analogy can be made between this distinct choice of coordinates, and the way in which geometric objects—infinite collections of points—are represented by geometers and graphics researchers. Both might represent a sphere similarly—say, by a center and radius. However, an algorithm to render the sphere must select a finite set of sample points on its surface. These sample points typically arise from the placement of a synthetic camera and from the locations of display elements on a two-dimensional display device, for example pixels on a computer monitor or ink dots on a page in a computer printer. The colors computed at these (zero-area) sample points, through some radiometric computation, then serve as an assignment to the discrete value of each (finite-area) display element.

CLOSED-FORM VS. NUMERICAL SOLUTION METHODS

Rarely does a problem in graphics demand a closed-form solution. Instead, graphics typically rely on numerical algorithms to estimate solution values in an iterative fashion. Numerical algorithms are chosen by reason of efficiency, or of simplicity. Often, these are antagonistic goals. Aside from the usual dangers of quantization into finite-precision arithmetic ([Chapter 41](#)), other types of error may arise from numerical algorithms. First, using a point-sampled value to represent a finite-area function’s value leads to discretization errors—differences between the reconstructed (interpolated) function, which may be piecewise-constant, piecewise-linear, piecewise-polynomial, etc., and the piecewise-continuous (but unknown) true function. These errors may be exacerbated by a poor choice of sampling points, by a poor piecewise function representation or basis, or by neglect of boundaries along which the true function or its derivative have strong discontinuities. Also, numerical algorithms may suffer bias and converge to incorrect solutions (e.g., due to the misweighting, or omission, of significant contributions).

TRADING SOLUTION QUALITY FOR COMPUTATION TIME

Many graphics algorithms recognize sources of error and seek to bound them by various means. Moreover, for efficiency’s sake an algorithm might deliberately introduce error. For example, during rendering, objects might be crudely approximated to

speed the geometric computations involved. Alternatively, in a more general illumination computation, many instances of combinatorial interactions (e.g., reflections) between scene elements might be ignored except when they have a significant effect on the computed image or radiometric values. Graphics practitioners have long sought to exploit this intuitive tradeoff between solution quality and computation time.

THEORY VS. PRACTICE

Graphics algorithms, while often designed with theoretical concerns in mind, are typically intended to be of practical use. Thus, while computational geometers and computer graphicists have a substantial overlap of interest in geometry, graphicists develop computational strategies that can feasibly be implemented on modern machines. Also, while computational geometric algorithms often assume “generic” inputs, in practice geometric degeneracies do occur, and inputs to graphics algorithms are at times highly degenerate (for example, comprised entirely of isothetic rectangles).

Thus, algorithmic strategies are shaped not only by challenging inputs that arise in practice, but also by the technologies available at the time the algorithm is proposed. The relative bandwidths of CPU, bus, memory, network connections, and tertiary storage have major implications for graphics algorithms involving interaction or large amounts of simulation data, or both. For example, in the 1980s the decreasing cost of memory, and the need for robust processing of general datasets, brought about a fundamental shift in most practitioners’ choice of computational techniques for resolving visibility (from combinatorial, object-space algorithms to brute force, screen-space algorithms). The increasing power of general-purpose processors, the emergence of sophisticated, robust visibility algorithms, and the wide availability of dedicated, programmable low-level graphics hardware may bring about yet another fundamental shift.

TOWARD A MORE FRUITFUL OVERLAP

Given such substantial overlap, there is potential for fruitful collaboration between geometers and graphicists [CAA⁺96]. One mechanism for spurring such collaboration is the careful posing of models and open problems to both communities. To that end, these are interspersed throughout the remainder of this chapter.

49.2 GRAPHICS AS A COMPUTATIONAL PROCESS

This section gives an overview of three fundamental graphics operations: *acquisition* of some *representation* of model data, its associated attributes and illumination sources; *rendering*, or simulating the appearance of static scenes; and simulating the *behavior* of dynamic scenes either in isolation or under the influence of user *interaction*.

GLOSSARY

Rendering problem: Given quantitative descriptions of surfaces and their properties, light sources, and the media in which all these are embedded, rendering is the application of a computational model to predict appearance; that is, rendering is the synthesis of images from simulation data. Rendering typically involves for each surface a *visibility* computation followed by a *shading* computation.

Visibility: Determining which pairs of a set of objects in a scene share an unobstructed line of sight.

Shading: The determination of radiometric values on a surface (eventually interpreted as colors) as viewed by the observer.

Simulation: The representation of a natural process by a computation.

Psychophysics: The study of the human visual system's response to electromagnetic stimuli.

REPRESENTATION: GEOMETRY, LIGHT, AND FORCES

Every computational process requires some representation in a form amenable to simulation. In graphics, the quantities to be represented span shape, appearance, and illumination. In simulation or interactive settings forces must also be represented; these may arise from the environment, from interactions among objects, or from the user's actions.

The graphics practitioner's choice of representation has significant implications. For example, how is the data comprising the representation to be acquired? For efficient manipulation or increased spatial or temporal coherence, the representation might have to include, or be amenable to, spatial indexing. A number of intrinsic (winged-edge, quad-edge, facet-edge, etc.) and extrinsic (quadtree, octree, *k*-d tree, BSP tree, B-rep, CSG, etc.) data structures have been developed to represent geometric data. Continuous, implicit functions have been used to model shape, as have discretized volumetric representations, in which data types or densities are associated with spatial "voxels." A subfield of modeling, Solid Modeling ([Chapter 56](#)), represents shape, mass, material, and connectivity properties of objects, so that, for example, complex object assemblies may be defined for use in Computer-Aided Machining environments ([Chapter 55](#)). Some of these data structures can be adaptively subdivided, and made persistent (that is, made to exist in memory and in nonvolatile storage; see [Chapter 34](#)), so that models with wide-scale variations, or simply enormous data size, may be handled. None of these data structures is universal; each has been brought to bear in specific circumstances, depending on the nature of the data (manifold vs. nonmanifold, polyhedral vs. curved, etc.) and the problem at hand. We forego here a detailed discussion of representational issues; see [Chapters 53](#) and [56](#).

The data structures alluded to above represent "macroscopic" properties of scene geometry—shape, gross structure, etc. Representing material properties, including reflectance over each surface, and possibly surface microstructure (such as roughness) and substructure (as with layers of skin or other tissue), is another fundamental concern of graphics. For each material, computer graphics researchers craft and employ quantitative descriptions of the interaction of radiant energy

and/or physical forces with objects having these properties. Examples include human-made objects such as machine parts, furniture, and buildings; organic objects such as flora and fauna; naturally occurring objects such as molecules, terrains, and galaxies; and wholly synthetic objects and materials. Analogously, suitable representations of radiant energy and physical forces also must be crafted in order that the simulation process can model such effects as erosion [DPH96].

ACQUISITION

In practice, algorithms require input. Realistic scene generation can demand complex geometric and radiometric models—for example, of scene geometry and reflectance properties, respectively. Nongeometric scene generation methods can use sparse or dense collections of images of real scenes. Geometric and image inputs must arise from some source; this *model acquisition* problem is a core problem in graphics. Models may be generated by a human designer (for example, using Computer-Aided Design packages), generated procedurally (for example, by applying recursive rules), or constructed by machine-aided manipulation of image data (for example, generating 3D topographical maps of terrestrial or extra-terrestrial terrain from multiple photographs), or other machine-sensing methods (e.g., [CL96]). Methods for completely automatic (i.e., not human-assisted) acquisition of large-scale geometric models are still in their infancy.

RENDERING

We partition the simulation process of *rendering* into *visibility* and *shading* sub-components, which are treated in separate subsections below.

For static scenes, and with more difficulty when conditions change with time, rendering can be factored into geometrically and radiometrically view-independent tasks (such as spatial partitioning for surface intervisibility, and the computation of diffuse illumination) and their view-dependent counterparts (culling and specular illumination, respectively). View-independent tasks can be cast as precomputations, while at least some view-dependent tasks cannot occur until the instantaneous viewpoint is known. These distinctions have been blurred by the development of data structures that organize lazily-computed, view-dependent information for use in interactive settings [TBD96].

INTERACTION (SIMULATION OF DYNAMICS)

Graphics brings to bear a wide variety of simulation processes to predict behavior. For example, one might detect collisions to simulate a pair of tumbling dice, or simulate frictional forces in order to provide haptic (touch) feedback through a mechanical device to a researcher manipulating a virtual object [LMC94]. Increasingly, graphics researchers are incorporating spatialized sounds into simulations as well. These physically-based simulations are integral to many graphics applications. However, the generation of synthetic imagery is the most fundamental operation in graphics. The next section describes this “rendering” problem.

When datasets become extremely large, some kind of hierarchical, persistent spatial database is required for efficient storage and access to the data [FKST96],

and simplification algorithms are necessary to store and display complex objects with varying fidelity (see, e.g., [CVM⁺96, HDD⁺92]).

We first discuss algorithmic aspects of model acquisition, a fundamental first step in graphics (Section 49.3). We next introduce rendering, with its intertwined operations of visibility determination, shading, and sampling (Section 49.4). We then pose several challenges for the future, listing problems of current or future interest in computer graphics on which computational geometry may have a substantial impact (Section 49.5). Finally, we list further references (Section 49.6).

49.3 ACQUISITION

Model acquisition is fundamental in achieving realistic, complex simulations. In some cases, the required model information may be “authored” manually, for example by a human user operating a computer-aided design application. Clearly manual authoring can produce only a limited amount of data. For more complex inputs, simulation designers have crafted “procedural” models, in which code is written to generate model geometry and attributes. However, such models often have limited expressiveness. To achieve both complexity and expressiveness, practitioners employ sensors such as cameras and range scanners to “capture” representations of real-world objects.

GLOSSARY

Model capture: Acquiring a data representation of a real-world object’s shape, appearance, or other properties.

GEOMETRY CAPTURE

In crafting a geometry capture method, the graphics practitioner must choose a sensor, for example a (passive) camera or multi-baseline stereo camera configuration, or an (active) laser range-finder. Regardless of sensor choice, data fusion from several sensors requires intrinsic and extrinsic sensor *calibration* and *registration* of multiple sensor observations. The fundamental algorithmic challenges here include handling noisy data, and solving the *data association* problem, i.e., determining which features match or correspond across sensor observations. When the device output (e.g., a point cloud) is not immediately useful as a geometric model, an intermediate step is required to infer geometric structure from the unorganized input [HDD⁺92, AB99]. These problems are particularly challenging in an interactive context, for example when merging range scans acquired at video rate [RHHL02]. In some applications, the datasize becomes enormous, as in the “Digital Michelangelo” project [LPC⁺00] or in GIS (geographical information systems) applied over large land areas (see [Chapter 59](#)).

One thrust common to both computer graphics and computer vision includes attempts to recover 3D geometry from many cameras situated outside or within the object or scene of interest. These “volumetric stereo” algorithms must face representational issues: a voxel data structures grows in size as the cube of the scene’s linear dimension, whereas a boundary representation is more efficient but

requires additional a priori information.

Another class of challenges arises from hybrids of procedural and data-driven methods. For example, there exist powerful “grammars” that produce complex synthetic flora using recursive elaboration of simple shapes [MP96]. These methods have a high “amplification factor” in the sense that they can produce complex geometry from a small number of parameters. However, they are notoriously difficult to invert; that is, given a set of observations of a tree, it is apparently difficult to recover an L-system (a particular string rewriting system) that reproduces the tree.

APPEARANCE CAPTURE

Another aspect of capture arises in the process of acquiring texture properties or other “appearance” attributes of geometric models. A number of powerful procedural methods exist for texture generation [Per85] and 3D volumetric effects such as smoke, fire, and clouds [SF95]. Researchers are challenged to make these methods data-driven, i.e., to find the procedural parameters that reproduce observations.

Recently, appearance capture approaches have emerged that attempt to avoid explicit geometry capture. These “image-based” modeling techniques [MB95] gather typically dense collections of images of the object or scene of interest, then use the acquired data to reconstruct images from novel viewpoints (i.e., viewpoints not occupied by the camera). Outstanding challenges for developers of these methods include: crafting effective sampling and reconstruction strategies; achieving effective storage and compression of the input images, which are often highly redundant; and achieving classical graphics effects such as re-illumination under novel lighting conditions when the underlying object geometry is unknown or only approximately known. Acquisition strategies are also needed when capturing materials with complex appearance due to, for example, subsurface effects (e.g., veined marble) [LPC⁺00].

MOTION CAPTURE

Capturing geometry and appearance of static scenes populated by rigid bodies is challenging. Yet this problem can itself be generalized in two ways. First, scenes may be dynamic, i.e., dependent on the passage of time. Second, scene objects may be articulated, i.e., composed of a number of rigid or deformable subobjects, linked through a series of geometric transformations. Although the dimensionality of the observed data may be immense, the actual number of degrees of freedom can be significantly lower; the computational challenge lies in discovering and representing the reduced dimensions efficiently and without an unacceptable loss of fidelity to the original motion. Thus motion capture yields a host of problems: segmenting objects from one another and from outlier data; inference of object substructure and degrees of freedom; and scaling up to complex articulated assemblies. Some of these problems have been addressed in Computer Vision (see also [Chapter 51](#)), although in graphics the same problems arise when processing 3D range (in contrast to 2D image) data.

OPEN PROBLEMS

- Given time-dependent range or motion data of several moving human figures, segment the figures from one another and produce as output an articulated model of each figure.

49.4 RENDERING

Rendering is the process through which a computer image of a model (acquired or otherwise) is created. To render an image that is perceived by the human visual system as being accurate is often considered to be the fundamental problem of computer graphics (*photorealistic rendering*). To do so requires visibility computations to determine which portions of objects are not obscured. Also required are shading computations to model the photometry of the situation. Because the resultant image will be sampled on a discrete grid, we must also consider techniques for minimizing sampling artifacts from the resultant image.

GLOSSARY

Visibility computation: The determination of whether some set of surfaces, or sample points, is visible to a synthetic observer.

Shading computation: The determination of radiometric values on the surface (eventually interpreted as colors) as viewed by the observer.

Pixel: A picture element, for example on a raster display.

Viewport: A 2D array of pixels, typically comprising a rectangular region on a computer display.

View frustum: A truncated rectangular pyramid, representing the synthetic observer's field of view, with the synthetic eyepoint at the apex of the pyramid. The truncation is typically accomplished using *near* and *far* clipping planes, analogous to the "left, right, top, and bottom" planes that define the rectangular field of view. (If the synthetic eyepoint is placed at infinity, the frustum becomes a rectangular parallelepiped.) Only those portions of the scene geometry that fall inside the view frustum are rendered.

Rasterization: The transformation of a continuous scene description, through discretization and sampling, into a discrete set of pixels on a display device.

Ray casting: A hidden-surface algorithm in which, for each pixel of an image, a ray is cast from the synthetic eyepoint through the center of the pixel [App68]. The ray is parametrized by a variable t such that $t = 0$ is the eyepoint, and $t > 0$ indexes points along the ray increasingly distant from the eye. The first intersection found with a surface in the scene (i.e., the intersection with minimum positive t) locates the visible surface along the ray. The corresponding pixel is assigned the intrinsic color of the surface, or some computed value.

Depth-buffering: (also **z-buffering**) An algorithm that resolves visibility by storing a discrete depth (initialized to some large value) at each pixel [Cat74]. Only when a rendered surface fragment's depth is less than that stored at the pixel can the fragment's color replace that currently stored at the pixel.

Irradiance: Total power per unit area impinging on a surface element. Units: POWER PER RECEIVER AREA.

BRDF: The Bidirectional Reflectance Distribution Function, which maps incident radiation (at general position and angle of incidence) to reflected exiting radiation (at general position and angle of exiting). Unitless, in $[0, 1]$.

BTDF: The Bidirectional Transmission Distribution Function, which maps incident radiation (at general position and angle of incidence) to transmitted exiting radiation (at general position and angle of exiting). Analogous to the BRDF.

Radiance: The fundamental quantity in image synthesis, which is conserved along a ray traveling through a nondispersive medium, and is therefore “the quantity that should be associated with a ray in ray tracing” [CW93]. Units: POWER PER SOURCE AREA PER RECEIVER STERADIAN.

Radiosity: A global illumination algorithm for ideal diffuse environments. Radiosity algorithms compute shading estimates that depend only on the surface normal and the size and position of all other surfaces and light sources, and that are independent of view direction. Also: a physical quantity, with units POWER PER SOURCE AREA.

Ray tracing: An image synthesis algorithm in which ray casting is followed, at each surface, by a recursive shading operation involving a spherical/hemispherical integral of irradiance at each surface point. Ray tracing algorithms are best suited to scenes with small light sources and specular surfaces.

Hybrid algorithm: A global illumination algorithm that models both diffuse and specular interactions (e.g., [SP89]).

VISIBILITY

LOCAL VISIBILITY COMPUTATIONS

Given a scene composed of modeling primitives (e.g., polygons, or spheres), and a viewing frustum defining an eyepoint, a view direction, and field of view, the visibility operation determines which scene points or fragments are *visible*—connected to the eyepoint by a line segment that meets the closure of no other primitive. The visibility computation is global in nature, in the sense that the determination of visibility along a single ray may involve all primitives in the scene. Typically, however, visibility computations can be organized to involve coherent subsets of the model geometry.

In practice, algorithms for visible surface identification operate under severe constraints. First, available memory may be limited. Second, the computation time allowed may be a fraction of a second—short enough to achieve interactive refresh rates under changes in viewing parameters (for example, the location or viewing direction of the observer). Third, visibility algorithms must be simple

enough to be practical, but robust enough to apply to highly degenerate scenes that arise in practice.

The advent of machine rendering techniques brought about a cascade of screen-space and object-space combinatorial hidden-surface algorithms, famously surveyed and synthesized in [SSS74]. However, a memory-intensive screen-space technique—*depth!buffering@-buffering*—soon won out due to its simplicity and the decreasing cost of memory. In depth-buffering, specialized hardware performs visible surface determination independently at each pixel. Each polygon to be rendered is rasterized, producing a collection of pixel coordinates and an associated depth for each. A polygon fragment is allowed to “write” its color into a pixel only if the depth of the fragment at hand is less than the depth stored at the pixel (all pixel depths are initialized to some large value). Thus, in a complex scene each pixel might be written many times to produce the final image, wasting computation and memory bandwidth. This is known as the *overdraw* problem.

Two decades of spectacular improvement in graphics hardware have ensued, and high-end graphics workstations now contain hundreds of increasingly complex processors that clip, illuminate, rasterize, and texture millions of polygons per second. This capability increase has naturally led users to produce ever more complex geometric models, which suffer from increasing *overdraw*. Object simplification algorithms, which represent complex geometric assemblages with simpler shapes, do little to reduce *overdraw*. Thus, visible-surface identification (hidden-surface elimination) algorithms have again come to the fore (Section 28.8.1).

GLOBAL VISIBILITY COMPUTATIONS

Real-time systems perform visibility computations from an instantaneous synthetic viewpoint along rays associated with one or more samples at each pixel of some viewport. However, visibility computations also arise in the context of global illumination algorithms, which attempt to identify *all* significant light transport among point and area emitters and reflectors, in order to simulate realistic visual effects such as diffuse and specular interreflection and refraction. A class of *global* visibility algorithms has arisen for these problems. For example, in radiosity computations, a fundamental operation is determining *area-area* visibility in the presence of *blockers*; that is, the identification of those (area) surface elements visible to a given element, and for those partially visible, all tertiary elements causing (or potentially causing) occlusion [HW91, HSA91].

CONSERVATIVE ALGORITHMS

Graphics algorithms often employ *quadrature* techniques in their innermost loops—for example, estimating the energy arriving at one surface from another by casting multiple rays and determining an energy contribution along each. Thus, any efficiency gains in this frequent process (e.g., omission of energy sources known not to contribute energy at the receiver, or omission of objects known not to be blockers) will significantly improve overall system performance. Similarly, occlusion culling algorithms (omission of objects known not to contribute pixels to the rendered image) can significantly reduce *overdraw*. Both techniques are examples of *conservative* algorithms, which overestimate some geometric set by combinatorial means, then perform a final sampling-based operation that produces a (discrete) solution or quadrature. Of course, the success of conservative algorithms in practice depends on two assumptions: first, that through a relatively simple computation, a

usefully tight bound can be attained on whatever set would have been computed by a more sophisticated (e.g., exact) algorithm; and second, that the aggregate time of the conservative algorithm and the sampling pass is less than that of an exact algorithm for input sizes encountered in practice.

This idea can be illustrated as follows. Suppose the task is to render a scene of n polygons. If visible fragments must be rendered *exactly*, any correct algorithm must expend at least kn^2 time, since n polygons (e.g., two slightly misaligned combs, each with $n/2$ teeth) can cause $O(n^2)$ visible fragments to arise. But a conservative algorithm might simply render all n polygons, incurring some overdraw (to be resolved by a depth-buffer) at each pixel, but expending only time linear in the size of the input.

This highlights an important difference between computational geometry and computer graphics. Standard computational geometry cost measures would show that the $O(n^2)$ algorithm is optimal in an output-sensitive model (Section 28.8.1). In computer graphics, hardware considerations motivate a fundamentally different approach: rendering a (judiciously chosen) superset of those polygons that will contribute to the final image. A major open problem is to unify these approaches by finding a cost function that effectively models such considerations (see below).

HARDWARE TRENDS

In recent years, several hybrid object-space/screen-space visibility algorithms have emerged (e.g., [GKM93]). As general-purpose processors continue to become faster, such hybrid algorithms have become more widely used. In certain situations, these algorithms operate entirely in object space, without relying on special-purpose graphics hardware [CT96]. Specialized hardware for hierarchical visibility determination as envisioned in [GKM93], and programmable hardware capable of dedicated higher-level visibility operations such as ray-object intersection and spatial index traversal [PBMH02], will become increasingly available in the future, perhaps bringing about another shift in the algorithmic techniques of choice.

SHADING

Through sampling and visibility operations, a visible surface point or fragment is identified. This point or fragment is then *shaded* according to a *local* or *global* illumination algorithm. Given scene light sources and material reflection and transmission properties, and the propagative media comprising and surrounding the scene objects, the shading operation determines the color and intensity of the incident and exiting radiation at the point to be shaded. Shading computations can be characterized further as *view-independent* (modeling only purely diffuse interactions, or directional interactions with no dependence on the instantaneous eye position) or *view-dependent*.

Most graphics workstations perform a local shading operation in hardware, which, given a point light source, a surface point, and an eye position, evaluates the energy reaching the eye via a single reflection from the surface. This local operation is implemented in the software and hardware offered by most workstations. However, this simple model cannot produce realistic lighting cues such as shadows, reflection, and refraction. These require more extensive, global computations as described below.

SHADING AS RECURSIVE WEIGHTED INTEGRATION

Most generally, the shading operation computes the energy leaving a differential surface element in a specified differential direction. This energy depends on the surface's emittance and on the product of the surface's reflectance with the total energy incident from all other surfaces. This relation is known as the *Rendering Equation* [Kaj86], which states intuitively that each surface fragment's appearance, as viewed from a given direction, depends on any light it emits, plus any light (gathered from other objects in the scene) that it reflects in the direction of the observer. Thus, shading can be cast as a recursive integration; to shade a surface fragment F , shade all fragments visible to F , then sum those fragments' illumination upon F (appropriately weighted by the BRDF or BTDF) with any direct illumination of F . Effects such as diffuse illumination, motion blur, Fresnel effects, etc., can be simulated by supersampling in space, time, and wavelength, respectively, and then averaging [CPC84].

Of course, a base case for the recursion must be defined. Classical ray tracers truncate the integration when a certain recursion depth is reached. If this maximum depth is set to 1, ray casting (the determination of visibility for eye rays only) results. More common is to use a small constant greater than one, which leads to "Whitted" or "classical" ray tracing [Whi80]. For efficiency, practitioners also employ a thresholding technique: when multiple reflections cause the weight with which a particular contribution will contribute to the shading at the root to drop below a specified threshold, the recursion ceases. These termination conditions can, under some conditions, cause important energy-bearing paths to be overlooked. For example, a bright light source (such as the sun) filtering through many parts of a house to reach an interior space may be incorrectly discounted by this condition.

In recent years, a hardware trend has developed in support of "programmable shading," in which a (typically short, straight-line) program can be downloaded into graphics hardware for application to every vertex or pixel processed.¹ This trend has spurred research into, for example, ways to "factor" complex shading calculations into suitable components for mapping to hardware.

ALIASING

From a purely physical standpoint, the amount of energy leaving a surface in a particular direction is the product of the spherical integral of incoming energy and the bidirectional reflectance (and transmittance, as appropriate) in the exiting direction. From a psychophysical standpoint, the perceived color is an inner product of the energy distribution incident on the retina with the retina's spectral response function. We do not explore psychophysical considerations further here.

Global illumination algorithms perform an integration of irradiance at each point to be shaded. Ray tracing and radiosity are examples of global illumination algorithms. Since no closed-form solutions for global illumination are known for general scenes, practitioners employ sampling strategies. Graphics algorithms typically attempt "reconstruction" of some illumination function (e.g., irradiance, or radiance), given some set of samples of the function's values and possibly other information, for example about light source positions, etc. However, such reconstruction is subject to error for two reasons.

First, the well-known phenomenon of *aliasing* occurs when insufficient samples are taken to find all high-frequency terms in a sampled signal. In image processing,

¹Current manufacturers include NVIDIA <http://nvidia.com/> and ATI <http://ati.com/>.

samples arise from measurements, and reconstruction error arises from samples that are too widely spaced. However, in graphics, the sample values arise from a simulation process, for example, the evaluation of a local illumination equation, or the numerical integration of irradiance. Thus, reconstruction error can arise from simulation errors in generating the samples. This second type of error is called *biasing*.

For example, classical ray tracers [Whi80] may suffer from biasing in three ways. First, at each shaded point, they compute irradiance only: from direct illumination by point lights; along the reflected direction; and along the refracted direction. Significant “indirect” illumination that occurs along any direction other than these is not accounted for. Thus, indirect reflection and focusing effects are missed. Classical ray tracers also suffer biasing by truncating the depth of the recursive ray tree at some finite depth d ; thus, they cannot find significant paths of energy from light source to eye of length greater than d . Third, classical ray tracers truncate ray trees when their weight falls below some threshold. This can fail to account for large radiance contributions due to bright sources illuminating surfaces of low reflectance.

SAMPLING

Sampling patterns can arise from a regular grid (e.g., pixels in a viewport) but these lead to a stair-stepping kind of aliasing. One solution is to *supersample* (i.e., take multiple samples per pixel) and average the results. However, one must take care to supersample in a way that does not align with the scene geometry or some underlying attribute (e.g., texture) in a periodic, spatially varying fashion; otherwise aliasing (including Moiré patterns) will result.

DISCREPANCY

The quality of sampling patterns can be evaluated with a measure known as *discrepancy* (Chapter 44). For example, if we are sampling in a pixel, features interacting with the pixel can be modeled by line segments (representing parts of edges of features) crossing the pixel. These segments divide the pixel into two regions. A good sampling strategy will ensure that the proportion of sample points in each region approximates the proportion of pixel area in that region. The difference between these quantities is the discrepancy of the point set with respect to the line segment. We define the discrepancy of a set of samples (in this case) as the maximum discrepancy with respect to all line segments. Other measures of discrepancy are possible, as described below. See also Chapter 13.

Sampling patterns are used to solve integral equations. The advantage of using a low-discrepancy set is that the solution will be more accurately approximated, resulting in a better image. These differences are expressed in solution convergence rates as a function of the number of samples. For example, truly random sampling has a discrepancy that grows as $O(N^{-\frac{1}{2}})$ where N is the number of samples. There are other sampling patterns (e.g., the *Hammersley points*) that have discrepancies growing as $O(N^{-1} \log^{k-1} N)$. Sometimes one wishes to combine values obtained by different sampling methods [VG95]. The search for good sampling patterns, given a fixed number of samples, is often done by running an optimization process which aims to find sets of ever-decreasing discrepancy. A crucial part of any such process is the ability to quickly compute the discrepancy of a set of samples.

COMPUTING THE DISCREPANCY

There are two common questions that arise in the study of discrepancy: first, given fixed N , how to construct a good sampling pattern in the model described above; second, how to construct a good sampling pattern in an alternative model.

For concreteness, consider the problem of finding low discrepancy patterns in the unit square, modeling an individual pixel. As stated above, the geometry of objects is modeled by edges that intersect the pixel dividing it into two regions, one where the object exists and one where it does not. An ideal sampling method would sample the regions in proportion to their relative areas.

We model this as a discrepancy problem as follows. Let S be a sample set of points in the unit square. For a line l (actually, a segment arising from a polygon boundary in the scene being rendered), define the two regions S^+ and S^- into which l divides S . Ideally, we want a sampling pattern that has the same fraction of samples in the region S^+ as the area of S^+ . Thus, in the region S^+ , the discrepancy with respect to l is

$$|\#(S \cap S^+)/\#(S) - \text{Area}(S^+)|,$$

where $\#(\cdot)$ denotes the cardinality operator. The discrepancy of the sample set S with respect to a line l is defined as the larger of the discrepancies in the two regions. The discrepancy of set S is then the maximum, over *all* lines l , of the discrepancy of S with respect to l .

Finding the discrepancy in this setting is an interesting computational geometry problem. First, we observe that we do not need to consider all lines. Rather, we need consider only those lines that pass through two points of S , plus a few lines derived from boundary conditions. This suggests the $O(n^3)$ algorithm of computing the discrepancy of each of the $O(n^2)$ lines separately. This can be improved to $O(n^2 \log n)$ by considering the fan of lines with a common vertex (i.e., one of the sample points) together. This can be further improved by appealing to duality. The traversal of this fan of lines is merely a walk in the arrangement of lines in dual space that are the duals of the sample points. This observation allows us to use techniques similar to those in [Chapter 24](#) to derive an algorithm that runs asymptotically as $O(n^2)$. Full details are given in [DEM93].

There are other discrepancy models that arise naturally. A second obvious candidate is to measure the discrepancy of sample sets in the unit square with respect to axis-oriented rectangles. Here we can achieve a discrepancy of $O(n^2 \log n)$, again using geometric methods. We use a combination of techniques, appealing to the incremental construction of 2D convex hulls to solve a basic problem, then using the sweep paradigm to extend this incrementally to a solution of the more general problem. The sweep is easier in the case in which the rectangle is anchored with one vertex at the origin, yielding an algorithm with running time $O(n \log^2 n)$.

The model given above can be generalized to compute **bichromatic discrepancy**. In this case, we have sample points that are colored either black or red. We can now define the discrepancy of a region as the difference between its number of red and black points. Alternatively, we can look for regions (of the allowable type) that are most nearly monochromatic in red while their complements are nearly monochromatic in black. This latter model has application in computational learning theory. For example, red points may represent situations in which a concept is true, black situations where it is false. The minimum discrepancy rectangle is now a classifier of the concept. This is a popular technique for computer-assisted medical diagnosis.

The relevance of these algorithms to computational geometry is that they will lead to faster algorithms for testing the “goodness” of sampling patterns, and thus eventually more efficient algorithms with bounded sampling error. Also, algorithms for computing the discrepancy relative to a particular set system are directly related to the system’s VC-dimension (see [Section 44.1](#)).

OPEN PROBLEMS

An enormous literature of adaptive, backward, forward, distribution, etc. ray tracers has evolved to address sampling and bias errors. However, the fundamental issues can be stated simply. (Each of the problems below assumes a geometric model consisting of n polygons.)

A related *inverse* problem arises in machine vision, now being adopted by computer graphics practitioners as a method for acquiring large-scale geometric models from imagery.

The problems below are open for both the unit cube and unit ball in all dimensions.

1. The set of visible fragments can have complexity $\Omega(n^2)$ in the worst case. However, the complexity is lower for many scenes. If k is the number of edge incidences (vertices) in the projected visible scene, the set of visible fragments can be computed in optimal output-sensitive $O(nk^{1/2} \log n)$ time [SO92]. Although specialized results have been obtained, optimality has not been reached in many cases. See [Table 28.8.1](#).
2. Give a spatial partitioning and ray casting algorithm that runs in amortized nearly-constant time (that is, has only a weak asymptotic dependence on total scene complexity). Identify a useful “density” parameter of the scene (e.g., the largest number of simultaneously visible polygons), and express the amortized cost of a ray cast in terms of this parameter.
3. Give an output-sensitive algorithm which, for specified viewing parameters, determines the set of “contributing” polygons—i.e., those which contribute their color to at least one viewport pixel.
4. Give an output-sensitive algorithm which, for specified viewing parameters, approximates the visible set to within ϵ . That is, produce a superset of the visible polygons of size (alternatively, total projected area) at most $(1 + \epsilon)$ times the size (resp., projected area) of the true set. Is the lower bound for this problem asymptotically smaller than that for the exact visibility problem?
5. For machine-dependent parameters A and B describing the transform (per-vertex) and fill (per-pixel) costs of some rendering architecture, give an algorithm to compute a superset S of the visible polygon set minimizing the rendering cost on the specified architecture.
6. In a local illumination computation, identify those polygons (or a superset) visible from the synthetic observer, and construct, for each visible polygon P , an efficient function $V(p)$ that returns 1 iff point $p \in P$ is visible from the viewpoint.

7. In a global illumination computation, identify all pairs (or a superset) of intervisible polygons, and for each such pair P, Q , construct an efficient function $V(p, q)$ that returns 1 iff point $p \in P$ is visible from point $q \in Q$.
8. **Image-based rendering** [MB95]: Given a 3D model, generate a minimal set of images of the model such that for all subsequent query viewpoints, the correct image can be recovered by combination of the sample images.
9. Given a geometric model M , a collection of light sources L , a synthetic viewpoint E , and a threshold ϵ , identify all optical paths to E bearing radiance greater than ϵ .
10. Given a geometric model M , a collection of light sources L , and a threshold ϵ , identify *all* optical paths bearing radiance greater than ϵ .
11. An observation of a real object comprises the *product* of irradiance and reflection (BRDF). How can one deduce the BRDF from such observations?
12. Given N , generate a minimum-discrepancy pattern of N samples.
13. Given a low-discrepancy pattern of K points, generate a low (or lower) discrepancy pattern of $K + 1$ points.

49.5 FURTHER CHALLENGES

We have described several core problems of computer graphics and illustrated the impact of computational geometry. We have only scratched the surface of a highly fruitful interaction; the possibilities are expanding, as we describe below. These computer graphics problems all build on the combinatorial framework of computational geometry and so have been, and continue to be, ripe candidates for application of computational geometry techniques. Numerous other problems remain whose combinatorial aspects are perhaps less obvious, but for which interaction may be equally fruitful.

INDEX AND SEARCH

The proliferation of geometric models leads to a problem analogous to that in document storage: how to index models so that they can be efficiently found later. In particular, we might wish to define the Google of 3D models. Searching by name is of limited utility, since in many cases a model's author may not have named it suggestively, or as expected by the seeker. Searching by attributes or appearance is likely to be more fruitful or at the least, a necessary adjunct to searching by name. Perhaps the most successful search mechanisms to date are those relying on geometric "shape signatures" of objects, along with name and attribute metadata where available [FMK⁺03]. One promising class of signatures related to the medial axis transform is the "shock graph" [LK01]. A first step toward building such a system appears in [OFCD02].

TRANSMISSION AND LEVEL OF DETAIL

Fast network connectivity is not yet universally deployed, and the number and size of available models is growing inexorably with time. Thus in many contexts it is important to store, transmit, and display geometric information efficiently. A variety of techniques have been developed for “progressive” [Hop97] or “multi-resolution” geometry representation [GSS99], as well as for automated level-of-detail generation from source objects [GH97]. For specific model classes, e.g., terrain, efficient algorithms have been developed for varying the fidelity of the display across the field of view [dBD98]. Finally, some practitioners have proposed techniques to choose levels of detail, within some time rendering budget, to optimize some image quality criterion [FKST96].

OPEN PROBLEM

- *Robust simplification.* Cheng et al. [SWCP02] recently gave a method for computing levels of details that preserve the genus of the original surface. Combine their techniques with techniques for robust computation to derive a robust and efficient scheme for simplification that can be easily implemented. See [Chapter 54](#).

INTERACTION

In addition to off-line or batch computations, graphics practitioners develop on-line computations which involve a user in an interactive loop with input and output (display) stages, such as scientific visualization. For responsiveness, such applications may have to produce many outputs per second: rendering applications typically must maintain 10Hz or faster, whereas haptic or force-feedback applications may operate at 1KHz. Modern applications must also cope with large datasets, only parts of which may be memory-resident at any moment. Thus effective techniques for indexing, searching, and transmitting model data are required. For out-of-core data, predictive fetching strategies are required to avoid high-latency “hiccups” in the user’s display.

Beyond seeing and feeling virtual representations of an object, new “3D printing” techniques have emerged for rapid prototyping applications that create real, physical models of objects. Computational geometry algorithms are required to plan the slicing or deposition steps needed. Also, “augmented reality” (AR) methods attempt to provide synthetically generated image overlays onto real scenes, for example using head-mounted displays or hand-held projectors. AR methods require good, low-latency 6-DOF tracking of the user’s head or device position and orientation in extended environments.

An exciting new class of “pervasive computing” and “mobile computing” applications attempts to move computation away from the desktop and out into the extended work, home, or outdoor environment. These applications are by nature integrative, encompassing geometric and functional models, position and orientation tracking, proximity data structures, ad hoc networks, and distributed self-calibration algorithms [PMBT01].

OPEN PROBLEM

- *Collision detection and force feedback.* Imagine that every object has an associated motion, and that some objects (e.g., virtual probes) are interactively controlled. Suppose further that when pairs of objects intersect, there is a reaction (due, e.g., to conservation of momentum). Here we wish to render frames and generate haptic feedback while accounting for such physical considerations. Are there suitable data structures and algorithms within computational geometry to model and solve this problem (e.g., [LMC94, MC95])?

DYNAMICS

When simulations include objects that affect each other through force exchange or collision, they must efficiently identify the actual interactions. Usually there is significant temporal coherence, i.e., the set of objects near a given object changes slowly over time. A number of techniques have been proposed to track moving objects in a spatial index or closest-pair geometric data structure in order to detect collisions efficiently [MC95, LMC94, BGH99]. The “object” of interest may be the geometric representation of a user, for example of a finger or hand probing a virtual scene. Recently, some authors have proposed synthesizing sound information to accompany the visual simulation outputs [OSG02].

We have focused this chapter on problems in which the parameters are static; that is, the geometry is unchanging, and nothing is moving (except perhaps the synthetic viewpoint). Now, we briefly describe situations where this is not the case and deeper analysis is required. In these situations it is likely that computational geometry can have a tremendous impact; we sketch some possibilities here.

Each of the static assumptions above may be relaxed, either alone or in combination. For example, objects may evolve with time; we may be interested in transient rather than steady-state solutions; material properties may change over time; object motions may have to be computed and resolved; etc. It is a challenge to determine how techniques of computational geometry can be modified to address state-of-the-art and future computer graphics tasks in dynamic environments.

Among the issues we have not addressed where these considerations are important are the following.

Model changes over time. In a realistic model, even unmoving objects change over time, for example becoming dirty or scratched. In some environments, objects rust or suffer other corrosive effects. Sophisticated geometric representations and algorithms are necessary to capture and model such phenomena [DPH96]. See [Chapter 50](#).

Inverse processes. Much of what we have described is a feed-forward process in which one specifies a model and a simulation process and computes a result. Of equal importance in design contexts is to specify a result and a simulation process, and compute a set of initial conditions that would produce the desired result. For example, one might wish to specify the appearance of a stage, and deduce the intensities of scores or hundreds of illuminating light sources that would result in this appearance [SDSA93]. Or, one might wish to solve an inverse kinematics problem in which an object with multiple parts and numerous degrees of freedom is specified.

Given initial and final states, one must compute a smooth, minimal energy path between the states, typically in an underconstrained framework. This is a common problem in robotics (see [Section 47.1](#)). However, the configurations encountered in graphics tend to have very high complexity. For example, convincingly simulating the motion of a human figure requires processing kinematic models with hundreds of degrees of freedom.

External memory algorithms. Computational geometry assumes a realm in which all data can be stored in RAM and accessed at no cost (or unit cost per word). Increasingly often, this is not the case in practice. For example, many large databases cannot be stored in main memory. Only a small subset of the model contributes to each generated image, and algorithms for efficiently identifying this subset, and maintaining it under small changes of the viewpoint or model, form an active research area in computer graphics. Given that motion in virtual environments is usually smooth, and that hard real-time constraints preclude the use of purely reactive, synchronous techniques, such algorithms must be *predictive* and *asynchronous* in nature [FKST96]. Achieving efficient algorithms for appropriately shuttling data between secondary (and tertiary) storage and main memory is an interesting challenge for computational geometry.

50 MODELING MOTION

Leonidas J. Guibas

50.1 INTRODUCTION

Motion is ubiquitous in the physical world, yet its study is much less developed than that of another common physical modality, namely shape. While we have several standardized mathematical shape descriptions, and even entire disciplines devoted to that area—such as *Computer-Aided Geometric Design* (CAGD)—the state of formal motion descriptions is still in flux. This in part because motion descriptions span many levels of detail; they also tend to be intimately coupled to an underlying physical process generating the motion (dynamics). Thus, until recently, proper abstractions were lacking and there was only limited work on algorithmic descriptions of motion and their associated complexity measures. This chapter aims to show how an algorithmic study of motion is intimately tied to discrete and computational geometry. After a quick survey of earlier work (Sections 50.2 and 50.3), we devote the bulk of this chapter to discussing the framework of *Kinetic Data Structures* (Section 50.4) [Gui98, BGH99]. We also briefly discuss methods for querying moving objects (Section 50.5).

50.2 MOTION IN COMPUTATIONAL GEOMETRY

Dynamic computational geometry refers to the study of combinatorial changes in a geometric structure, as its defining objects undergo prescribed motions. For example, we may have n points moving linearly with constant velocities in $\mathbb{R}^2$, and may want to know the time intervals during which a particular point appears on their convex hull, the steady-state form of the hull (after all changes have occurred), or get an upper bound on how many times the convex hull changes during this motion. Such problems were introduced and studied in [Ata85].

A number of other authors have dealt with geometric problems arising from motion, such as collision detection (Chapter 35) or minimum separation determination [GJS96, ST95, ST96]. For instance, [ST96] shows how to check in subquadratic time whether two collections of simple geometric objects (spheres, triangles) collide with each other under specified polynomial motions.

50.3 MOTION MODELS

An issue in the above research is that object motion(s) are assumed to be known in advance, sometimes in explicit form (e.g., points moving as polynomial functions

of time). Indeed, the proposed methods reduce questions about moving objects to other questions about derived static objects.

While most evolving physical systems follow known physical laws, it is also frequently the case that discrete events occur (such as collisions) that alter the motion law of one or more of the objects. Thus motion may be predictable in the short term, but becomes less so further into the future. Because of such discrete events, algorithms for modeling motion must be able to adapt in a dynamic way to motion model modifications. Furthermore, the occurrence of these events must be either predicted or detected, incurring further computational costs. Nevertheless, any truly useful model of motion must accommodate this *on-line* aspect of the temporal dimension, differentiating it from spatial dimensions, where all information is typically given at once.

In real-world settings, the motion of objects may be imperfectly known and better information may only be obtainable at considerable expense. The model of *data in motion* of [Kah91] assumes that upper bounds on the rates of change are known, and focuses on being selective in using sensing to obtain additional information about the objects, in order to answer a series of queries.

50.4 KINETIC DATA STRUCTURES

Suppose we are interested in tracking high-level attributes of a geometric system of objects in motion such as, for example, the convex hull of a set of n points moving in $\mathbb{R}^2$. Note that as the points move continuously, their convex hull will be a continuously evolving convex polygon. At certain discrete moments, however, the combinatorial structure of the convex hull will change (that is, the circular sequence of a subset of the points that appear on the hull will change). In between such moments, tracking the hull is straightforward: its geometry is determined by the positions of the sequence of points forming the hull. How can we know when the combinatorial structure of the hull changes? The idea is that we can focus on certain elementary geometric relations among the n points, a set of *cached assertions*, which altogether certify the correctness of the current combinatorial structure of the hull. Furthermore, we can hope to choose these relations in such a way so that when one of them fails because of point motion, both the hull and its set of certifying relations can be updated locally and incrementally, so that the whole process can continue.

GLOSSARY

Kinetic data structure: A kinetic data structure (KDS) for a geometric attribute is a collection of simple geometric relations that certifies the combinatorial structure of the attribute, as well as a set of rules for repairing the attribute and its certifying relations when one relation fails.

Certificate: A certificate is one of the elementary geometric relations used in a KDS.

Event: An event is the failure of a KDS certificate during motion. Events are classified as *external* when the combinatorial structure of the attribute changes, and *internal*, when the structure of the attribute remains the same, but its

certification needs to change.

Event queue: In a KDS, all certificates are placed in an event queue, according to their earliest failure time.

The inner loop of a KDS consists of repeated certificate failures and certification repairs, as depicted in Figure 50.4.1.

FIGURE 50.4.1
The inner loop of a kinetic data structure.

We remark that in the KDS framework, objects are allowed to change their motions at will, with appropriate notification to the data structure. When this happens all certificates involving the object whose motion has changed must re-evaluate their failure times.

CONVEX HULL EXAMPLE

Suppose we have four points a , b , c , and d in $\mathbb{R}^2$, and wish to track their convex hull. For the convex hull problem, the most important geometric relation is the CCW predicate: $\text{CCW}(a, b, c)$ asserts that the triangle abc is oriented counterclockwise. Figure 50.4.2 shows a configuration of four points and four CCW relations that hold among them. It turns out that these four relations are sufficient to prove that the convex hull of the four points is the triangle abc . Indeed the points can move and form different configurations, but as long as the four certificates shown remain valid, the convex hull must be abc .

Now suppose that points a , b , and c are stationary and only point d is moving, as shown in Figure 50.4.3. At some time t_1 the certificate $\text{CCW}(d, b, c)$ will fail, and at a later time t_2 $\text{CCW}(d, a, b)$ will also fail. Note that the certificate $\text{CCW}(d, c, a)$ will never fail in the configuration shown even though d is moving. So the certificates $\text{CCW}(d, b, c)$ and $\text{CCW}(d, a, b)$ schedule events that go into the event queue. At time t_1 , $\text{CCW}(d, b, c)$ ceases to be true and its negation, $\text{CCW}(c, b, d)$, becomes true. In this simple case the three old certificates, plus the new certificate $\text{CCW}(c, b, d)$, allow us to conclude that the convex hull has now changed to $abdc$.

If the certificate set is chosen judiciously, the KDS repair can be a local, incremental process—a small number of certificates may leave the cache, a small number may be added, and the new attribute certification will be closely related to the old one. A good KDS exploits the continuity or coherence of motion and change in the world to maintain certifications that themselves change only incrementally and locally as assertions in the cache fail.

Proof of correctness:

- $CCW(a, b, c)$
- $CCW(d, b, c)$
- $CCW(d, c, a)$
- $CCW(d, a, b)$

FIGURE 50.4.2

$CCW(d, b, c)$	$CCW(c, b, d)$
$CCW(d, c, a)$	$CCW(d, c, a)$
$CCW(d, a, b)$	$CCW(d, a, b)$

FIGURE 50.4.3
Updating the convex hull of the points.

PERFORMANCE MEASURES FOR KDS

Because a KDS is not intended to facilitate a terminating computation but rather an on-going process, we need to use somewhat different measures to assess its complexity. In classical data structures there is usually a tradeoff between operations that interrogate a set of data and operations that update the data. We commonly seek a compromise by building indices that make queries fast, but such that updates to the set of indexed data are not that costly as well. Similarly in the KDS setting, we must at the same time have access to information that facilitates or trivializes the computation of the attribute of interest, yet we want information that is relatively stable and not so costly to maintain. Thus, in the same way that classical data structures need to balance the efficiency of access to the data with the ease of its update, kinetic data structures must tread a delicate path between “knowing too little” and “knowing too much” about the world. A good KDS will select a certificate set that is at once economical and stable, but also allows a quick repair of itself and the attribute computation when one of its certificates fails.

GLOSSARY

responsiveness: A KDS is *responsive* if the cost, when a certificate fails, of repairing the certificate set and updating the attribute computation is small. By

“small” we mean polylogarithmic in the problem size—in general we consider small quantities that are polylogarithmic or $O(n^\epsilon)$ in the problem size.

efficiency: A KDS is *efficient* if the number of certificate failures (total number of events) it needs to process is comparable to the number of required changes in the combinatorial attribute description (external events), over some class of allowed motions. Technically, we require that the ratio of total events to external events is small. The class of allowed motions is usually specified as the class of *pseudo-algebraic* motions, in which each KDS certificate can flip between true and false at most a bounded number of times.

compactness: A KDS is *compact* if the size of the certificate set it needs is close to linear in the degrees of freedom of the moving system.

locality: A KDS is *local* if no object participates in too many certificates; this condition makes it easier to re-estimate certificate failure times when an object changes its motion law. (The existence of local KDSs is an intriguing theoretical question for several geometric attribute functions.)

CONVEX HULL, REVISITED

We now briefly describe a KDS for maintaining the convex hull of n points moving around in the plane [BGH99].

The key goal in designing a KDS is to produce a *repairable certification* of the geometric object we want to track. In the convex hull case it turns out that it is a bit more intuitive to look at the dual problem, that of maintaining the upper (and lower) envelope of a set of moving lines in the plane, instead of the convex hull of the primal points. For simplicity we focus only on the upper envelope part from now on; the lower envelope case is entirely symmetric. Using a standard divide-and-conquer approach, we partition our lines into two groups of size roughly $n/2$ each, and assume that recursive invocations of the algorithm maintain the upper envelopes of these groups. For convenience call the groups red and blue.

In order to produce the upper envelope of all the lines, we have to merge the upper envelopes of the red and blue groups and also certify this merge, so we can detect when it ceases to be valid as the lines move; see [Figure 50.4.4](#).

Conceptually, we can approach this problem by sweeping the envelopes with a vertical line from left to right. We advance to the next red (blue) vertex and determine if it is above or below the corresponding blue (red) edge, and so on. In this process we determine when red is above blue or vice versa, as well as when the two envelopes cross. By stitching together all the upper pieces, whether red or blue, we get a representation of the upper envelope of all the lines.

The certificates used in certifying the above merge are of three flavors:

- x -certificates ($<_x$) are used to certify to x -ordering among the red and blue vertices; these involve four original lines.
- y -certificates ($<_y$) are used to certify that a vertex is above or below an edge of the opposite color; these involve three original lines and are exactly the duals of the CCWcertificates discussed earlier.
- s -certificates ($<_s$) are slope comparisons between pairs of original lines; though these did not arise in our sweep description above, they are needed to make the KDS local [BGH99].

FIGURE 50.4.4

Merging the red and blue upper envelopes. In this example, the red envelope (solid line) is above the blue (dotted line), except at the extreme left and right areas. Vertical double-ended arrows represent y -certificates and horizontal double-ended arrows represent x -certificates, as described below.

Figure 50.4.5 shows examples of how these types of certificates can be used to specify x -ordering constraints and to establish intersection or non-intersection of the envelopes.

FIGURE 50.4.5

Using the different types of certificates to certify the red-blue envelope merge.

A total of $O(n)$ such certificates suffices to verify the correctness of the upper envelope merge.

Whenever the motion of the lines causes one of these certificates to fail, a local, constant-time process suffices to update the envelope and repair the certification. Figure 50.4.6 shows an example where an y -certificate fails, allowing the blue envelope to poke up above the red.

It is straightforward to prove that this kinetic upper envelope algorithm is responsive, local, and compact, using the logarithmic depth of the hierarchical structure of the certification. In order to bound the number of events processed,

FIGURE 50.4.6

Envelope repair after a certificate failure. In the event shown lines b , d , and e become concurrent, producing a red-blue envelope intersection

however, we must assume that the line motions are polynomial or at least pseudo-algebraic. A proof of efficiency can be developed by extruding the moving lines into space-time surfaces. Using certain well-known theorems about the complexity of upper envelopes of surfaces [Sha94] and the overlays of such envelopes [ASS96] (cf. Chapter 47), it can be shown that in the worst case the number of events processed by this algorithm is near quadratic ($O(n^{2+\epsilon})$). Since the convex hull of even linearly moving points can change $\Omega(n^2)$ times [AGHV01], the efficiency result follows.

No comparable structure is known for the convex hull of points in dimensions $d \geq 3$.

EXTENT PROBLEMS

A number of the original problems for which kinetic data structures were developed are aimed at different measures of how “spread out” a moving set of points in $\mathbb{R}^2$ is—one example is the convex hull, whose maintenance was discussed in the previous subsection. Other measures of interest include the diameter, width, and smallest area or perimeter bounding rectangle for a moving set S of n points. All these problems can be solved using the kinetic convex hull algorithm above; the efficiency of the algorithms is $O(n^{2+\epsilon})$, for any $\epsilon > 0$. There are also corresponding $\Omega(n^2)$ lower bounds for the number of combinatorial changes in these measures. Surprisingly, the best upper bound known for maintaining the smallest enclosing disk containing S is still near-cubic. Extensions of these results to dimensions higher than two are also lacking.

These costs can be dramatically reduced if we consider approximate extent measures. If we are content with $(1 + \epsilon)$ approximations to the measures, then an approximate smallest orthogonal rectangle, diameter, and smallest enclosing disk can be maintained with a number of events that is a function of ϵ only and not of n [AHP01]. For example, the bound of the number of approximate diameter updates in $\mathbb{R}^2$ under linear motion of the points is $O(1/\epsilon)$.

PROXIMITY PROBLEMS

The fundamental proximity structures in computational geometry are the Voronoi diagram and the Delaunay triangulation (Chapter 23). The edges of the Delaunay triangulation contain the closest pair of points, the closest neighbor to each point, as well as a wealth of other proximity information among the points. From the

kinetic point of view, these are nice structures, because they admit completely local certifications. Delaunay’s 1934 theorem [Del34] states that if a local empty sphere condition is valid for each $(d-1)$ -simplex in a triangulation of points in $\mathbb{R}^d$, then that triangulation must be Delaunay. This makes it simple to maintain a Delaunay triangulation under point motion: an update is necessary only when one of these empty sphere conditions fails. Furthermore, whenever that happens, a local retiling of space (of which the classic “edge-flip” in $\mathbb{R}^2$ is a special case; cf. Section 25.3) easily restores Delaunayhood. Thus the KDS for Delaunay (and Voronoi) that follows from this theorem is both responsive and efficient—in fact, each KDS event is an external event in which the structure changes. Though no redundant events happen, an exact upper bound for the total number of such events in the worst-case is still elusive even in $\mathbb{R}^2$, where the best upper bound known is nearly cubic, while the best lower bound is only quadratic [AGMR98].

This principle of a set of easily checked local conditions that implies a global property has been used in kinetizing other proximity structures as well. For instance, in the *power diagram* [Aur87] of a set of disjoint balls, the two closest balls must be neighbors [GZ98]—and this diagram can be kinetized by a similar approach. Voronoi diagrams of more general objects, such as convex polytopes, have also been investigated. For example, in $\mathbb{R}^2$ [GSZ00] shows how to maintain a compact Voronoi-like diagram among moving disjoint convex polygons; again, a set of local conditions is derived which implies the global correctness of this diagram. As the polygons move, the structure of this diagram allows one to know the nearest pair of polygons at all times.

In many applications the exact L_2 -distance between objects is not needed and more relaxed notions of proximity suffice. Polyhedral metrics (such as L_1 or L_∞) are widely used, and the normal unit ball in L_2 can be approximated arbitrarily closely by polyhedral approximants. It is more surprising, however, that if we partition the space around each point into a set of polyhedral cones and maintain a number of directional nearest neighbors to each point in each cone, then we can still capture the globally closest pair of points in the L_2 metric. By directional neighbors here we mean that we measure distance only along a given direction in that cone. This geometric fact follows from a packing argument and is exploited in [BGZ97] to give a different method for maintaining the closest pair of points in $\mathbb{R}^d$. The advantage of this method is that the kinetic events are changes of the sorted order of the points along a set of directions fixed *a priori*, and therefore the total number of events is provably quadratic.

TRIANGULATIONS AND TILINGS

Many areas in scientific computation and physical modeling require the maintenance of a triangulation (or more generally a simplicial complex) that approximates a manifold undergoing deformation. The problem of maintaining the Delaunay triangulation of moving points in the plane mentioned above is a special case. More generally, local re-triangulations are necessitated by collapsing triangles, and sometimes required in order to avoid undesirably “thin” triangles. In certain cases the number of nodes (points) may also have to change in order to stay sufficiently faithful to the underlying physical process; see, for example, [CDES01]. Because in general a triangulation meeting certain criteria is not unique or canonical, it becomes more difficult to assess the efficiency of kinetic algorithms for solving such

problems. The lower-bound results in [ABdB⁺99] indicate that one cannot hope for a subquadratic bound on the number of events in the worst case for the maintenance of *any* triangulation, even if a linear number of additional Steiner points is allowed.

There is large gap between the desired quadratic upper bound and the current state of the art. Even for maintaining an arbitrary triangulation of a set of n points moving linearly in the plane, the best-known algorithm processes $O(n^{7/3})$ events [ABG⁺00] in the worst case. The algorithm actually maintains a pseudotriangulation of the convex hull of the point set and then a triangulation of each pseudotriangle. Although there are only $O(n^2)$ events in the pseudotriangulation, some of the events change too many triangles because of high-degree vertices. Unless additional Steiner points are allowed, there are point configurations for which high-degree vertices are inevitable and therefore some of the events will be expensive. A more clever, global argument is needed to prove a near-quadratic upper bound on the total number of events in the above algorithm. Methods that choose to add additional points, on the other hand, have the burden of defining appropriate trajectories for these Steiner points as well. Finally, today no triangulation that guarantees certain quality on the shapes of triangles as well as a subcubic bound on the number of retiling events is known.

COLLISION DETECTION

Kinetic methods are naturally applicable to the problem of collision detection between moving geometric objects. Typically collisions occur at irregular intervals, so that fixed-time stepping methods have difficulty selecting an appropriate sampling rate to fit both the numerical requirements of the integrator as well as those of collision detection. A kinetic method based on the discrete events that are the failures of relevant geometric conditions can avoid the pitfalls of both oversampling and undersampling the system. For two moving convex polygons in the plane, a kinetic algorithm where the number of events is a function of the relative separation of the two polygons is given in [EGSZ99]. The algorithm is based on constructing certain outer hierarchies on the two polygons. Analogous methods for 3D polytopes were presented in [GXZ01], together with implementation data.

A tiling of the free space around objects can serve as a proof of non-intersection of the objects. If such a tiling can be efficiently maintained under object motion, then it can be the basis of a kinetic algorithm for collision detection. Several papers have developed techniques along these lines, including the case of two moving simple polygons in the plane [BEG⁺99], or multiple moving polygons [ABG⁺00, KSS00]. These developments all exploit deformable pseudotriangulations of the free space—tilings which undergo fewer combinatorial changes than, for example, triangulations. An example from [ABG⁺00] is shown in [Figure 50.4.7](#). The figure shows how the pseudotriangulation adjusts by local retiling to the motion of the inner quadrilateral. The approach of [ABG⁺00] maintains a canonical pseudotriangulation, while others are based on letting a pseudotriangulation evolve according to the history of the motion. It is unclear at this point which is best. An advantage of all these methods is that the number of certificates needed is close to the size of the min-link separating subdivision of the objects, and thus sensitive to how intertwined the objects are.

Deformable objects are more challenging to handle. Classical methods, such as

FIGURE 50.4.7

Snapshots of the mixed pseudotriangulation of $[ABG^+00]$. As the center trapezoid-like polygon moves to the right, the edges corresponding to the next about-to-fail certificate are highlighted.

bounding volume hierarchies [GLM96], become expensive, as the fixed object hierarchies have to be rebuilt frequently. One possibility for mitigating this cost is to let the hierarchies themselves deform continuously, by having the bounding volumes defined implicitly in terms of object features. Such an approach was developed for flexible linear objects (such as rope or macromolecules), using combinatorially defined sphere hierarchies in [GNRZ02]. In that work a bounding sphere is defined not in the usual way, via its center and radius, but in an implicit combinatorial way, in terms of four feature points of the enclosed object geometry. As the object deforms these implicitly defined spheres automatically track their assigned features, and therefore the deformation. Of course the validity of the hierarchy has to be checked at each time step and repaired if necessary. What helps here is that the implicitly defined spheres change their combinatorial description rather infrequently, even under extreme deformation. An example is shown in Figure 50.4.8 where the rod shown is bent substantially, yet only the top-level sphere needs to update its description.

The pseudotriangulation-based methods above can also be adapted to deal with object deformation.

CONNECTIVITY AND CLUSTERING

Closely related to proximity problems is the issue of maintaining structures encoding connectivity among moving geometric objects. Connectivity problems arise frequently in *ad hoc* mobile communication and sensor networks, where the viability of links may depend on proximity or direct line-of-sight visibility among the sta-

FIGURE 50.4.8

A thin rod bending from a straight configuration, and a portion of its associated bounding sphere hierarchy. The combinatorially defined sphere hierarchy is stable under deformation. Only the top level sphere differs between the two conformations.

tions desiring to communicate. With some assumptions, the communication range of each station can be modeled by a geometric region, so that two stations can establish a link if and only if their respective regions overlap. (See also [Section 58.4.3.](#)) There has been work on kinetically maintaining the connected components of the union of a set of moving geometric regions for the case of rectangles [HS99] and unit disks [GHSZ00].

Clustering mobile nodes is an essential step in many algorithms for establishing communication hierarchies, or otherwise structuring *ad hoc* networks. Nodes in close proximity can communicate directly, using simpler protocols; correspondingly, well-separated clusters can reuse scarce resources, such the same frequency or time-division multiplexing communication scheme, without interference. Maintaining clusters of mobile nodes requires a tradeoff between the tightness, or optimality of the clustering, and its stability under motion. In [GGH⁺01b] a randomized clustering scheme is discussed based on an iterated leader-election algorithm that produces a number of clusters within a constant factor of the optimum, and in which the number of cluster changes is also asymptotically optimal. This scheme was used in [GGH⁺01a] to maintain a routing graph on mobile nodes that is always sparse and in which communication paths exist that are nearly as good as those in the full communication graph.

Another fundamental kinetic question is the maintenance of a minimum spanning tree (MST) among n mobile points in the plane, closely related to earlier work on parametric spanning trees [FBSE96] in a graph whose edge weights are functions of a parameter λ (λ is time in the kinetic setting). Since the MST is determined by the sorted order of the edge weights in the graph, a simple algorithm can be obtained by maintaining the sorted list of weights and some auxiliary data structures (such an algorithm is quadratic in the graph size, or $O(n^4)$ in our case). This was improved when the weights are linear functions of time to nearly $O(n^{11/6})$ (sub-quadratic) for planar graphs or other minor-closed families [AEGH98]. When the weights are the Euclidean distances between moving points, only approximation algorithms are known and the best event bounds are nearly cubic [BGZ97]. For many other optimization problems on geometric graphs, such as shortest paths for example, the corresponding kinetic questions are wide open.

VISIBILITY

The problem of maintaining the visible parts of the environment when an observer is moving is one of the classic questions in computer graphics and has motivated significant developments, such as binary space partition trees, the hardware depth buffer, etc. The difficulty of the question increases significantly when the environment itself includes moving objects; whatever visibility structures accelerate occlusion culling for the moving observer must now themselves be maintained under object motion.

Binary space partitions (BSP) are hierarchical partitions of space into convex tiles obtained by performing planar cuts (Chapter 28.8.2). Tiles are refined by further cuts until the interior of each tile is free of objects or contains geometry of limited complexity. Once a BSP tree is available, a correct visibility ordering for all geometry fragments in the tiles can be easily determined and incrementally maintained as the observer moves. A kinetic algorithm for visibility can be devised by maintaining a BSP tree as the objects move. The key insight is to certify the correctness of the BSP tree through certain combinatorial conditions, whose failure triggers localized tree rearrangements — most of the classical BSP construction algorithms do not have this property. In $\mathbb{R}^2$, a randomized algorithm for maintaining a BSP of moving disjoint line segments is given in [AGMV00]. The algorithm processes $O(n^2)$ events, the expected cost per tree update is $O(\log n)$, and the expected tree size is $O(n \log n)$. The maintenance cost increases to $O(n \lambda_{s+2}(n) \log^2 n)$ [AEG98] for disjoint moving triangles in $\mathbb{R}^3$ (s is a constant depending on the triangle motion). Both of these algorithms are based on variants of vertical decompositions (many of the cuts are parallel to a given direction). It turns out that in practice these generate “sliver-like” BSP tiles that lead to robustness issues [Com99].

As the pioneering work on the visibility complex has shown [PV96], another structure that is well suited to visibility queries in $\mathbb{R}^2$ is an appropriate pseudotriangulation. Given a moving observer and convex moving obstacles, a full radial decomposition of the free space around the observer is quite expensive to maintain. One can build pseudotriangulations of the free space that become more and more like the radial decomposition as we get closer to the observer. Thus one can have a structure that compactly encodes the changing visibility polygon around the observer, while being quite stable in regions of the free space well occluded from the observer [OH02].

RESULT SUMMARY

We summarize in [Table 50.4.1](#) the efficiency bounds on the main KDSs discussed above.

OPEN PROBLEMS

As mentioned above, we still lack efficient kinetic data structures for many fundamental geometric questions. Here is a short list of such open problems:

1. Find an efficient (and responsive, local, and compact) KDS for maintaining the convex hull of points moving in dimensions $d \geq 3$.

TABLE 50.4.1 Bounds on the number of combinatorial changes.

STRUCTURE	BOUNDS ON EVENTS	SOURCE
Convex hull	$\Omega(n^{2+\epsilon})$	[BGH99]
Pseudotriangulation	$O(n^2)$	[ABG ⁺ 00]
Triangulation (arb.)	$\Omega(n^{7/3})$	[ABG ⁺ 00]
MST	$O(n^{11/6} \log^{3/2} n)$	[AEGH98]
BSP	$\tilde{O}(n^2)$	[AGMV00, AEG98]

2. Find an efficient KDS for maintaining the smallest enclosing disk in $d \geq 2$. For $d = 2$, a goal would be an $O(n^{2+\epsilon})$ algorithm.
3. Establish tighter bounds on the number of Voronoi diagram events, narrowing the gap between quadratic and near-cubic.
4. Obtain a near-quadratic bound on the number of events maintaining an arbitrary triangulation of linearly moving points.
5. Maintain a kinetic triangulation with a guarantee on the shape of the triangles, in subcubic time.
6. Find a KDS to maintain the MST of moving points under the Euclidean metric achieving subquadratic bounds.

Beyond specific problems, there are also several important structural issues that require further research in the KDS framework. These include:

Recovery after multiple certificate failures. We have assumed up to now that the KDS assertion cache is repaired after each certificate failure. In many realistic scenarios, however, it is impossible to predict exactly when certificates will fail because explicit motion descriptions may not be available. In such settings we may need to sample the system and thus we must be prepared to deal with multiple (but hopefully few) certificate failures at each time step. A general area of research that this suggests is the study of how to efficiently update common geometric structures, such as convex hulls, Voronoi and Delaunay diagrams, arrangements, etc., after “small motions” of the defining geometric objects.

There is also a related subtlety in the way that a KDS assertion cache can certify the value, or a computation yielding the value, of the attribute of interest. Suppose our goal is to certify that a set of moving points in the plane, in a given circular order, always forms a convex polygon. A plausible certificate set for convexity is that all interior angles of the polygon are convex. See Figure 50.4.9. In the normal KDS setting where we can always predict accurately the next certificate failure, it turns out that the above certificate set is sufficient, *as long as at the beginning of the motion the polygon was convex*. One can draw, however, nonconvex self-intersecting polygons all of whose interior angles are convex, as also shown in the same figure. The point here is that a standard KDS can offer a *historical* proof of the convexity of the polygon by relying on the fact that the certificate set is valid

and that the polygon was convex during the prior history of the motion. Indeed the counterexample shown cannot arise under continuous motion without one of the angle certificates failing first. On the other hand, if an oracle can move the points when ‘we are not looking,’ we can wake up and find all the angle certificates to be valid, yet our polygon need not be convex. Thus in this oracle setting, since we cannot be sure that no certificates failed during the time step, we must insist on *absolute* proofs — certificate sets that in any state of the world fully validate the attribute computation or value.

FIGURE 50.4.9

Certifying the convexity of a polygon.

Hierarchical motion descriptions. Objects in the world are often organized into groups and hierarchies and the motions of objects in the same group are highly correlated. For example, though not all points in an elastic bouncing ball follow exactly the same rigid motion, the trajectories of nearby points are very similar and the overall motion is best described as the superposition of a global rigid motion with a small local deformation. Similarly, the motion of an articulated figure, such as a man walking, is most succinctly described as a set of relative motions, say that of the upper right arm relative to the torso, rather than by giving the trajectory of each body part in world coordinates.

What both of these examples suggest is that there can be economies in motion description, if the motion of objects in the environment can be described as a superposition of terms, some of which can be shared among several objects. Such hierarchical motion descriptions can simplify certificate evaluations, as certificates are often local assertions concerning nearby objects, and nearby objects tend to share motion components. For example, in a simple articulated figure, we may wish to assert $\text{CCW}(A, B, C)$ to indicate that an arm is not fully extended, where $\overline{AB}$ and $\overline{BC}$ are the upper and lower parts of the arm, respectively. Evaluating this certificate is clearly better done in the local coordinate frame of the upper arm than in a world frame—the redundant motions of the legs and torso have already been factored out.

Motion sensitivity. As already mentioned, the motions of objects in the world are often highly correlated and it behooves us to find representations and data structures that exploit such motion coherence. It is also important to find mathematical measures that capture the degree of coherence of a motion and then use this as a parameter to quantify the performance of motion algorithms. If we do not do this, our algorithm design may be aimed at unrealistic worst-case behavior, without capturing solutions that exploit the special structure of the motion

data that actually arise in practice — as already discussed in a related setting in [dBK⁺97]. Thus it is important to develop a class of kinetic *motion-sensitive* algorithms, whose performance can be expressed as a function of how coherent the motions of the underlying objects are.

Noncanonical structures. The complexity measures for KDSs mentioned earlier are more suitable for maintaining *canonical* geometric structures, which are uniquely defined by the position of the data, e.g., convex hull, closest pair, and Delaunay triangulation. In these cases the notion of external events is well defined and is independent of the algorithm used to maintain the structure. On the other hand, as we already discussed, suppose we want to maintain a triangulation of a moving point set. Since the triangulation of a point set is not unique, the external events depend on the triangulation being maintained, and thus depend on the algorithm. This makes it difficult to analyze the efficiency of a kinetic triangulation algorithm. Most of the current approaches for maintaining noncanonical structures artificially impose canonicity and maintain the resulting canonical structure. But this typically increases the number of events. So it is entirely possible that methods in which the current form of the structure may depend on its past history can be more efficient. Unfortunately, we lack mathematical techniques for analyzing such history-dependent structures.

50.5 QUERYING MOVING OBJECTS

Continuous tracking of a geometric attribute may be more than is needed for some applications. There may be time intervals during which the value of the attribute is of no interest; in other scenarios we may be just interested to know the attribute value at certain discrete query times. For example, given n moving points in $\mathbb{R}^2$, we may want to pose queries asking for all points inside a rectangle R at time t , for various values of R and t , or for an interval of time Δt , etc. Such problems can be handled by a mixture of kinetic and static techniques, including standard range-searching tools such as partition trees and range trees [dBvK⁺00]. They typically involve tradeoffs between evolving indices kinetically, or prebuilding indices for static snapshots. An especially interesting special case is when we want to be able answer queries about the near future faster than those about the distant future—a natural desideratum in many real-time applications.

A number of other classical range-searching structures, such as k -d-trees and R -trees have recently been investigated for moving objects [AHPP02, AGG02].

50.6 SOURCES AND RELATED MATERIALS

SURVEYS

Results not given an explicit reference above may be traced in these surveys.

[Gui98]: An early, and by now somewhat dated, survey of KDS work.

[AG⁺ar]: A report based on an NSF-ARO workshop, addressing several issues on modeling motion from the perspective of a variety of disciplines.

[Gui02]: A “popular-science” type article containing material related to the costs of sensing and communication for tracking motion in the real world.

51 PATTERN RECOGNITION

Joseph O'Rourke and Godfried T. Toussaint

INTRODUCTION

The two fundamental problems in a pattern recognition system are feature extraction (shape measurement) and classification. The problem of extracting a vector of shape measurements from a digital image can be further decomposed into three subproblems. The first is the image segmentation problem, i.e., the separation of objects of interest from their background. The cluster analysis methods discussed in Section 51.1 are useful here. The second subproblem is that of finding the objects in the segmented image. An example is the location of text lines in a document as illustrated in Section 51.2. The final subproblem is extracting the shape information from the objects detected. Here there are many tools available depending on the properties of the objects that are to be classified. The Hough transform (Section 51.2), polygonal approximation (Section 51.3), shape measurement (Section 51.4), and polygon decomposition (Section 51.6), are some of the favorite tools used here. Important to many of these tasks is finding a nice viewpoint from which extraction is robust and efficient (Section 51.5). Proximity graphs, discussed in Section 51.2, are used extensively for both cluster analysis and shape measurement.

The classification problem involves the design of efficient decision rules with which to classify the feature vector. The most powerful decision rules are the nonparametric rules which make no assumptions about the underlying distributions of the feature vectors. Of these the nearest-neighbor (NN) rule, treated in Section 51.7, is the most well known. This section covers the three main issues concerning NN-rules: how to edit the data set so that little storage space is used, how to search for the nearest neighbor of a vector efficiently, and how to estimate the future performance of a rule both reliably and efficiently.

51.1 CLUSTER ANALYSIS AND CLASSIFICATION

GLOSSARY

Cluster analysis problem: Partitioning a collection of n points in some fixed-dimensional space into $m < n$ groups that are “natural” in some sense. Here m is usually much smaller than n .

Image segmentation problem: Partitioning the pixels in an image into “meaningful” regions, usually such that each region is associated with one physical object.

Dendrogram: A tree representing a hierarchy of categories or clusters.

Hierarchical clustering algorithms: Those that produce a dendrogram whose root is the whole set and whose leaves are the individual points.

Graph-theoretic clustering: Clustering based on deleting edges from a proximity graph.

K-means clustering: Tracking clusters over time by comparing new data with old means.

Data mining: Intelligent and efficient information retrieval from huge (and often unstructured) data repositories.

Classical cluster analysis requires partitioning points into natural clumps. “Natural” may mean that the clustering agrees with human perception, or it may simply optimize some natural mathematical measure of similarity or distance so that points that belong to one cluster are similar to each other and points far away from each other are assigned to different clusters. It is not surprising that such a general and fundamental tool has been applied to widely different subproblems in pattern recognition. One obvious application is to the determination of the number and description of classes in a pattern recognition problem where the classes are not known a priori, such as disease classification in particular or taxonomy in general. In this case m is not known beforehand and the cluster analysis reveals it.

A fundamental problem in pattern recognition of images is the segmentation problem: distinguishing the figure from the background. Clustering is one of the most powerful approaches to image segmentation, applicable even to complicated images such as those of outdoor scenes. In this approach each pixel in the $N \times N$ image is treated as a complicated object by associating it with a local neighborhood. For example, we may define the 5×5 neighborhood of pixel p_{ij} , denoted by $N_5[p_{ij}]$, as $\{p_{mn} \mid i - 2 \leq m \leq i + 2, j - 2 \leq n \leq j + 2\}$. We next measure k properties of p_{ij} by making k measurements in $N_5[p_{ij}]$. Such measurements may include various moments of the intensity values (grey levels) found in $N_5[p_{ij}]$, etc. Thus each pixel is mapped into a point in k -dimensional pixel-space. Performing a cluster analysis of all the resulting $N \times N$ points in pixel-space yields the desired partitioning of the pixels into categories. Labeling each category of pixels with a different color then produces the segmentation.

See [Gor96] for a survey of clustering methods in which the objects in one class are not only required to be similar to each other but must satisfy other constraints on the distances between the objects or on the topology of the resulting dendrograms.

HIERARCHICAL CLUSTERING

In taxonomy there is no special number m that we want to discover; rather the goal is the production of a *dendrogram* (tree) that grows all the way from one cluster to n clusters and shows us at once how good a partitioning is obtained for any number of clusters between one and n . Such methods are referred to as *hierarchical* methods. They fall into two groups: **agglomerative** (bottom-up, merging) and **divisive** (top-down, splitting). Furthermore, each of these methods can be used with a variety of distance measures between subsets to determine when to merge or split. Two popular agglomerative clustering algorithms are the **single-link** and the **complete-linkage** (or farthest-neighbor) algorithm. In the former, cluster similarity is measured by the minimum of the distances between all pairs

of elements, one in each subset, whereas in the latter similarity is measured by the maximum pairwise distance. The complete-linkage criterion tends to produce more compact clusters, while the single-link criterion can suffer from chaining [JMF99]. Krznaric and Levkopoulos [KL02] show that a complete-linkage hierarchy can be computed in optimal $O(n \log n)$ time and $O(n)$ space.

GRAPH-THEORETIC CLUSTERING

The most powerful methods of clustering in difficult problems, which give results having the best agreement with human performance, are the graph-theoretic methods [JT92]. The idea is simple: Compute some proximity graph (such as the minimum spanning tree) of the original points. Then delete (in parallel) any edge in the graph that is much longer (according to some criterion) than its neighbors. The resulting forest is the clustering (each tree in this forest is a cluster). Proximity graphs have also been used effectively to design cluster validity tests [PB97].

K-MEANS TYPE CLUSTERING

There are many applications where we know that there are exactly K clusters, for example in character recognition. However, because of external factors such as the variations in people's hand-printing over time, or a change in the parameters of a machine due to wear or weather conditions, the clusters must be "tracked" over time. One of the most popular methods for doing this is the ***K-means algorithm***. The k -means algorithm searches for k cluster centroids in $\mathbb{R}^d$ with the property that the mean squared (Euclidean) distance between each point and its nearest centroid is minimized [Mac67]. A determining characteristic of this approach is that the number of clusters k is fixed. A typical heuristic starts with an initial partition, computes centers, assigns data points to their nearest center, recomputes the centroids, and iterates until convergence is achieved according to some criterion. (A neural network equivalent was developed by Kohonen [Koh95, BB95].) Unfortunately, this attractively simple algorithm's performance depends upon the initial partitioning, and in fact can be forced into a suboptimal solution of arbitrarily high approximation ratio (with respect to the optimal mean squared distance). This led recently to developing algorithms with performance guarantees. Matoušek achieved an $O(n \log^k n)$ ϵ -approximation algorithm under the assumption that k and d are fixed [Mat00]. This was improved to an $(9 + \epsilon)$ -approximation algorithm via a center-swap heuristic with this provable upper bound [KM⁺02]. On the other hand, there is some evidence that the exact k -means algorithm can be implemented to work well in practice for small d [PM99].

A variation on the k -means algorithm permits splitting and merging of clusters. This technique is employed by the ISODATA algorithm (Interactive Self-Organizing Data Analysis Technique) [Jen96].

DISTANCES BETWEEN SETS

A fundamental computational primitive of almost all clustering algorithms is the frequent computation of some distance measure between two sets (subsets) of points. This is especially so in the popular hierarchical methods discussed above. There exists a large variety of distance and more general similarity measures for this purpose. Here we mention a few. Most efficient algorithms for distance between sets apply only in $\mathbb{R}^2$ but some methods extend to higher dimensions; see [Smi00]. Let P and Q be two convex polygons of n sides each. Two distance measures should be distinguished: the minimum *element* distance, the smallest distance between a vertex or edge of P and a vertex or edge of Q , and the minimum *vertex* distance, the minimum distance between a vertex of P and a vertex of Q . The minimum element distance can be computed in $O(\log n)$ time [Ede85]. On the other hand, computation of the minimum vertex distance between P and Q has a linear lower bound. For the case of two nonintersecting convex polygons several different $O(n)$ time algorithms are available, and the same bound can be achieved for crossing convex polygons [Tou84].

Let R be a set of n red points and B a set of n blue points in the plane. Both the minimum distance and the maximum distance between R and B can be computed in $O(n \log n)$ time. For the latter problem, two algorithms are available. The first [TM82] is simple but does not appear to generalize to higher dimensions. The second [BT83] works by reducing the maximum distance problem between R and B to computing the diameter of 81 convex polygons. These are obtained by computing the convex hulls of the unions of 81 carefully selected subsets of R and B , and then reporting the maximum of these 81 diameters as the maximum distance. These ideas can be extended to obtain efficient algorithms for all dimensions [Rob93]. Therefore, any improvement in high-dimensional diameter algorithms automatically improves maximum-distance algorithms.

DATA MINING

The explosion of the Web has given new impetus to intelligent and efficient information retrieval from huge, often unstructured, data repositories. This activity has become known as ***data mining***. Clustering is often used to segment the data set, to support subsequent “mining.” The k -means algorithm and its variants remain popular, not only in geometric domains (e.g., in geological databases [JMF99], celestial databases [PM99], image databases, and so on), but even for text databases. For example, Fayyad et al. [FRB98] report some success on a Reuter’s database using the 302 most frequently occurring words, i.e., the dimension is $d = 302$. There is some movement in the literature away from point distances for categorical attributes, for which the iterative centroid-based clustering algorithms are often inappropriate. For example, recent work uses “links” [GRS00] or context-based measures [DM00], which places this work close to graph-theoretic clustering. A related new direction is finding “unusual” strings of ACTG characters within the human genome [ABL02].

51.2 EXTRACTING SHAPE FROM DOT PATTERNS

HOUGH TRANSFORMS

The *Hough transform* was originally proposed (and patented) as an algorithm to detect straight lines in digital images [Lea92]. The method may be used to detect any parametrizable pattern, and has been generalized to locate arbitrary shapes in images. The basic idea is to let each above-threshold pixel in the image vote for the points in the parameter space that could generate it. The votes are accumulated in a quantized version of the parameter space, with high vote tallies indicating detection.

Examples

1. *Lines.* Let the lines in the (x, y) image plane be parametrized as $y = mx + b$. Then a pixel at (x_0, y_0) is a witness to a line passing through it, that is, an (m, b) pair satisfying $y_0 = mx_0 + b$. Thus, (x_0, y_0) votes for all those (m, b) pairs: the line in parameter space dual to the pixel.
2. *Circles.* Parametrize the circles by their center and radius, (x_c, y_c, r) . Then a pixel (x_0, y_0) gives evidence for all the parameter triples on the circular cone in the 3-parameter space with apex at $(x_0, y_0, 0)$ and axis parallel to the r -axis.
3. *Object location.* Suppose a known but arbitrary shape S is expected to be found in an image, and its most likely location is sought. For translation-only, the parameter space represents the location of some fixed point of S . Each pixel in the image of the right shading or color votes for all those translations that cover it appropriately.

The above approaches are not necessarily optimal for the tasks listed. For example, it was shown in [CT77] that nonuniform (maximum entropy) quantization with $\rho - \theta$ parametrization for lines is superior to uniform quantization with $m - b$ parametrization.

The demands of high-dimensional vote accumulators have engendered the study of *dynamic quantization* of the parameter space, and *geometric hashing*. This latter technique has features in the image vote for each member of a library of shapes by hashing into a table using the feature coordinates as a key. Each table entry may correspond to several shapes at several displacements, but all receive votes. Geometric hashing has been applied with some success to the *molecular docking* problem [LW88]; see also [MSW02].

More recently, new variants of the Hough transform inspired by results in computational geometry have appeared. In [AK96] two such algorithms are presented and studied with respect to the tradeoff that exists between computational complexity and effectiveness of line detection. They obtain efficient implementations by using the plane-sweep paradigm.

TEXT-LINE ORIENTATION INFERENCE

In an automated document analysis system, given a block (paragraph) of text, the text-line orientation inference problem consists of determining the location and direction of the lines of text on the page. Almost always these lines are either horizontal (e.g., English) or vertical (e.g., Chinese). The fundamental geometric property that allows this problem to be solved is the fact that according to a universal typesetting convention guided by ease of reading, characters are printed closer together within textlines than between textlines.

One of the most successful, robust, skew-tolerant, simple, and elegant techniques for text-line orientation inference was proposed by Ittner [Itt93]. Assume that the given text block B consists of n black connected components (characters). The three key steps in the procedure are: (1) idealize each character by a point, thus obtaining a set S of n points in the plane; (2) construct the Euclidean minimum spanning tree $\text{MST}(S)$ of the n points obtained in (1); and (3) determine the textline orientation by analysis of the distribution of the orientations of the edges in $\text{MST}(S)$. Step (1) is done by computing the center of the bounding box of each character. Cheriton and Tarjan proposed a simple algorithm for computing the MST of a graph in $O(E)$ time where E is the number of edges in the graph [CT76]. Fortunately there are many graphs defined on S (usually belonging to the class of proximity graphs [JT92]) that have the property that they contain the $\text{MST}(S)$ and also have $O(n)$ edges. For these graphs the Cheriton-Tarjan algorithm runs in $O(n)$ time.

RELATIVE NEIGHBORHOOD GRAPHS

Relative neighborhood graphs (RNG's), introduced in [Tou80b], capture proximity between points by connecting nearby points with a graph edge. The many possible notions of "nearby" (in several metrics) lead to a variety of related graphs. It is easiest to view the graphs as connecting points only when certain regions of space are empty. Let V be a set of n points in $\mathbb{R}^d$.

GLOSSARY

$\delta(p, q)$: the distance between two points p and q .

L_p : The distance metric L_p defined as $\delta_p(x, y) = (\sum_{i=1}^d |x_i - y_i|^p)^{1/p}$. For L_1 this reduces to $\sum_{i=1}^d |x_i - y_i|$, and for L_∞ , to $\max_{1 \leq i \leq d} |x_i - y_i|$.

Ball $B(x, r)$: The open ball $B(x, r) = \{y \mid \delta(x, y) < r\}$.

Nearest-neighbor Graph $\text{NNG}(V)$: The graph with vertex set V and an edge (p, q) iff $B(p, \delta(p, q)) \cap V = \emptyset$.

Lune $L(p, q)$: $L(p, q) = B(p, \delta(p, q)) \cap B(q, \delta(p, q))$.

Relative neighborhood graph $\text{RNG}(V)$: The graph with vertex set V and an edge (p, q) iff $L(p, q) \cap V = \emptyset$. Thus the edge is present iff

$$\delta(p, q) \leq \max_{v \in V \setminus \{p, q\}} \{\delta(p, v), \delta(q, v)\}.$$

Gabriel graph $\text{GG}(V)$: The graph with vertex set V and an edge (p, q) iff

$$B\left(\frac{p+q}{2}, \frac{\delta(p, q)}{2}\right) \cap V = \emptyset.$$

β -lune: $L_\beta(p, q) = B\left(p(1 - \frac{\beta}{2}) + q\frac{\beta}{2}, \frac{\beta}{2}\delta(p, q)\right) \cap B\left(q(1 - \frac{\beta}{2}) + p\frac{\beta}{2}, \frac{\beta}{2}\delta(p, q)\right).$

β -skeleton: The graph $G_\beta(V)$ with vertex set V and an edge (p, q) iff $L_\beta(p, q) \cap V = \emptyset$. The range $1 \leq \beta \leq 2$ is especially relevant, with $G_2(V) = \text{RNG}(V)$ and $G_1(V) = \text{GG}(V)$.

Sphere-of-influence graph $\text{SIG}(V)$: Let C_p be the circle centered on p with radius equal to the distance to a nearest neighbor of p . $\text{SIG}(V)$ has node set V and an edge (p, q) iff C_p and C_q intersect in at least two points.

Minimum-Weight Triangulation $\text{MWT}(V)$: A triangulation of minimum total edge length.

The *relative neighborhood graph* connects two points if the *lune* they determine is empty of points of V . The *Gabriel graph* is defined similarly, but with the *diameter sphere* required to be empty. The β -skeletons are a continuous generalization of the Gabriel graph. These graph definitions are motivated by various applications: computer vision, texture discrimination, geographic analysis, pattern analysis, cluster analysis, and others.

Proximity graphs form a nested hierarchy, a version of which was first established in [Tou80b]:

THEOREM 51.2.1 *Hierarchy*

In any L_p metric, for a fixed set V and $1 \leq \beta \leq 2$,

$$\text{NNG} \subseteq \text{MST} \subseteq \text{RNG} \subseteq G_\beta \subseteq \text{GG} \subseteq \text{DT}.$$

MST is the minimum spanning tree, and DT the Delaunay triangulation, of V .

Neighborhood graphs can have at most $O(n^2)$ edges, and $\Theta(n^2)$ complexity is achieved in many instances. For the L_2 metric in $\mathbb{R}^2$, however, RNG's (and their relatives) have linear size, which increases their usefulness. See Table 51.2.1.

TABLE 51.2.1 Size of relative neighborhood graphs.

DIM	METRIC	SIZE
2	$L_p, 1 < p < \infty$	$\Theta(n): \in [n-1, 3n-6]$
≥ 2	L_1, L_∞	$\Theta(n^2)$
3	L_2	$O(n^{4/3})$
$d > 4$	L_p	$\Theta(n^2)$

The many applications of neighborhood graphs have stimulated considerable effort on developing efficient algorithms for constructing them. The RNG has the most applications and has received the most attention. $O(n^3)$ time complexity is trivial to achieve. Exploiting the fact that the Delaunay triangulation is a superset

leads easily to $O(n^2)$ in the plane. Further development is more difficult. Two milestones in algorithm development were Supowit's $O(n \log n)$ algorithm for L_2 in $\mathbb{R}^2$ [Sup83], and Agarwal and Matoušek's near- $O(n^{3/2})$ algorithm for general position points in $\mathbb{R}^3$ [AM92]. See Table 51.2.2.

TABLE 51.2.2 Relative neighborhood graph algorithms.

DIM	METRIC	COMPLEXITY
2	L_2	$O(n \log n)$
2	L_1, L_∞	$O(n \log n)$
3	L_2	$O(n^{3/2+\epsilon})$
3	L_1, L_∞	$O(n \log^2 n)$
d	L_2	$O(n^{2(1-\frac{1}{d+1})+\epsilon})$
d	L_1, L_∞	$O(n \log^{d-1} n)$

A related graph is the *sphere-of-influence* (SIG) graph. It has at most $15n = O(n)$ edges in $\mathbb{R}^2$ and can be computed in $\Theta(n \log n)$ time. The SIG can serve as a type of graph-theoretical “primal sketch.” It, in some sense, explains the dot-pattern version of the Mueller-Lyer illusion.

See the survey [JT92] for further details on neighborhood graphs.

An important connection between β -skeletons and minimum-weight triangulations (MWT) was discovered by Keil [Kei94]: for $\beta = \sqrt{2}$, $G_\beta \subseteq \text{MWT}$. This was subsequently sharpened to $\beta = \frac{1}{6}\sqrt{2\sqrt{3} + 45}$, which is optimal [WY99].

OPEN PROBLEMS

1. What is the maximum number of edges of an RNG in $\mathbb{R}^3$? It is known that it has at most $O(n^{4/3})$ edges, but no supra-linear lower bound is known.
2. That the SIG has at most $15n$ edges in the plane follows from a theorem of Erdős and Panwitz [Sos99], but the best lower bound is $9n$. It is also known that the SIG has a linear number of edges in any fixed dimension [GPS94], and bounds on the expected number of edges are known [Dwy95], but again tight results are not available.

51.3 POLYGONAL APPROXIMATION

Let $P = (p_1, p_2, \dots, p_n)$ be a polygonal curve or chain in the plane, consisting of n points p_i joined by line segments $p_i p_{i+1}$. In general P may be closed and self-intersecting. Polygonal curves occur frequently in pattern recognition either as representations of the boundaries of figures or as functions of time representing, e.g., speech. In order to reduce the complexity of costly processing operations,

it is often desirable to approximate a curve P with one that is composed of far fewer segments, yet is a close enough replica of P for the intended application. Some methods of reduction attempt smoothing as well. An important instance of the problem is to determine a new curve $Q = (q_1, q_2, \dots, q_m)$ such that (1) m is significantly smaller than n ; (2) the q_j are selected from among the p_i ; and (3) any segment $q_j q_{j+1}$ that replaces the chain $q_j = p_r, \dots, p_s = q_{j+1}$ is such that the distance between $q_j q_{j+1}$ and each p_k , $r \leq k \leq s$, is less than some predetermined error tolerance ω . Different notions of distance, or error criteria, lead to different algorithmic issues. Moreover, for each distance definition, there are two constrained optimization problems that are of interest, Min-# and Min- ϵ .

GLOSSARY

Distance from point p to segment s : Minimum distance from p to any point of s .

Parallel-strip criterion: All the vertices $p_i, \dots, p_t$ lie in a parallel strip of width 2ω whose center line is collinear with $q_j q_{j+1}$ [ET94].

Segment criterion: For each p_k , $r \leq k \leq s$, the distance from p_k to $q_j q_{j+1}$ is less than ω [MO88, CC96].

Min-# problem: Given the error tolerance ω , find a curve $Q = (q_1, \dots, q_m)$ satisfying the constraint such that m is minimum.

Min- ϵ problem: Given m , find a curve $Q = (q_1, \dots, q_m)$ satisfying the constraint such that the error tolerance is minimized.

The main results obtained are listed in Table 51.3.1.

TABLE 51.3.1 Polygonal approximation algorithm time complexities.

ERROR CRITERION	MIN-#	MIN- ϵ
Parallel strip	$O(n^2 \log n)$	$O(n^2 \log^2 n)$
Segment	$O(n^2)$	$O(n^2 \log n)$

The task of polygonal approximation has been given new significance in three-dimensions for its importance in simplifying polyhedral models in computer graphics, e.g., [CVM⁺96, LE97]. This topic is covered in detail in [Chapter 54](#).

OPEN PROBLEMS

Find algorithms for the strip criterion problems that match those for the segment problems. Perhaps quadratic performance is achievable for all four problems.

ITERATIVE ENDPOINT FITTING

There are many algorithms in both the pattern recognition and automated cartography literatures that are intended to yield approximations with few, but not necessarily the minimum number of, segments. This suffices for many applications,

and often can be obtained more efficiently in both time and space complexities. One of the most popular such algorithms is *iterative endpoint fitting*, which employs the parallel-strip criterion. Given a tolerance ω , the algorithm first attempts to use only one segment $Q = (p_1, p_n)$ to approximate P . If the error tolerance is exceeded, then that vertex of P whose distance to the line through $p_1 p_n$ is maximum is chosen to divide P into two subchains. The procedure is then recursively applied to these subchains. This procedure can be implemented to run in $O(n \log n)$ time.

51.4 SHAPE MEASUREMENT AND REPRESENTATION

MEDIAL AXIS

GLOSSARY

Medial axis: The set of points of a region P with more than one closest point among the boundary points ∂P of the region. Equivalently, it is the set of centers of maximal balls, i.e., of balls in P that are themselves not enclosed in another ball in P .

Voronoi diagram: The partition of a polygonal region P into cells each consisting of the points closer to a particular open edge or vertex than to any other.

The *medial* or *symmetric axis* was introduced by Blum [Blu67] to capture biological shape, and it has since found many other applications, for example, to geometric modeling (*offset* computations; see [Section 47.2](#)) and to mesh generation [SNT⁺92] (Section 22.4). It provides a central “skeleton” for an object that has found many uses. It connects to several other mathematical concepts, including the *cut locus* and most importantly, the Voronoi diagram ([Chapter 20](#)).

The medial axis of a convex polygon is a tree with each vertex a leaf. For a nonconvex polygon, the medial axis may have a parabolic arc associated with each reflex vertex (Figure 47.1.5). The basic properties of the medial axis were detailed by Lee [Lee82], who showed that the medial axis of a polygon P is just the Voronoi diagram minus the Voronoi edges incident to reflex vertices, and provided an $O(n \log n)$ algorithm for constructing it. After a long search by the community, an $O(n)$ algorithm was obtained [CSW95]. The simplest implementations are, however, quadratic [YR91]. See Table 52.4.1.

The medial axis has also found much use in image processing, where its digital computation is via *thinning algorithms*. Pioneered by Rosenfeld, these algorithms are very simple and easily parallelized [Cyc94].

The definition of medial axis extends to $\mathbb{R}^d$. Some work has explored $\mathbb{R}^3$ [SPB95], but currently the lack of reliable software hampers extensive applications.

POINT PATTERN MATCHING

Exact point pattern matching is an interesting algorithmic question related to string matching, but pattern recognition applications usually require some type of approximate matching. Two types may be distinguished [AG00]: one-to-one matching, and Hausdorff matching.

GLOSSARY

One-to-one approximate matching: Let two finite sets of points A and B have the same cardinality. One-to-one matching requires finding a transformation (of a given type) of B such that each point of B is mapped to within a distance of ϵ of a matched point of A . The matches are either determined by *labels* on the points, or the points are *unlabeled* and the match is to be discovered.

Decision problem: Given ϵ , is there such a matching?

Optimization problem: Find the minimum ϵ for which an approximate matching exists.

Hausdorff distance: For two finite sets A and B , perhaps of different cardinalities, the largest of the between-sets nearest-neighbor distances.

Hausdorff matching: Find a transformation of B that minimizes the Hausdorff distance from A .

The most combinatorially interesting point matching (unrealistically) demands exact matching. One version of this is the **congruent subset detection problem**: Given a pattern set A of m points, find all subsets of a background set B of n points that are congruent to A . Solving this in the plane relies on the unsolved Erdős problem of bounding the number of unit-distance pairs among n points, whose best upper bound is $O(n^{4/3})$ (Chapter 10). Important variations are obtained by acting on the pattern by some group, e.g., translations. Results here are surveyed in [Bra02], from which the results shown in Table 51.4.1 are gathered ($\alpha()$ is the near-constant inverse Ackermann function; cf. Chapter 47).

TABLE 51.4.1 Subset detection of m points among n points.

GROUP	DIM	MATCHES	ALGORITHM
Congruence	2	$O(n^{4/3})$	$O(mn^{4/3} \log n)$
Congruence	3	$\Omega(n^{4/3})$	$O(mn^{5/3} \log n 2^{O(\alpha(n)^2)})$
Translation	d	$n - \Theta(n^{1-1/k}), k \leq d$	$O(mn \log n)$
Homothets	d	$O(n^{1+1/k}), k \leq d$	$O(mn^{1+1/d} \log n)$
Similarity	d	$O(n^d)$	$O(mn^d \log n)$
Affine	d	$O(n^{d+1})$	$O(mn^{d+1} \log n)$

A window-restricted version of the problem led Brass to pose the following interesting Conjecture:

- Any set of n points in the plane contains only $O(n)$ empty congruent triangles.

There are sets with $\binom{n}{3}$ empty triangles.

Results on **one-to-one approximate matching** algorithms obtained in [AM⁺88] for a variety of permissible transformations are shown in Table 51.4.2.

Hausdorff matching leads to analysis of envelopes of *Voronoi surfaces*. Typical results are shown in Table 51.4.3. Here we show the complexities when $|A| = |B| = n$, although the algorithms work for sets of different cardinalities.

TABLE 51.4.2 One-to-one point matching in two dimensions.

MOVEMENTS	LABELLED	ϵ	COMPLEXITY
Translation	labeled	dec, opt	$O(n)$
Translation	unlabeled	decision	$O(n^6)$
Translation	unlabeled	optimization	$O(n^6 \log n)$
Rotation	labeled	decision	$O(n \log n)$
Rotation	labeled	optimization	$O(n^2)$
Trans+rot+refl	labeled	decision	$O(n^3 \log n)$
Trans+rot+refl	unlabeled	decision	$O(n^8)$

TABLE 51.4.3 Hausdorff matching in the L_2 metric.

MOVEMENTS	DIM	COMPLEXITY
Translation	2	$O(n^3 \log n)$
Translation + rotation	2	$O(n^6 \log n)$
Translation	3	$O(n^{5+\epsilon})$

Another type of matching is *order type matching* (cf. Section 5.2). In [GP83], an $O(n^3)$ algorithm is given for finding all matchings between two planar point configurations in which their order types agree.

SYMMETRY DETECTION

Symmetry is an important feature in the analysis and synthesis of shape and form and has received considerable attention in the pattern recognition and computer graphics literatures. In [WWV85] an $O(n \log n)$ algorithm is presented for computing the rotational symmetries of polygons and polyhedra of n vertices, but the constant in $\mathbb{R}^3$ is very large. Jiang and Bunke [JB91] give a simple and practical $O(n^2)$ time algorithm for polyhedra. One of the earliest applications of computational geometry to symmetry detection was the algorithm of Akl and Toussaint [AT79] to check for polygon similarity. Since then attention has been given to other aspects of symmetry and for objects other than polygons. Sugihara [Sug84] shows how a modification of the planar graph-isomorphism algorithm of Hopcroft and Tarjan can be used to find all symmetries of a wide class of polyhedra in $O(n \log n)$ time.

A related topic is centers of symmetry. Given a convex polygon P , associate with each point p in P the minimum area of the polygon to the left of any chord through p . The maximum over all points in P is known as *Winternitz's measure of symmetry* and the point p^* that achieves this maximum is called the *center of area*. Diaz and O'Rourke [DO94] show that p^* is unique and propose an algorithm for computing p^* in time $O(n^6 \log^2 n)$. For a survey of the early work on detecting symmetry, see [Ead88].

THE ALPHA HULL

The α -shape $\mathcal{S}_\alpha$ of a set S of n points in $\mathbb{R}^3$ is a polyhedral surface whose boundary is a particular collection of triangles, edges, and vertices determined by the points of S [EM94]. It is similar in spirit to the β -skeleton of Section 51.2 in that it is a parametrized collection of shapes determined by an empty balls condition, but it emphasizes the external rather than the internal structure of the set. Let T be a subset of S of 1, 2, or 3 points. Then the convex hull of T , $\text{conv}(T)$, is part of the boundary $\partial\mathcal{S}_\alpha$ of the α -shape iff the surface of some ball of radius α includes exactly the points of T while its interior is empty of points of S . Thus a triangle $\text{conv}(T)$ is part of $\partial\mathcal{S}_\alpha$ iff there is an open α -ball that can “erase” all of the triangle but leave its vertices. $\mathcal{S}_\alpha$ is defined for all $0 \leq \alpha \leq \infty$, with $\mathcal{S}_0 = S$ and $\mathcal{S}_\infty = \text{conv}(S)$.

Every edge and triangle of $\mathcal{S}_\alpha$ is present in the Delaunay triangulation DT of S , and every edge and triangle in DT is present in some $\mathcal{S}_\alpha$. If α is varied continuously over its full range starting from ∞ , the convex hull of S is gradually “eaten away” by smaller and smaller α -ball erasers, eventually exposing the original set of points. In between, the α -shape bounds a subcomplex of DT that represents the shape of S .

The alpha shape has been used for cluster analysis, molecular modeling, and the analysis of medical data, among other applications. High-quality code is available [EF99]; now CGAL includes alpha shapes in its basic library ([Chapter 65](#)).

51.5 NICE VIEWPOINTS AND PROJECTIONS

A robot navigating in 3D space faces a variety of pattern recognition problems that involve classifying objects modeled as polyhedra. A polyhedral object in 3D space is often well represented by a set of points (vertices) and line segments (edges) that act as its features. The feature extraction process involves obtaining *nice* viewpoints of the polyhedron. By a nice viewpoint of an object we mean a projective view in which all (or most) of the features of the object, relevant for some task, are clearly visible. Such a view is often called a nondegenerate view or projection. A recent survey of this topic can be found in [Tou00].

GLOSSARY

Nice viewpoint: A projection of a 3D object (set of points, etc) onto a plane such that it has some desirable special property.

Knot diagram: A regular projection of a polygon in 3-dimensions onto a plane.

Degeneracies: Properties of objects such as three points collinear.

General position: A configuration of an object such that some specified degeneracies are absent.

Orthogonal projection: A projection from a point at infinity.

Perspective projection: A projection from a point not at infinity.

Robust algorithm: One that works correctly even in the presence of degeneracies.

Regular projection: An orthogonal projection of S such that no three points of S project to the same point on H , and no vertex of S projects to the same point on H as any other point of S .

Wirtinger projections: Regular projections in which no two consecutive edges of the 3D polygon have collinear projections.

Robust nondegenerate projection: A projection that remains nondegenerate even if the object is slightly perturbed.

Decision problem: Given an object and a projection of it, does the projection contain a degeneracy?

Computation problem: Given an object, compute a projection that does not contain a specified degeneracy.

Optimization problem: Given an object, compute the most robust nondegenerate projection.

REGULAR PROJECTIONS

The earliest work on nondegenerate orthogonal projections appears to be in the area of knot theory. Let S be a set of n disjoint line segments in $\mathbb{R}^3$ specified by the cartesian coordinates of their endpoints (vertices of S) and let H be a plane. Let SH be the orthogonal projection of S onto H . An orthogonal projection of S is said to be *regular* if no three points of S project to the same point on H and no vertex of S projects to the same point on H as any other point of S [Liv93]. This definition implies that for disjoint line segments (1) no point of SH corresponds to more than one vertex of S , (2) no point of SH corresponds to a vertex of S and an interior point of an edge of S , and (3) no point of SH corresponds to more than two interior points of edges of S . Therefore the only crossing points (intersections) allowed in a regular projection are those points that belong to the interiors of precisely two edges of S . This condition is crucial for the successful visualization and manipulation of knots [Liv93].

Regular projections of 3D polygons were first studied by the knot theorist K. Reidemeister [Rei32] in 1932 who showed that all 3D polygons (knots) admit a regular projection, and in fact almost all projections of polygons are regular. Reidemeister however was not concerned with computing regular projections. The computational aspects of regular projections of knots were first investigated by Bose et al., [BGRT99] under the real RAM model of computation. Given a polygonal object (geometric graph, wire-frame or skeleton) in $\mathbb{R}^3$ (such as a simple polygon, knot, skeleton of a Voronoi diagram or solid model mesh), they consider the problem of computing several “nice” orthogonal projections of the object. One such projection, well known in the graph-drawing literature, is a projection with few crossings. They consider the most general polygonal object, i.e., a set of n disjoint line segments, and show that deciding whether it admits a crossing-free projection can be done in $O(n^2 \log n + k)$ time and $O(n^2 + k)$ space, where k is the number of intersections among a set of “forbidden” quadrilaterals on the direction sphere, and $k = O(n^4)$. This implies for example that, given a knot, one can determine if there exists a plane on which its projection is a simple polygon, within the same complexity. Furthermore, if such a projection does not exist, a minimum-crossing projection can be found in $O(n^4)$ time and $O(n^2)$ space. They showed (independently of Reidemeister) that a set of line segments in space (which includes polygonal objects

as special cases) always admits a regular projection, and that such a projection can be obtained in $O(n^3)$ time. A description of the set of all directions which yield regular projections can be computed in $O(n^3 \log n + k \log n)$ time, where k is the number of intersections of a set of quadratic arcs on the direction sphere and $k = O(n^6)$. Finally, when the objects are polygons and trees in space, they consider monotonic projections, i.e., projections such that every path from the root of the tree to every leaf is monotonic in some common direction on the projection plane. For example, given a polygonal chain P , they can determine in $O(n)$ time if P is monotonic on the projection plane, and in $O(n \log n)$ time they can find all the viewing directions with respect to which P is monotonic. In addition, in $O(n^2)$ time, they can determine all directions for which a given tree or a given simple polygon is monotonic.

COMPUTER VISION

In the computer vision field there is both a theoretical [BWR93] interest in nondegenerate projections and a practical one [DWT99]. The theoretical work resembles the work described in the previous section in that it is assumed that the object consists of idealized points and line segments or polygons and polyhedra. A tool used for computing viewpoints from which the maximum number of faces of a solid polyhedron is visible, is the *aspect graph* [PD90] ([Chapter 28](#)).

WIRTINGER PROJECTIONS

That certain types of nondegenerate orthogonal projections of 3D polygons always exist for some directions of projection was rediscovered by Bhattacharya and Rosenfeld [BR94] for a restricted class of regular projections. Those regular projections, in which it is also required that no two consecutive edges of the 3D polygon have collinear projections, are known as *Wirtinger projections*. Bose et al. [BGRT99] study the complexity of computing a single Wirtinger projection as well as constructing a description of all such projections for the more general input consisting of disjoint line segments. These results include therefore results for 3D chains, polygons, trees and geometric graphs in general. The description of all projections allows one to obtain Wirtinger projections that optimize additional properties. For example, one may be interested in obtaining the most robust projection in the sense that it maximizes the deviation of the viewpoint required to violate the Wirtinger property.

VISUALIZATION

In computer graphics one is interested in visualizing objects well, and therefore *nice* views and nondegenerate views are major concerns. For example, Kamada and Kawai [KK88] proposed a method to obtain nice projections by making sure that in the projection, parallel line segments on a plane in 3D project as far away from each other as possible. Intuitively, the viewer should be as orthogonal as possible to every face of the 3D object. Of course this is not possible and therefore they suggest minimizing (over all faces) the maximum angle deviation between a normal to the face and the line of sight from the viewer. They then propose an

algorithm to solve this problem in $O(n^6 \log n)$ time, where n is the number of edges in the polyhedral object in 3D. Gómez et al. [GRT01] reduce this complexity to $O(n^4)$ time. Furthermore, they show that if one is restricted to viewing an object from only a hemisphere, as is the case with a building on top of flat ground, then a further reduction in complexity is possible to $O(n^2)$ time.

REMOVING DEGENERACIES

Algorithms in computational geometry are usually designed for the real RAM (random access machine) assuming that the input is in *general position*. More specifically, the general position assumption implies that the input to an algorithm for solving a specific problem is free of certain degeneracies. Yap [Yap90] has distinguished between intrinsic or *problem-induced* and extrinsic or *algorithm-induced* degeneracies (see also Chapter 41). For example, in computing the convex hull of a set of points in the plane, where “left” turns and “right” turns are fundamental primitives, three collinear points constitute a problem-induced degeneracy. On the other hand, for certain vertical line-sweep algorithms two points with the same x -coordinate constitute an algorithm-induced degeneracy. Computational geometers make these assumptions because doing so makes it not only much easier to design algorithms but often yields algorithms with reduced worst-case complexities. On the other hand, to the implementers of geometric algorithms these assumptions are frustrating. Programmers would like the algorithms to work for any input that they may encounter in practice, regardless of the degeneracies that such an input may contain.

Often a typical computational geometry paper will make a nondegeneracy assumption that can in fact be removed (*without* perturbing the input) by a global rigid transformation of the input (such as a rotation, for example). Once the solution is obtained on the transformed nondegenerate input, the solution can be transformed back trivially (by an inverse rotation) to yield the solution to the original problem. In these situations, by applying suitable *pre-* and *post-* processing steps, one obtains the *exact* solution to the *original* problem using an algorithm that assumes a nondegenerate input, even when that input is in fact degenerate. This approach not only handles algorithm-induced degeneracies via orthogonal projections but some problem-induced degeneracies as well with the aid of perspective projections.

Gómez et al. [GRT01] consider several nondegeneracy assumptions that are typically made in the literature, propose efficient algorithms for performing the suitable rotations that remove these degeneracies, analyze their complexity in the real RAM model of computation and, for some of these problems, give lower bounds on their worst-case complexity. The assumptions considered in [GRT01] are summarized in Tables 51.5.1 and 51.5.2 ($\lambda(\cdot)$ is nearly linear; cf. Chapter 47.4).

PERSPECTIVE PROJECTIONS AND INTRINSIC DEGENERACIES

Intrinsic degeneracies cannot be removed by rotations of the input. If a set of points S in 3D contains three collinear points then so does every orthogonal projection of S . This is where *perspective* projections come to the rescue. However, not all

TABLE 51.5.1 Removing degeneracies: Point sets.

No face of polyhedron vertical	$\Theta(n)$	$\Theta(n)$	$O(n^2)$ time, space $O(n \lambda_6(n) \log n)$ time, $O(n)$ space

intrinsic degeneracies can be removed with perspective projections. Intrinsic degeneracies that can be removed via perspective projections are called *quasi-intrinsic degeneracies* [HS97, GHS⁺01].

Gómez et al. [GHS⁺01] consider computing nondegenerate *perspective* projections of sets of points and line segments in 3D space. For sets of points they give algorithms for computing perspective projections such that (1) all points have distinct x -coordinates, (2) all points have both distinct x - and y -coordinates, (3) no three points in the projection are collinear, and (4) no four points in the projection are cocircular. For sets of line segments they present an algorithm for computing

a perspective projection with no two segments parallel. All their algorithms have time and space complexities bounded by low degree polynomials.

FINITE-RESOLUTION MODELS OF VIEW DEGENERACY

View degeneracy is a central concern in robotics where a robot must navigate and recognize objects based on views of the scene at hand [DPR92a, DPR92b]. In the idealized world assumed in the previous sections, degenerate views are not much of a problem if a viewpoint is chosen at random, since almost all projections are not degenerate. On the other hand, real world digital cameras have a finite resolution and therefore view degeneracy can no longer be ignored [KF87].

OPEN PROBLEMS

A more practical approach would give some thickness to the objects, i.e., consider the points as little balls and the edges of the polyhedra as thin cylinders, and then to redesign the algorithms accordingly. This may turn out to be rather expensive. In practice it may be much more efficient to perform a half-dozen *random* rotations to obtain a nice projection. After all, for many problems in the idealized infinite precision model, a single random rotation yields a nice projection with probability one. Computing optimal projections on the other hand is another matter. Here approximate algorithms may yield efficient solutions that are near-optimal, but these are open problems.

51.6 POLYGON DECOMPOSITION

COVERS AND PARTITIONS

A typical strategy for recognizing a shape as a particular member of a library of shapes is to decompose the shape into “primitive” parts, and then compare these with the library entries via a similarity function. This has led to considerable effort on decomposing shapes and, in particular, polygons into simpler components.

GLOSSARY

Let P be a polygon.

Cover of P : A collection of sets $S_1, \dots, S_k$ such that $S_1 \cup \dots \cup S_k = P$.

Partition of P : A collection of sets $S_1, \dots, S_k$ with pairwise disjoint interiors such that $S_1 \cup \dots \cup S_k = P$.

Diagonal of P : A segment s between two vertices x and y of P such that $s \subseteq P$ and $s \cap P = \{x, y\}$.

Steiner point of P : A point of P that is not a vertex.

Polygon with holes: A multiply connected region bounded by polygonal chains.

Decompositions may be classified along two primary dimensions: covers or parti-

tions, and with or without Steiner points. A cover permits a polygon in the shape of the symbol ‘+’ to be represented as the union of two rectangles, whereas a minimal partition requires three rectangles, a less natural decomposition. Decompositions without Steiner points use diagonals, and are in general easier to find but less parsimonious. For each of the four types of decomposition, different primitives may be considered. The ones most commonly used are rectangles, convex polygons, star-shaped polygons, spiral polygons, and trapezoids (see [Section 23.1](#) for definitions). Restrictions on the shape of the piece being decomposed are often available; for example, orthogonal polygons for rectangle covers. Lastly, the distinction between simple polygons and polygons with holes is often relevant for algorithms.

Finding minimum covers of polygons is NP-hard in nearly every instance explored. Minimum partitions of polygons are somewhat easier, in that polynomial algorithms exist for convex pieces with Steiner points, star-shaped pieces without Steiner points, and rectangles for orthogonal polygons. See [Section 23.2](#) for specific results.

Shape decomposition has a wide variety of applications, including character recognition (spiral and convex pieces), VLSI design (rectangles), and electron-beam lithography (trapezoids) [AAI86].

OPEN PROBLEM

Finding approximation algorithms with proven bounds with respect to optimality remains largely unexplored for most decomposition problems. There are, however, many heuristic algorithms.

SUM-DIFFERENCE DECOMPOSITIONS

Permitting set subtraction as well as set union leads to natural shape decompositions. This is evident from the field of Constructive Solid Geometry, where shapes are described with CSG trees whose nodes are union or difference operators, and whose leaves are primitive shapes (Section 47.1). Batchelor developed a similar concept for shape description, the *convex deficiency tree* [Bat80]. For a shape P , the root of this tree is its hull $\text{conv}(P)$, the children of the root the hulls of the convex deficiencies $\text{conv}(P) \setminus P$, and so on [O’R98, p. 98].

Chazelle suggested [Cha79] representing a shape by the difference of convex sets: $A \setminus B$ where A and B are unions of convex polygons. It has been established that finding the minimum number of convex pieces in such a sum-difference decomposition of a multiply connected polygonal region is NP-hard [Con90].

TEXT-BLOCK ISOLATION

The text-block isolation problem consists of extracting blocks of text (paragraphs) from a digitized document. By finding the enclosing rectangles around each connected component (character) and around the entire set of characters we obtain a well structured geometric object, namely, a rectangle with n rectangular “holes.” This problem is ideally suited to a computational geometric treatment. Here we mention an elegant method that analyzes the empty (white) spaces in the document [BJF90]. This approach enumerates all maximal white rectangles implied by

the black rectangles. A white rectangle is called maximal if it cannot be enlarged while remaining outside the black rectangles. Their enumeration algorithm takes $O(n \log n + m)$ time, where m is the number of maximal rectangles generated in the search. In the worst case $m = O(n^2)$. However, using a clever heuristic to exploit some properties of layouts they obtain $O(n)$ expected time.

51.7 NEAREST-NEIGHBOR DECISION RULES

GLOSSARY

Nearest-neighbor decision rule: Classifies a feature vector with the closest sample point in parameter space.

In the typical nonparametric classification problem (see Devroye, Györfy and Lugosi [DGL96]) we have available a set of d measurements or observations (also called a feature vector) taken from each member of a data set of n objects (patterns) denoted by $\{X, Y\} = \{(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)\}$, where X_i and Y_i denote, respectively, the feature vector on the i th object and the class label of that object. One of the most attractive decision procedures is the nearest-neighbor rule (1-*NN*-rule) [FH51]. Let Z be a new pattern (feature vector) to be classified and let X_j be the feature vector in $\{X, Y\} = \{(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)\}$ closest to Z . The nearest neighbor decision rule classifies the unknown pattern Z into class Y_j . In the 1960s and 1970s many pattern recognition practitioners resisted using the 1-*NN*-rule on the grounds of the mistaken assumptions that (1) all the data $\{X, Y\}$ must be stored in order to implement such a rule, (2) to determine Y_j , distances must be computed between the unknown vector Z and all the members of $\{X, Y\}$, and (3) such a rule is difficult to implement in parallel using a neural network. Computational geometry research in the 1980s and 1990s along with faster and cheaper hardware has made the *NN*-rules a practical reality [Tou02].

MINIMAL-SIZE TRAINING-SET CONSISTENT SUBSETS

A question that has received a lot of attention in the past fifty years concerns the problem of reducing the number of patterns in the training set $\{X, Y\}$ without degrading the performance of the decision rule. In 1968 Hart was the first to propose an algorithm for reducing the size of the stored data for the nearest neighbor decision rule [Har68]. Hart defined a *consistent* subset of the data as one that classified the entire set correctly with the nearest neighbor rule. He then proposed an $O(n^3)$ time algorithm that he called *CNN* (Condensed Nearest Neighbor) for selecting a consistent subset by heuristically searching for data that were near the decision boundary. However, the method does not in general yield a minimal-size consistent subset.

The first researchers to deal with computing a *minimal-size* consistent subset were Ritter et al. [RWLI75]. They proposed a procedure they called a *selective* nearest neighbor rule (*SNN*) to obtain a minimal-size consistent subset of $\{X, Y\}$, call it S , with one additional property that Hart's *CNN* does not have. Any

consistent subset C obtained by CNN has the property that every element of $\{X, Y\}$ is nearer to an element in C of the same class than to any element in C of a different class. On the other hand, the consistent subset S of Ritter et al. [RWLI75] has the additional property that every element of $\{X, Y\}$ is nearer to an element in S of the same class than to any element, in the *complete* set, $\{X, Y\}$ of a different class. This additional property of SNN tends to keep points closer to the decision boundary than does CNN , and allows Ritter et al. [RWLI75] to compute the selected subset S without testing all possible subsets of $\{X, Y\}$. Nevertheless, their algorithm still runs in time exponential in n (Wilfong [Wil91]) in the worst case. However, Wilson and Martinez [WM97] and Wilson [WM00] claim that the average running time of SNN is $O(n^3)$. In 1994 Dasarathy [Das94] proposed a complicated algorithm intended to compute a *minimal-size* consistent subset but did not provide a proof of optimality. However, counter-examples to this claim were found by Kuncheva and Bezdek [KB98], Cerverón and Fuertes [CF98] and Zhang and Sun [ZS02]. Wilfong [Wil91] showed in 1991 that the problem of finding the smallest size training-set consistent subset is NP-complete when there are three or more classes. The problem is still open for two classes. Furthermore, he showed that even for only two classes the problem of finding the smallest size consistent *selective* subset (Ritter et al. [RWLI75]) is also NP-complete.

TRAINING-DATA EDITING RULES

Methods have been developed [TBP85] to edit (delete) “redundant” members of $\{X, Y\}$ in order to obtain a subset of $\{X, Y\}$ that implements exactly the same decision boundary as would be obtained using all of $\{X, Y\}$. Such methods depend on the computation of Voronoi diagrams and of other proximity graphs that are subgraphs of the Delaunay triangulation, such as the Gabriel graph. Furthermore, the fraction of data discarded in such a method is a useful measure of the resulting reliability of the rule. If few vectors are discarded the feature space is relatively empty and more training data are needed. During the past twenty years proximity graphs have proven to be very useful both in theory and in practice for solving many of the problems encountered with NN -rules. A description of many of these graphs along with related computational geometry problems can be found in [Tou02].

NEAREST-NEIGHBOR SEARCHING

Another important issue in the implementation of nearest-neighbor decision rules, whether editing has or has not been performed, concerns the efficient search for the nearest neighbor of an unknown vector in order to classify it. Various methods exist for computing a nearest neighbor without computing distances to all the candidates. The problem is in general quite difficult when the dimension is high, which it is for most pattern recognition tasks. Simple brute-force search yields $O(dn)$ query time. To improve upon this, one builds a data structure for the points that supports more efficient queries, often at the expense of space for the data structure. For a set of n points in $\mathbb{R}^d$, one could construct a Voronoi diagram for the points of size $O(n^{\lceil d/2 \rceil})$ (Chapter 22), and respond to a query in $O(\log n)$ time. But the exponential space makes this impractical beyond $d \leq 3$. Range searching (Chapter 31) supports structures with linear space and achieving slightly sublinear

time. But all constants are exponential in d . This has led to intensive work on approximate nearest-neighbor search, where one seeks a point within $(1 + \epsilon)$ of the distance to the true nearest neighbor. An example of an important early milestone along these lines is an algorithm by Arya et al. [AMN⁺98], which constructs a data structure of size $O(dn)$ that can report approximate nearest neighbors in $O(c \log n)$ time, with $c = O(d(1 + d/\epsilon)^d)$. The algorithm traverses down a balanced box-tree decomposition (BDD) of $O(\log n)$ height and stops when the approximation criterion is satisfied. The query time is logarithmic in n but still the constant is exponential in d . The many advances beyond this and similar algorithms with exponential query time or space requirements are described in [Chapter 39](#).

ESTIMATION OF MISCLASSIFICATION

A very important problem in pattern recognition is the estimation of the performance of a decision rule [McL92]. Many geometric problems occur here also, for which computational geometry offers elegant and efficient solutions. For example, a good method of estimating the performance of the NN-rule is to delete each member of $\{X, Y\} = \{(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)\}$ in turn and classify it with the remaining set. Geometrically this problem reduces to computing for a given set of points in d -space the nearest neighbor of each (the *all-nearest neighbors problem*). Vaidya [Vai89] gives an $O(n \log n)$ time algorithm to solve this problem.

52 GRAPH DRAWING

Roberto Tamassia, Giuseppe Liotta

INTRODUCTION

Graph drawing addresses the problem of constructing geometric representations of graphs, and has important applications to key computer technologies such as software engineering, database systems, visual interfaces, and computer-aided design. Research on graph drawing has been conducted within several diverse areas, including discrete mathematics (topological graph theory, geometric graph theory, order theory), algorithmics (graph algorithms, data structures, computational geometry, VLSI), and human-computer interaction (visual languages, graphical user interfaces, software visualization). This chapter overviews aspects of graph drawing that are especially relevant to computational geometry. Basic definitions on drawings and their properties are given in Section 52.1. Bounds on geometric and topological properties of drawings (e.g., area and crossings) are presented in Section 52.2. Section 52.3 deals with the time complexity of fundamental graph drawing problems. An example of a drawing algorithm is given in Section 52.4. General techniques for drawing graphs are surveyed in Section 52.5. Section 52.6 covers selected topics that have recently attracted considerable research interest.

52.1 DRAWINGS AND THEIR PROPERTIES

TYPES OF GRAPHS

First, we define some terminology on graphs pertinent to graph drawing. Throughout this chapter let n and m be the number of graph vertices and edges respectively, and d the maximum vertex degree (i.e., number of incident edges).

GLOSSARY

Degree- k graph: Graph with maximum degree $d \leq k$.

Digraph: Directed graph, i.e., graph with directed edges (drawn as arrows).

Acyclic digraph: Without directed cycles.

Transitive edge: Edge (u, v) of a digraph is transitive if there is a directed path from u to v not containing edge (u, v) .

Reduced digraph: Without transitive edges.

Source: Vertex of a digraph without incoming edges.

Sink: Vertex of a digraph without outgoing edges.

st -digraph: Acyclic digraph with exactly one source and one sink, which are joined by an edge (also called **bipolar digraph**).

Connected graph: Any two vertices are joined by a path.

Biconnected graph: Any two vertices are joined by two vertex-disjoint paths.

Triconnected graph: Any two vertices are joined by three (pairwise) vertex-disjoint paths.

Tree: Connected graph without cycles.

Rooted tree: Directed tree with a distinguished vertex, the **root**, such that each vertex lies on a directed path to the root.

Binary tree: Rooted tree where each vertex has at most two incoming edges.

Layered (di)graph: The vertices are partitioned into sets, called layers. A rooted tree can be viewed as a layered digraph where the layers are sets of vertices at the same distance from the root.

k-layered (di)graph: Layered (di)graph with k layers.

TYPES OF DRAWINGS

In a drawing of a graph, vertices are represented by points (or by geometric figures such as circles or rectangles) and edges are represented by curves such that any two edges intersect at most in a finite number of points. Except for Section 52.6, which covers 3D drawings, we consider drawings in the plane.

GLOSSARY

Polyline drawing: Each edge is a polygonal chain (Figure 52.1.1(a)).

Straight-line drawing: Each edge is a straight-line segment (Figure 52.1.1(b)).

Orthogonal drawing: Each edge is a chain of horizontal and vertical segments (Figure 52.1.1(c)).

Bend: In a polyline drawing, point where two segments belonging to the same edge meet (Figure 52.1.1(a)).

Orthogonal Representation: Representation of orthogonal drawing in terms of bends along each edge and angles around each vertex.

Crossing: Point where two edges intersect (Figure 52.1.1(b)).

Grid drawing: Polyline drawing such that vertices, crossings, and bends have integer coordinates.

Planar drawing: No two edges cross (see Figure 52.1.1(d)).

Planar (di)graph: Admits a planar drawing.

Embedded (di)graph: Planar (di)graph with a prespecified topological embedding (i.e., set of faces), which must be preserved in the drawing.

Upward drawing: Drawing of a digraph where each edge is monotonically non-decreasing in the vertical direction (see Figure 52.1.1(d)).

Upward planar digraph: Admits an upward planar drawing.

Layered drawing: Drawing of a layered graph such that vertices in the same layer lie on the same horizontal line (also called **hierarchical drawing**).

Face: A region of the plane defined by a planar drawing, where the unbounded region is called the **external face**.

Convex drawing: Planar straight-line drawing such that the boundary of each face is a convex polygon.

Visibility drawing: Drawing of a graph based on a geometric visibility relation, e.g., the vertices might be drawn as horizontal segments, and the edges associated with vertically visible segments.

Proximity drawing: Drawing of a graph based on a geometric proximity relation, e.g., a tree is drawn as the Euclidean minimum spanning tree of a set of points.

Dominance drawing: Upward drawing of an acyclic digraph such that there exists a directed path from vertex u to vertex v if and only if $x(u) \leq x(v)$ and $y(u) \leq y(v)$, where $x(\cdot)$ and $y(\cdot)$ denote the coordinates of a vertex.

hv-drawing: Upward orthogonal straight-line drawing of a binary tree such that the drawings of the subtrees of each node are separated by a horizontal or vertical line.

FIGURE 52.1.1

Types of drawings: (a) *polyline drawing of $K_{3,3}$* ; (b) *straight-line drawing of $K_{3,3}$* ; (c) *orthogonal drawing of $K_{3,3}$* ; (d) *planar upward drawing of an acyclic digraph*.

Straight-line and orthogonal drawings are special cases of polyline drawings. Polylines provide great flexibility since they can approximate drawings with curved edges. However, edges with more than two or three bends may be difficult to “follow” for the eye. Also, a system that supports editing of polyline drawings is more complicated than one limited to straight-line drawings. Hence, depending on the application, polyline or straight-line drawings may be preferred. If vertices are represented by points, orthogonal drawings exist only for graphs of maximum vertex degree 4.

PROPERTIES OF DRAWINGS

GLOSSARY

Crossings χ : Total number of crossings in a drawing.

Area: Area of the convex hull of the drawing.

Total edge length: Sum of the lengths of the edges.

Maximum edge length: Maximum length of an edge.

Total number of bends: Total number of bends on the edges of a polyline drawing.

Maximum number of bends: Maximum number of bends on an edge of a polyline drawing.

Angular resolution ρ : Smallest angle formed by two edges, or segments of edges, incident on the same vertex or bend, in a polyline drawing.

Aspect ratio: Ratio of the longest to the shortest side of the smallest rectangle with horizontal and vertical sides covering the drawing.

There are infinitely many drawings for a graph. In drawing a graph, we would like to take into account a variety of properties. For example, planarity and the display of symmetries are highly desirable in visualization applications. Also, it is customary to display trees and acyclic digraphs with upward drawings. In general, to avoid wasting valuable space on a page or a computer screen, it is important to keep the area of the drawing small. In this scenario, many graph drawing problems can be formalized as multi-objective optimization problems (e.g., construct a drawing with minimum area and minimum number of crossings), so that tradeoffs are inherent in solving them. Typically, it is desirable to maximize the angular resolution and to minimize the other measures.

The following examples illustrate two typical tradeoffs in graph drawing problems. Figure 52.1.2(a–b) shows two drawings of K_4 , the complete graph on four vertices. The drawing of part (a) is planar, while the drawing of part (b) “maximizes symmetries.” It can be shown that no drawing of K_4 is optimal with respect to both criteria, i.e., the maximum number of symmetries cannot be achieved by a planar drawing. Figure 52.1.2(c–d), shows two drawing of the same acyclic digraph G . The drawing of part (c) is upward, while the drawing of part (d) is planar. It can be shown that there is no drawing of G which is both planar and upward.

FIGURE 52.1.2

(a–b) Tradeoff between planarity and symmetry in drawing K_4 . (c–d) Tradeoff between planarity and upwardness in drawing an acyclic digraph G .

52.2 BOUNDS ON DRAWING PROPERTIES

For various classes of graphs and drawing types, many universal/existential upper and lower bounds for specific drawing properties have been discovered. Such bounds typically exhibit tradeoffs between drawing properties. A universal bound applies to all the graphs of a given class. An existential bound applies to infinitely many graphs of the class. Whenever we give bounds on the area or edge length, we assume that the drawing is constrained by some resolution rule that prevents it from being reduced by an arbitrary scaling (e.g., requiring a grid drawing, or stipulating a minimum unit distance between any two vertices).

BOUNDS ON THE AREA

Table 52.2.1 summarizes selected universal upper bounds and existential lower bounds on the area of drawings of graphs. In the table, a is an arbitrary constant $0 \leq a < 1$, and b and c are fixed constants $1 < b < c$, and ϵ for an arbitrary positive

constant. The abbreviations “PSL” and “PSLg” are used for “planar straight-line” “planar straight-line grid,” respectively. In general, the effect of bends on the area

TABLE 52.2.1 Universal upper and existential lower bounds on area.

	CLASS OF GRAPHS	DRAWING TYPE	AREA	
			$\Omega(n)$	$O(n \log n)$
1	Rooted tree	upward PSLg	$\Omega(n)$	$O(n \log n)$
2	Rooted tree	strictly upward PSLg	$\Omega(n \log n)$	$O(n \log n)$
3	deg- $O(n^a)$ rooted tree	upward planar polyline grid	$\Omega(n)$	$O(n)$
4	Binary tree	upward planar orthog grid	$\Omega(n \log \log n)$	$O(n \log \log n)$
5	Binary tree	strictly upward order preserving PSLg	$\Omega(n)$	$O(n^{1+\epsilon})$
6	Fibonacci tree	strictly upward order preserving PSLg	$\Omega(n)$	$O(n)$
7	AVL tree	strictly upward order preserving PSLg	$\Omega(n)$	$O(n)$
8	Balanced tree	strictly upward order preserving PSLg	$\Omega(n)$	$O(n)$
9	Binary tree	PSLg	$\Omega(n)$	$O(n)$
10	Tree	PSLg	$\Omega(n)$	$O(n \log n)$
11	deg- $O(n^a)$ tree	planar polyline grid	$\Omega(n)$	$O(n)$
12	deg-4 tree	planar orthog grid	$\Omega(n)$	$O(n)$
13	Planar graph	planar polyline grid	$\Omega(n^2)$	$O(n^2)$
14	Planar graph	PSL	$\Omega(c^n)$	
15	Planar graph	PSLg	$\Omega(n^2)$	$O(n^2)$
16	Triconn planar graph	PSL convex grid	$\Omega(n^2)$	$O(n^2)$
17	Planar graph	planar orthog grid	$\Omega(n^2)$	$O(n^2)$
18	Planar degree-4 graph	orthog grid	$\Omega(n \log n)$	$O(n \log^2 n)$
19	Upward planar digraph	upward PSLg	$\Omega(b^n)$	$O(c^n)$
20	Reduced planar <i>st</i> -digraph	upward PSLg dominance	$\Omega(n^2)$	$O(n^2)$
21	Upward planar digraph	upward planar grid polyline	$\Omega(n^2)$	$O(n^2)$
22	General graph	polyline grid	$\Omega(n + \chi)$	$O((n + \chi)^2)$

requirement is dual. On the one hand, bends occupy space and hence negatively affect the area. On the other hand, bends may help in routing edges without using additional space. The following comments apply to Table 52.2.1, where specific rows of the table are indicated within parentheses. Linear or almost-linear bounds on the area can be achieved for trees (1–12). See Table 52.2.4 for tradeoffs between area and aspect ratio in drawings of trees. Planar graphs admit planar drawings with quadratic area (13–18). However, the area requirement of planar straight-line drawings may be exponential if high angular resolution is also desired (14). Almost linear area instead can be achieved in nonplanar drawings of planar graphs (18), which have applications to VLSI circuits. Upward planar drawings provide an interesting tradeoff between area and the total number of bends (19–21). Indeed, unless the digraph is reduced (20), the area can become exponential if a straight-line drawing is required (19). A quadratic area bound is achieved only at the expense of a linear number of bends (21).

BOUNDS ON THE ANGULAR RESOLUTION

Table 52.2.2 summarizes selected universal lower bounds and existential upper bounds on the angular resolution of drawings of graphs. Here c is a fixed constant with $c > 1$.

TABLE 52.2.2 Universal lower and existential upper bounds on angular resolution.

CLASS OF GRAPHS	DRAWING TYPE	ANGULAR RESOLUTION	
General graph	straight-line	$\Omega(\frac{1}{d^2})$	$O(\frac{\log d}{d^2})$
Planar graph	straight-line	$\Omega(\frac{1}{d})$	$O(\frac{1}{d})$
Planar graph	planar straight-line	$\Omega(\frac{1}{cd})$	$O(\sqrt{\frac{\log d}{d^3}})$

BOUNDS ON THE NUMBER OF BENDS

Table 52.2.3 summarizes selected universal upper bounds and existential lower bounds on the total and maximum number of bends in orthogonal drawings. Some bounds are stated for $n \geq 5$ or $n \geq 7$ because the maximum number of bends is at least 2 for K_4 and at least 3 for the skeleton graph of an octahedron, in any planar orthogonal drawing.

TABLE 52.2.3 Orthogonal drawings: universal upper and existential lower bounds on the number of bends. Notes: † $n \geq 7$; ‡ $n \geq 5$.

CLASS OF GRAPHS	DRAWING TYPE	TOTAL # BENDS		MAX # BENDS	
deg-4 †	orthog	$\geq n$	$\leq 2n + 2$	≥ 2	≤ 2
Planar deg-4 †	orthog planar	$\geq 2n - 2$	$\leq 2n + 2$	≥ 2	≤ 2
Embedded deg-4	orthog planar	$\geq 2n - 2$	$\leq \frac{12}{5}n + 2$	≥ 3	≤ 3
Biconn embedded deg-4	orthog planar	$\geq 2n - 2$	$\leq 2n + 2$	≥ 3	≤ 3
Triconn embedded deg-4	orthog planar	$\geq \frac{4}{3}(n - 1) + 2$	$\leq \frac{3}{2}n + 4$	≥ 2	≤ 2
Embedded deg-3 ‡	orthog planar	$\geq \frac{1}{2}n + 1$	$\leq \frac{1}{2}n + 1$	≥ 1	≤ 1

TRADEOFF BETWEEN AREA AND ASPECT RATIO

The ability to construct area-efficient drawings is essential in practical visualization applications, where screen space is at a premium. However, achieving small area is not enough, e.g., a drawing with high aspect ratio may not be conveniently placed on a workstation screen, even if it has modest area. Hence, it is important to keep the aspect ratio small. Ideally, one would like to obtain small area for any given aspect ratio in a wide range. This would provide graphical user interfaces with the flexibility of fitting drawings into arbitrarily shaped windows. A variety of tradeoffs for the area and aspect ratio arise even when drawing graphs with a simple structure, such as trees. Table 52.2.4 summarizes selected universal bounds that can be simultaneously achieved on the area and the aspect ratio of various types of drawings of trees. In the table, a is an arbitrary constant with $0 \leq a < 1$ and the abbreviations “PSLog” is used for “planar straight-line orthogonal grid,” that is, a PLSg with edges either horizontal or vertical segments. Only for a few

cases there exist algorithms that guarantee efficient area performance and that can accept any user-specified aspect ratio in a given range. For such cases the aspect ratio in Table 52.2.4 is given as an interval.

TABLE 52.2.4 Trees: Universal upper bounds simultaneously achievable for area and aspect ratio.

CLASS OF GRAPHS	DRAWING TYPE	AREA	ASPECT RATIO
Rooted tree	upward PSL layered grid	$O(n^2)$	$O(1)$
Rooted tree	upward PSLg	$O(n \log \log n)$	$O(n \log \log n / \log^2 n)$
Rooted deg- $O(1)$ tree	upward planar polyline grid	$O(n)$	$O(n^a)$
Binary tree	upward planar orthog grid	$O(n \log \log n)$	$O(n \log \log n / \log^2 n)$
Binary tree	PSLg	$O(n)$	$[O(1), O(n^a)]$
Binary tree	PSLog	$O(n \log \log n)$	$[O(1), O(n \log \log n / \log^2 n)]$
Binary tree	upward PSLog	$O(n \log n)$	$O(1)$
deg-4 tree	orthog grid	$O(n)$	$O(1)$
deg-4 tree	orthog grid, leaves on hull	$O(n \log n)$	$O(1)$

While upward planar straight-line drawings are the most natural way of visualizing rooted trees, the existing drawing techniques are unsatisfactory with respect to either the area requirement or the aspect ratio. The situation is similar for orthogonal drawings. Regarding polyline drawings, linear area can be achieved with a prescribed aspect ratio. However, experiments show that this is done at the expense of a somehow aesthetically unappealing drawing. For nonupward drawings of trees, linear area and optimal aspect ratio are possible for planar orthogonal drawings, and a small (logarithmic) amount of extra area is needed if the leaves are constrained to be on the convex hull of the drawing (e.g., pins on the boundary of a VLSI circuit). However, the nonupward drawing methods do not seem to yield aesthetically pleasing drawings, and are suited more for VLSI layout than for visualization applications.

TRADEOFF BETWEEN AREA AND ANGULAR RESOLUTION

Table 52.2.5 summarizes selected universal bounds that can be simultaneously achieved on the area and the angular resolution of drawings of graphs. Here b and c are fixed constants, $b > 1$ and $c > 1$. Universal lower bounds on the angular resolution exist that depend only on the degree of the graph. Also, substantially better bounds can be achieved by drawing a planar graph with bends or in a non-planar way.

TABLE 52.2.5 Universal upper bounds for area and lower bounds for angular resolution, simultaneously achievable.

CLASS OF GRAPHS	DRAWING TYPE	AREA	ANGULAR RESOLUTION
Planar graph	straight-line	$O(d^6 n)$	$\Omega(\frac{1}{d^2})$
Planar graph	straight-line	$O(d^3 n)$	$\Omega(\frac{1}{d})$
Planar graph	planar straight-line grid	$O(n^2)$	$\Omega(\frac{1}{n^2})$
Planar graph	planar straight-line	$O(b^n)$	$\Omega(\frac{1}{c^d})$
Planar graph	planar polyline grid	$O(n^2)$	$\Omega(\frac{1}{d})$

OPEN PROBLEMS

1. Determine the area requirement of (upward) planar straight-line drawings of trees. There is currently an $O(\log n)$ gap between the known upper and lower bounds (Table 52.2.1).
2. Determine the area requirement of strictly upward planar order preserving straight-line drawings of binary trees (Table 52.2.1).
3. Determine the area requirement of orthogonal (or, more generally, polyline) nonplanar drawings of planar graphs. There is currently an $O(\log n)$ gap between the known upper and lower bounds (Table 52.2.1).
4. Close the wide gap between the $\Omega(\frac{1}{d^2})$ universal lower bound and the $O(\frac{\log d}{d^2})$ existential upper bound on the angular resolution of straight-line drawings of general graphs (Table 52.2.2).
5. Close the gap between the $\Omega(\frac{1}{c^d})$ universal lower bound and the $O(\sqrt{\frac{\log d}{d^3}})$ existential upper bound on the angular resolution of planar straight-line drawings of planar graphs (Table 52.2.2).
6. Determine the best possible aspect ratio and area that can be simultaneously achieved for (upward) planar straight-line and orthogonal drawings of trees (Table 52.2.4).

52.3 COMPLEXITY OF GRAPH DRAWING PROBLEMS

Tables 52.3.1–52.3.3 summarize selected results on the time complexity of some fundamental graph drawing problems.

It is interesting that apparently similar problems exhibit very different time complexities. For example, while planarity testing can be done in linear time, upward planarity testing is NP-hard. Note that, as illustrated in Figure 52.1.2(c–d), planarity and acyclicity are necessary but not sufficient conditions for upward planarity. While many efficient algorithms exist for constructing drawings of trees and planar graphs with good universal area bounds, exact area minimization for most types of drawings is NP-hard, even for trees.

TABLE 52.3.1 Time complexity of some fundamental graph drawing problems:
general graphs and digraphs.

CLASS OF GRAPHS	PROBLEM	TIME COMPLEXITY	
General graph	minimize crossings	NP-hard	
2-layered graph	minimize crossings in layered drawing with preassigned order on one layer	NP-hard	
General graph	maximum planar subgraph	NP-hard	
General graph	planarity testing and computing a planar embedding	$\Omega(n)$	$O(n)$
General graph	maximal planar subgraph	$\Omega(n + m)$	$O(n + m)$
General digraph	upward planarity testing	NP-hard	
Embedded digraph	upward planarity testing	$\Omega(n)$	$O(n^2)$
Single-source digraph	upward planarity testing	$\Omega(n)$	$O(n)$
General graph	draw as the intersection graph of a set of unit diameter disks in the plane	NP-hard	

OPEN PROBLEMS

1. Reduce the time complexity of upward planarity testing for embedded digraphs (currently $O(n^2)$), or prove a superlinear lower bound (Table 52.3.1).
2. Reduce the time complexity of bend minimization for planar orthogonal drawings of embedded graphs (currently $O(n^{7/4} \log n)$), or prove a superlinear lower bound (Table 52.3.2).
3. Reduce the time complexity of bend minimization for planar orthogonal drawings of degree-3 graphs (Table 52.3.2).

52.4 EXAMPLE OF A GRAPH DRAWING ALGORITHM

In this section we outline the algorithm in [Tam87] for computing, for an embedded degree-4 graph G , a planar orthogonal grid drawing with minimum number of bends and using $O(n^2)$ area (see Table 52.3.2). This algorithm is the core of a practical drawing algorithm for general graphs (see Section 52.5 and Figure 52.4.1(d)). The algorithm consists of two main phases:

1. Computation of an orthogonal representation for G , where only the bends and the angles of the orthogonal drawing are defined.
2. Assignment of integer lengths to the segments of the orthogonal representation.

Phase 1 uses a transformation into a network flow problem (Figure 52.4.1(a–c)), where each unit of flow is associated with a right angle in the orthogonal drawing. Hence, angles are viewed as a commodity that is produced by the vertices, transported across faces by the edges through their bends, and eventually consumed by

TABLE 52.3.2 Time complexity of some fundamental graph drawing problems: Planar graphs and digraphs.

CLASS OF GRAPHS	PROBLEM	TIME COMPLEXITY	
Planar graph	planar straight-line drawing with prescribed edge lengths	NP-hard	
Planar graph	planar straight-line drawing with maximum angular resolution	NP-hard	
Embedded graph	test the existence of a planar straight-line drawing with prescribed angles between pairs of consecutive edges incident on a vertex	NP-hard	
Maximal planar graph	test the existence of a planar straight-line drawing with prescribed angles between pairs of consecutive edges incident on a vertex	$\Omega(n)$	$O(n)$
Planar graph	planar straight-line grid drawing with $O(n^2)$ area and $O(1/n^2)$ angular resolution	$\Omega(n)$	$O(n)$
Planar graph	planar polyline drawing with $O(n^2)$ area, $O(n)$ bends, and $O(1/d)$ angular resolutions	$\Omega(n)$	$O(n)$
Triconn planar graph	planar straight-line convex grid drawing with $O(n^2)$ area and $O(1/n^2)$ angular resolution	$\Omega(n)$	$O(n)$
Triconn planar graph	planar straight-line strictly convex drawing	$\Omega(n)$	$O(n)$
Reduced planar <i>st</i> -digraph	upward planar grid straight-line dominance drawing with minimum area	$\Omega(n)$	$O(n)$
Upward planar digraph	upward planar polyline grid drawing with $O(n^2)$ area and $O(n)$ bends	$\Omega(n)$	$O(n)$
Planar deg-4 graph	planar orthogonal grid drawing with minimum number of bends	NP-hard	
Planar deg-3 graph	planar orthogonal grid drawing with minimum number of bends and $O(n^2)$ area	$\Omega(n)$	$O(n^5 \log n)$
Embedded deg-4 graph	planar orthogonal grid drawing with minimum number of bends and $O(n^2)$ area	$\Omega(n)$	$O(n^{7/4} \log n)$
Planar deg-4 graph	planar orthogonal grid drawing with $O(n^2)$ area and $O(n)$ bends	$\Omega(n)$	$O(n)$
Planar orthog rep	planar orthogonal grid drawing with minimum area	NP-hard	

the faces. From the embedded graph G we construct a flow network N as follows. The nodes of network N are the vertices and faces of G . Let $\deg(f)$ denote the number of edges of the circuit bounding face f . Each vertex v supplies $\sigma(v) = 4$ units of flow, and each face f consumes $\tau(f)$ units of flow, where

$$\tau(f) = \begin{cases} 2 \deg(f) - 4 & \text{if } f \text{ is an internal face} \\ 2 \deg(f) + 4 & \text{if } f \text{ is the external face} \end{cases}.$$

By Euler's formula, $\sum_v \sigma(v) = \sum_f \tau(f)$, i.e., the total supply is equal to the total consumption.

TABLE 52.3.3 Time complexity of some fundamental graph drawing problems: trees.

CLASS OF GRAPHS	PROBLEM	TIME COMPLEXITY	
Tree	draw as the Euclidean minimum spanning tree of a set of points in the plane	NP-hard	
degree-4 tree	minimize area in planar orthogonal grid drawing	NP-hard	
degree-4 tree	minimize total/maximum edge length in planar orthogonal grid drawing	NP-hard	
Rooted tree	minimize area in a planar straight-line upward layered grid drawing that displays symmetries and isomorphisms of subtrees	NP-hard	
Rooted tree	minimize area in a planar straight-line upward layered drawing that displays symmetries and isomorphisms of subtrees	$\Omega(n)$	$O(n^k)$, $k \geq 1$
Binary tree	minimize area in hv-drawing	$\Omega(n)$	$O(n\sqrt{n \log n})$
Rooted tree	planar straight-line upward layered grid drawing with $O(n^2)$ area	$\Omega(n)$	$O(n)$
Rooted tree	planar polyline upward grid drawing with $O(n)$ area	$\Omega(n)$	$O(n)$

Network N has two types of arcs:

- arcs of the type (v, f) , where f is a face incident on vertex v ; the flow in (v, f) represents the angle at vertex v in face f , and has lower bound 1, upper bound 4, and cost 0;
- arcs of the type (f, g) , where face f shares an edge e with face g ; the flow in (f, g) represents the number of bends along edge e with the right angle inside face f , and has lower bound 0, upper bound $+\infty$, and cost 1.

The conservation of flow at the vertices expresses the fact that the sum of the angles around a vertex is equal to 2π . The conservation of flow at the faces expresses the fact that the sum of the angles at the vertices and bends of an internal face is equal to $\pi(p - 2)$, where p is the number of such angles. For the external face, the above sum is equal to $\pi(p + 2)$. It can be shown that every feasible flow ϕ in network N corresponds to an admissible orthogonal representation for graph G , whose number of bends is equal to the cost of flow ϕ . Hence, an orthogonal representation for G with the minimum number of bends can be computed from a minimum-cost flow in G . This flow can be constructed in $O(n^2 \log n)$ time with standard flow-augmentation methods. Phase 2 uses a simple compaction strategy derived from VLSI layout, where the lengths of the horizontal and vertical segments are computed independently after a preliminary refinement of the orthogonal representation that decomposes each face into rectangles. The resulting drawing is shown in [Figure 52.4.1\(d\)](#).

52.5 TECHNIQUES FOR DRAWING GRAPHS

In this section we outline some of the most successful techniques that have been devised for drawing general graphs.

PLANARIZATION

The planarization approach is motivated by the availability of many efficient and well-analyzed drawing algorithms for planar graphs (see [Table 52.3.2](#)). If the graph is nonplanar, it is transformed into a planar graph by means of a preliminary planarization step that replaces each crossing with a fictitious vertex. Finding the minimum number of crossings or a maximum planar subgraph are NP-hard problems. Hence, existing planarization algorithms use heuristics. The best available heuristic for the maximum planar subgraph problem is described in [JM96]. This method has a solid theoretical foundation in polyhedral combinatorics, and achieves good results in practice. A successful drawing algorithm based on the planarization approach and a bend-minimization method [Tam87] is described in [TDB88] ([Figure 52.4.1\(d\)](#) was generated by this algorithm). It has been widely used in software visualization systems.

LAYERING

The layering approach for constructing polyline drawings of directed graphs transforms the digraph into a layered digraph and then constructs a layered drawing. A typical algorithm based on the layering approach consists of the following main steps:

1. Assign each vertex to a layer, with the goal of maximizing the number of edges oriented upward.
2. Insert fictitious vertices along the edges that cross layers, so that each edge in the resulting digraph connects vertices in consecutive layers. (The fictitious vertices will be displayed as bends in the final drawing.)
3. Permute the vertices on each layer with the goal of minimizing crossings.
4. Adjust the positions of the vertices in each layer with the goal of distributing the vertices uniformly and minimizing the number of bends.

Most of the subproblems involved in the various steps are NP-hard, hence heuristics must be used. The layering approach was pioneered by Sugiyama et al. [STT81]. The most notable developments of this technique are due to Gansner et al. [GNV88, GKNV93]. For a survey on heuristics for the layering approach see also the paper by Jünger and Mutzel [JM97].

PHYSICAL SIMULATION

This approach uses a physical model where the vertices and edges of the graph are viewed as objects subject to various forces. Starting from an initial random configuration, the physical system evolves into a final configuration of minimum

energy, which yields the drawing. Rather than solving a system of differential equations, the evolution of the system is usually simulated using numerical methods (e.g., at each step, the forces are computed and corresponding incremental displacements of the vertices are performed). Drawing algorithms based on the physical simulation approach are often able to detect and display symmetries in the graph. However, their running time is typically high. The physical simulation approach was pioneered in [Ead84, KS80]. Sophisticated developments and applications include [DH96, EH00, FR91, GGK01, LMP01]. Related topics include declarative methods for graph drawing and approaches to graph drawing based on graph grammars; see, e.g. [CG95, LE95, Bra95].

52.6 RECENT RESEARCH TRENDS

In this section, we present an overview of selected areas of graph drawing that have recently attracted increasing attention.

THREE-DIMENSIONAL STRAIGHT-LINE DRAWINGS

The increasing demand of visualization algorithms to draw and browse very large networks makes it natural to investigate how much benefit can be obtained from the third dimension to represent the overall structure of a huge graph in a small portion of a virtual 3D environment. While the problem of computing small-sized crossing-free straight-line drawings in the plane has a long tradition, its 3D counterpart has become the subject of much attention only in recent years.

Chrobak, Goodrich, and Tamassia [CGT96] gave an algorithm for constructing 3D convex drawings of triconnected planar graphs with $O(n)$ volume and non-integer coordinates. Cohen, Eades, Lin, and Ruskey [CELR97] showed that every graph admits a straight-line crossing-free 3D drawing on an integer grid of $O(n^3)$ volume, and proved that this is asymptotically optimal. Calamoneri and Sterbini [CS97] showed that all 2-, 3-, and 4-colorable graphs can be drawn in a 3D grid of $O(n^2)$ volume with $O(n)$ aspect ratio and proved a lower bound of $\Omega(n^{1.5})$ on the volume of such graphs. For r -colorable graphs, Pach, Thiele and Tóth [PTT97] showed a bound of $\theta(n^2)$ on the volume. Garg, Tamassia, and Vocca [GTV96] showed that all 4-colorable graphs (and hence all planar graphs) can be drawn in $O(n^{1.5})$ volume and with $O(1)$ aspect ratio by using a grid model without restriction to integer vertex-coordinates.

Felsner, Liotta, and Wismath [FGW01] showed that all outerplanar graphs can be drawn in a restricted integer 3D grid of linear volume consisting of three parallel lines at distance 1 from each other. Dujmović, Morin, and Wood [DMW02] present $O(n \log^2 n)$ volume drawings of graphs with bounded tree-width and $O(n)$ volume for graphs with bounded path-width. Wood [Woo02] shows that also graphs with bounded queue number have 3D straight-line grid drawings of $O(n)$ volume. A result by Dujmović and Wood [DWo03a] shows that linear volume can also be achieved for graphs with bounded tree-width; they show 3D straight-line grid drawings of volume $c \times n$ for these graphs, where c is a constant whose value exponentially depends on the tree-width. Di Giacomo, Liotta, and Wismath [DLW02a, DLW02b] show $4 \times n$ and $32 \times n$ volume for two subclasses of series-parallel graphs. Very

recently Dujmović and Wood [DWo03b] proved that several families of graphs, including planar graphs, admit a 3D straight-line grid drawing of $O(n^{1.5})$ volume.

PROXIMITY DRAWINGS

Recently much attention has been devoted to the study of the combinatorial properties of different types of proximity graphs. In a proximity graph two points are connected by an edge if and only if they are deemed *close* by some proximity measure. It is the measure that determines the type of graphs that result. Examples of proximity graphs include well-known geometric graphs such as minimum spanning trees, Gabriel graphs, minimum weight triangulations, rectangle of influence graphs, visibility graphs, and Delaunay diagrams. See [Section 51.2](#).

Proximity graphs can be regarded as straight-line drawings that satisfy some additional geometric constraints. Thus the problem of analyzing the combinatorial properties of a given type of proximity graph naturally raises the question of the characterization of those graphs admitting the given type of drawing. This, in turn, leads to the investigation of the design of efficient algorithms for computing such a drawing when one exists. These questions are far from being resolved in general, and only partial answers have appeared in the literature so far (see, e.g., [Dil90, LL96, LL02, LLMW98, LM03, LS93, WCY00]). One example is provided by a *minimum-weight drawing* of a planar triangulated graph G : a straight-line drawing Γ of G with the additional property that Γ is a minimum-weight triangulation of the points representing the vertices. If a graph admits a minimum weight drawing, it is called *minimum-weight drawable*; otherwise it is called *minimum-weight forbidden*. Little is known about the problem of constructing a minimum-weight drawing of a planar triangulation. Moreover, it is still not known whether computing a minimum-weight triangulation of a set of points in the plane is an NP-hard problem (see Garey and Johnson [GJ79]).

In [LL96] Lenhart and Liotta show that all maximal outerplanar triangulations are minimum-weight drawable, and gave a linear time (real RAM) algorithm for constructing such a drawing. This naturally leads to investigation of the internal structure of minimum-weight drawable triangulations. In [LL02] Lenhart and Liotta examine the *endoskeleton*—or *skeleton*, for short—of a triangulation: that is, the subgraph induced by the internal vertices of the triangulation. They construct skeletons that cannot appear in any minimum weight drawable triangulation; skeletons that do appear in minimum weight drawable triangulations; and skeletons that guarantee minimum weight drawability. Wang, Chin, and Yang [WCY00] also focus on the minimum weight drawability of triangulations with acyclic skeletons and show examples of triangulations of this type that do not admit a minimum weight drawing.

GRAPH DRAWING CHECKERS

The intrinsic structural complexity of the implementation of geometric algorithms makes the problem of formally proving the correctness of code infeasible in most cases. This has motivated research on *checkers*. A checker is an algorithm that receives as input a geometric structure and a predicate stating a property that should hold for the structure. The task of the checker is to verify whether the

structure satisfies or not the given property. Here, the expectation is that it is often easier to evaluate the quality of the output than the correctness of the software that produces it. Different papers (see, e.g., [DLPT98, MSNS⁺99]) have agreed on the basic features that a “good” checker should have:

Correctness: The checker should be correct beyond any reasonable doubt. (Otherwise, one is faced with checking the checker.)

Simplicity: The implementation should be straightforward.

Efficiency: The checker should not be less efficient than the algorithm producing the geometric structure.

Robustness: The checker should be able to handle degenerate input configurations and should not be affected by errors in flow control due to round-off approximations.

Checking is especially relevant in the graph drawing context. Indeed, graph drawing algorithms are among the most sophisticated of the entire computational geometry field, and their goal is to construct complex geometric structures with specific properties. Also, because of their immediate impact on application areas, graph drawing algorithms are usually implemented soon after invention. Further, such implementations are often available on the Web without any certification of their correctness. Of course, the checking problem becomes crucial when the drawing algorithm deals with very large data sets, when a simple complete visual inspection of the drawing is difficult. Devising graph drawing checkers involves answering only apparently innocent questions such as: “Is this drawing planar?” or “Is this drawing upward?” or “Are the faces convex?” The problem of checking the planarity of a subdivision has been independently studied by Mehlhorn et al. [MSNS⁺99] and by Devillers et al. [DLPT98]. In these papers linear-time algorithms are given to check the planarity of a subdivision composed by convex faces. Di Battista and Liotta [DL98] check the upward planarity of straight-line oriented drawings that may also have nonconvex faces.

INCREMENTAL GRAPH DRAWING

In several applications, such as software engineering and database design, users interact extensively with a displayed graph, continuously adding or deleting vertices and edges. Under such a scenario, a graph drawing system should update the drawing each time the displayed graph is modified by the user. Unfortunately, traditional drawing algorithms may not be suitable in these situations. Since they typically construct a drawing from scratch, they may fail to update the drawing quickly after the user modifies the displayed graph. Also, the new drawing constructed after the modification may be significantly different from the previous one, even if only a small change has been made in the displayed graph. In this case, the user’s *mental map* [ELMS95], that is, the mental image the user has of the graph, is not preserved, and a considerable cognitive effort is required to correlate the new drawing and the previous one. Bridgeman and Tamassia [BT00a] formulate and validate several difference metrics that can be used to measure how much a drawing algorithm changes the user’s mental map in an interactive environment. Tradeoffs between running time, optimization of the drawing properties, and preservation

of the mental map are typical issues to be addressed in incremental graph drawing. Several papers dealing with these issues have recently appeared in journal and conference proceedings. A limited list includes the work by Cohen, Di Battista, Tamassia, and Tollis [CDTT95] on data structures for dynamic graph drawing; the Bayesian framework of Brandes and Wagner [BW97]; the definition and experimental investigation of four scenarios for interactive orthogonal graph drawing by Papakostas and Tollis [PT98] and Papakostas, Six, and Tollis [PST97]; the papers on interactive orthogonal graph drawing by Biedl and Kaufmann [BK97], and by Brandes and Wagner [BW98]; the fully dynamic algorithms for orthogonal drawings in 3D-space by Closson, Gartshore, Johansen, and Wismath [CGJW00]; and the work by North and Woodhull [NW02] on on-line hierarchical graph drawing.

EXPERIMENTATION

Many graph drawing algorithms have been implemented and used in practical applications. Most papers show sample outputs, and some also provide limited experimental results on small test suites. However, in order to evaluate the practical performance of a graph drawing algorithm in visualization applications, it is essential to perform extensive experimentations with input graphs derived from the application domain and over a large set of aesthetic requirements that are desirable for the user to have in the drawing. Among papers that test the human perception of the aesthetic properties of graph drawing we mention the work by Purchase, Allder, and Carrington [PAC02] and by Bridgeman and Tamassia in an incremental setting [BT00b]. The first broad-view experimental study on graph drawing algorithms is due to Himsolt [Him95] presents a comparative study of twelve graph drawings algorithms based on various approaches. Di Battista et al. [DGL⁺97] report on an extensive experimental study comparing four orthogonal drawing algorithms based on the planarization approach. The test data are 11,582 graphs, ranging from 10 to 100 vertices, which are generated from a core set of 112 graphs used in “real-life” software engineering and database applications. A similar experimental setting is then used to analyze the performance of four graph drawing algorithms for directed acyclic graphs in [DGL⁺00]. Heuristics for computing orthogonal drawings with good area performance are experimentally validated in the works by Klau, Klein, and Mutzel [KKM01] and by Di Battista et al. [BDD⁺00]. Experimentation of graph drawing techniques for computing graphical representations of database schemas are conducted by Di Battista, Didimo, Patrignani, and Pizzonia [DDPP02]. An extensive experimental comparison of five algorithms based on force-directed and randomized methods is described in the work by Brandenburg, Himsolt, and Roher [BHR96]. Jünger and Mutzel [JM97] experimentally compare the performance of eight heuristics for straight-line drawings of 2-layer graphs. An extensive survey on experimental studies on graph drawing can be found in [VBL⁺00].

FIXED PARAMETER TRACTABILITY

Recently, the theory of parametrized complexity [DF97] has been applied with success to some computationally difficult graph drawing problems. A problem Π specified in terms of one or more parameters is *fixed-parameter tractable*, or in the

FPT class, if there is an algorithm that solves Π in $O(f(k) \cdot n^c)$ time, where n is the input size, k is the parameter size, c is a constant, and f is an arbitrary function dependent only on parameter k . For example it is NP-complete to decide, given a graph G and a positive integer k , whether G can be drawn on the plane with at most k edge crossings (edges are drawn as simple curves). However it has been shown by Grohe [Gro01] that this problem is fixed-parameter tractable since there exists a quadratic time algorithm that solves it for any fixed value of k . Other relevant NP-hard graph drawing problems have been proved to be in the FPT class [DFH⁺01b, DFH⁺01a, DW03]; some of these results are summarized in Table 52.6.1. In the table, h and k denote integer positive constants. It must be noted, however, that the constants hidden in the time complexities shown in Table 52.6.1 may depend heavily on the values of the parameter. For example, the crossing minimization problem for general graph has time complexity $O(f(k) \cdot n^2)$ where $f(k)$ is a doubly exponential function [Gro01]. Thus, it is equally important to find time-complexity bounds that can be of practical use for fixed-parameter tractable problems.

TABLE 52.6.1 Some NP-hard graph drawing problems that are fixed-parameter tractable.

GRAPH CLASS	NP-HARD PROBLEM	TIME COMPLEXITY
2-layered graph	<i>2-layers planarization</i> : remove at most k edges so biplanar	$O(f(k) + G)$
2-layered graph	<i>2-layers crossing minimization</i> : compute straight-line drawing on two layers with at most k crossings	$O(f(k) \cdot n^2)$
general graph	<i>h-layers planarization</i> : remove at most k edges so h -level planar	$O(f(h, k) \cdot n)$
general graph	<i>h-layers crossing minimization</i> : compute a straight-line drawing on h layers with at most k crossings	$O(f(h, k) \cdot n^2)$
general graph	<i>crossing minimization</i> : compute a straight-line drawing with at most k crossings	$O(f(k) \cdot n^2)$

52.7 SOURCES AND RELATED MATERIAL

Three books devoted to graph drawing have been published [DETT99, KE01, Sug02]. The proceedings of the annual Symposium on *Graph Drawing* are published by Springer-Verlag in the *Lecture Notes in Computer Science* series (volumes 2265, 1984, 1731, 1547, 1353, 1190, 1027, 894). Surveys on various aspects of graph drawing appear in [DLL95, DPS02, GT95, HMM00, JM97, Riv93, San99, SSV95, Tam90a, Tam90b, Tam99, VBL⁺00]. Special issues devoted to graph drawing have appeared in *Algorithmica* (vol. 16, no. 1, 1996), *Computational Geometry: Theory and Applications* (vol. 9, no. 1–2, 1998), the *Journal of Visual Languages and*

Computing (vol. 6, 1995), and the *Journal of Graph Algorithms and Applications* (vol. 3, no. 4, 1999; vol. 4, no. 3, 2000; vol. 6, no. 1, 2002; vol. 6, no.3, 2002).

53 SPLINES AND GEOMETRIC MODELING

Chandrajit L. Bajaj

INTRODUCTION

Piecewise polynomials of fixed degree and continuously differentiable up to some order are known as *splines* or *finite elements*. Splines are used in applications ranging from computer-aided design, computer graphics, data visualization, geometric modeling, and image processing to the solution of partial differential equations via finite element analysis. The spline-fitting problem of constructing a mesh of finite elements that interpolate or approximate multivariate data is by far the primary research problem in geometric modeling. *Parametric splines* are vectors of a set of multivariate polynomial (or rational) functions while *implicit splines* are zero contours of collections of multivariate polynomials. This chapter dwells mainly on spline surface fitting methods in real Euclidean space. We first discuss tensor product surfaces (Section 53.1), perhaps the most popular. The next sections cover generalized spline surfaces (Section 53.2), free-form surfaces (Section 53.3), and subdivision surfaces (Section 53.4). This classification is not strict, and some overlap exists. Interactive editing of surfaces is discussed in the final section (Section 53.5).

The various spline methods may be distinguished by several criteria:

- Implicit or parametric representations.
- Algebraic and geometric degree of the spline basis.
- Number of surface patches required.
- Computation (time) and memory (space) required.
- Stability of fitting algorithms.
- Local or nonlocal interpolation.
- Splitting or nonsplitting of input mesh.
- Convexity or nonconvexity of the input and solution.
- Fairness of the solution (first- and second-order variation).

These distinctions will guide the discussions throughout the chapter.

53.1 TENSOR PRODUCT SURFACES

Tensor product B-splines have emerged as the polynomial basis of choice for working with parametric surfaces. The theory of tensor product patches requires that data have a rectangular geometry and that the parametrizations of opposite boundary curves be similar. It is based on the concept of bilinear interpolation. The most general results obtained to date are summarized in [Table 53.1.1](#), and will be discussed below.

GLOSSARY

Affine invariance: A property of a curve or surface generation scheme, implying invariance with respect to whether computation of a point on a curve or surface occurs before or after an affine map is applied to the input data.

A-spline: Collection of bivariate Bernstein-Bézier polynomials, each over a triangle and with prescribed geometric continuity, such that the zero contour of each polynomial defines a smooth and single-sheeted real algebraic curve segment. (“A” stands for “algebraic.”)

A-patch: Smooth and “functional” zero contour of a Bernstein-Bézier polynomial over a tetrahedron.

Barycentric combination: A weighted average where the sum of the weights equals one.

Barycentric coordinates: A point in $\mathbb{R}^2$ may be written as a unique barycentric combination of three points. The coefficients in this combination are its barycentric coordinates. Similarly, a point in $\mathbb{R}^3$ may be written as a unique barycentric combination of four points. See Figure 28.2.1.

Basis function: Functions form linear spaces, which have bases. The elements of these bases are the basis functions.

Bernstein-Bézier form: Let $p_1, p_2, p_3, p_4 \in \mathbb{R}^3$ be affinely independent. Then the tetrahedron with these points as vertices is $V = [p_1 p_2 p_3 p_4]$. Any polynomial $f(p)$ of degree n can be expressed in the Bernstein-Bézier (BB) form over V as

$$f(p) = \sum_{|\lambda|=n} b_\lambda B_\lambda^n(\alpha), \quad \lambda \in \mathcal{Z}_+^4, \quad (53.1.1)$$

where

$$B_\lambda^n(\alpha) = \frac{n!}{\lambda_1! \lambda_2! \lambda_3! \lambda_4!} \alpha_1^{\lambda_1} \alpha_2^{\lambda_2} \alpha_3^{\lambda_3} \alpha_4^{\lambda_4}$$

are Bernstein polynomials, $|\lambda| = \sum_{i=1}^4 \lambda_i$ with $\lambda = (\lambda_1, \lambda_2, \lambda_3, \lambda_4)^T$, the barycentric coordinates of p are $\alpha = (\alpha_1, \alpha_2, \alpha_3, \alpha_4)^T$, $b_\lambda = b_{\lambda_1 \lambda_2 \lambda_3 \lambda_4}$ are the *control points*, and $\mathcal{Z}_+^4$ is the set of all four-dimensional vectors with nonnegative integer components.

Bernstein polynomials: The basis functions for Bézier curves and surfaces.

Bézier curve: A curve whose points are determined by the parameter u in the equation $\sum_{i=0}^n B_i^n(u) P_i$, where the $B_i^n(u)$ are basis functions, and the P_i control points.

Bilinear interpolation: A tensor product of two orthogonal linear interpolants and the “simplest” surface defined by values at four points on a rectangle.

Blending functions: The basis functions used by interpolation schemes such as Gordon surfaces.

B-spline surface: Traditionally, a tensor product of curves defined using piecewise basis polynomials (B-spline basis). Any B-spline can be written in piecewise Bézier form. (“B” stands for “basis.”)

C^k continuity: Smoothness defined in terms of matching of up to k th order derivatives along patch boundaries.

Control point: The coefficients in the expansion of a Bézier curve in terms of Bernstein polynomials.

Convex hull: The smallest convex set that contains a given set.

Convex set: A set such that the straight line segment connecting any two points of the set is completely contained within the set.

G^k continuity: Geometric continuity with smoothness defined in terms of matching of up to k th order derivatives allowing for reparametrization. For example, G^1 smoothness is defined in terms of matching tangent planes along patch boundaries.

Knots: A spline curve is defined over a partition of an interval of the real line. The points that define the partition are called knots.

Mesh: A decomposition of a geometric domain into finite elements; see [Section 22.4](#).

Ruled (lofted) surface: A surface that interpolates two given curves using linear interpolation.

Tensor product surfaces: A surface represented with basis functions that are constructed as products of univariate basis functions. A tensor product Bézier surface is given by the equation $\sum_{i=0}^n \sum_{j=0}^m B_i^n(u) B_j^m(v) P_{ij}$, where the $B_i^n(u)$ and $B_j^m(v)$ are the univariate Bernstein polynomial basis functions, and the P_{ij} are control points.

Transfinite interpolation: Interpolating entire curves as opposed to values at discrete points.

Variation diminishing: A curve or surface scheme has this property if its output “wiggles less” than the control points from which it is constructed.

PARAMETRIC BÉZIER AND B-SPLINES

Tensor product Bézier surfaces are obtained by repeated applications of bilinear interpolation. Properties of tensor product Bézier patches include affine invariance, the “convex hull property,” and the variation diminishing property. The boundary curves of a patch are polynomial curves that have their Bézier polygon given by the boundary polygons of the control net of the patch. Hence the four corners of the control net lie on the patch.

Piecewise bicubic Bézier patches may be used to fit a C^1 surface through a rectangular grid of points. After the rectangular network of curves has been created, there are four coefficients left to determine the corner twists of each patch. These four corner twists cannot be specified independently and must satisfy a “compatibility constraint.” Common twist estimation methods include zero twists, Adini’s twist, Bessel twist, and Brunet’s twist [Far98]. To obtain C^1 continuity between two patches the directions and lengths of the polyhedron edges must be matched across the common polyhedron boundary defining the common boundary curve. Piecewise bicubic Hermite patches are similar to the piecewise bicubic Bézier patches, but take points, partials, and mixed partials as input. The mixed partials affect only the interior shape of the patch, and are also called **twist vectors**.

It is not possible to model a general closed surface or a surface with handles as a single nondegenerate B-spline. To represent free-form surfaces a significant amount of recent work has been done in the areas of geometric continuity, nontensor product

TABLE 53.1.1 Tensor product surfaces.

TYPE	INPUT	PROPERTIES
Piecewise Bézier and Hermite	rectangular grid of points, corner twists	C^1 , initial global data survey data to determine the tangent and cross-derivative vectors at patch corners
Bicubic B-spline	rectangular grid of points	C^1
Coons patches	4 boundary curves	C^1
Gordon surfaces	rectangular network of curves	C^1 , Gregory square
Biquadratic B-spline	limit of Doo-Sabin subdivision of rectangular faces	C^1
Bicubic B-spline	limit of Catmull-Clark subdivision of rectangular faces	C^1
Biquadratic splines	control points on mesh with arbitrary topology	G^1 , system of linear equations for smoothness conditions around singular vertices
Biquartic splines	cubic curve mesh	C^1 , interpolate second-order data at mesh points
Bisextic B-spline	rectangular network of cubic curves	C^1
Triquadratic/tricubic A-patches	rectilinear 3D grid points	C^1 , local calculation of first-order cross derivatives
Triple products of B-splines	rectangular boxes	

patches, and generalizing B-splines [CF83, Pet90a, Pet90b, GW91, DM83, GH87]. Common schemes include splitting, convex combinations of blending functions, subdivision, and local interpolation by construction [for95, HF84, MLL⁺92, Pet93, Pet02].

IMPLICIT BÉZIER AND B-SPLINES

Patrikalakis and Kriezis [PK89] demonstrate how implicit algebraic surfaces can be manipulated in rectangular boxes as functions in a tensor product B-spline basis. This work, however, leaves open the problem of selecting weights or specifying knot sequences for C^1 meshes of tensor product implicit algebraic surface patches that fit given spatial data. Moore and Warren [MW91] extend the “marching cubes” scheme to compute a C^1 piecewise tensor product triquadratic approximation to scattered data using a Powell-Sabin-like split over subcubes. In [BBCS99] an incremental and adaptive approach is used to construct C^1 spline functions defined over an octree subdivision that approximate a dense set of multiple volumetric scattered scalar values. Further details are provided in subsequent sub-sections on A-patches and implicit free-form surfaces.

COONS PATCHES AND GORDON SURFACES

Coons patches interpolate four boundary curves. They are constructed by composing two ruled, or lofted, surfaces and one bilinear surface, and hence are called *bilinearly blended surfaces*. A Coons patch has four blending functions $f_i(u)$, $g_i(v)$, $i = 1, 2$. There are only two restrictions on the f_i and g_i : each pair must

sum to one, and we must have $f_1(0) = g_1(0) = 1$ and $f_2(1) = g_2(1) = 0$ in order to interpolate.

A network of curves may be filled in with a C^1 surface using bicubically blended Coons patches. For this the four twists at the data points and the four cross boundary derivatives must be computed. Compatibility problems may arise in computing the twists. If $\mathbf{x}(u, v)$ is twice differentiable, we have $\mathbf{x}_{uv} = \mathbf{x}_{vu}$, but this simplification does not apply here. One approach is to adjust the given data so that the incompatibilities disappear. Or if the data cannot be changed one can use a method known as *Gregory's square* that replaces the constant twist terms by variable twists that are computed from the cross boundary derivatives. The resulting surface does not have continuous twists at the corners and is rational parametric, which may not be acceptable geometry for certain geometric modeling systems.

Gordon surfaces are a generalization of Coons patches used to construct a surface that interpolates a rectangular network of curves. The idea is to take a univariate interpolation scheme, apply it to all curves, add the resulting surfaces, and subtract the tensor product interpolant that is defined by the univariate scheme. Polynomial interpolation or spline interpolation schemes may be used. Methods for Coons patches and Gordon surfaces can be formulated in terms of Boolean sums and projectors. This has also been generalized to create triangular Coons patches.

53.2 GENERALIZED SPLINE SURFACES

B-PATCHES

The B-patches developed by Seidel [Sei89, DMS92] are based on the study of symmetric recursive evaluation algorithms, and are defined by generalizing the deBoor algorithm for the evaluation of a B-spline segment from curves to surfaces. A polynomial surface that has a symmetric recursive evaluation algorithm is called a *B-patch*. B-patches generalize Bézier patches over triangles, and are characterized by control points and a three-parameter family of knots. Every bivariate polynomial $F : \mathbb{R}^2 \rightarrow \mathbb{R}^d$ of degree n has a unique representation

$$F(U) = \sum_{|\vec{i}|=n} N_i^n(U) P_i, \quad P_i \in \mathbb{R}^d$$

as a B-patch, with parameters $\mathcal{K} = R_0, \dots, R_{n-1}, S_0, \dots, S_{n-1}, T_0, \dots, T_{n-1}$ in $\mathbb{R}^2$, if the parameters (R_i, S_j, T_k) are affinely independent for $0 \leq |\vec{i}| \leq n-1$. The real-valued polynomials $N_i^n(U)$ are called the *normalized B-weights* of degree n over $\mathcal{K}$.

MULTISIDED PATCHES

Multisided patches can be generated in basically two ways. Either the polygonal domain which is to be mapped into $\mathbb{R}^3$ is subdivided in the parametric plane, or one uniform equation is used as a combination of equations. In the former case,

triangular or rectangular elements are put together or recursive subdivision is applied. In the latter case, either the known control point methods are generalized, or a weighted sum of interpolants is used. With constrained domain mapping, a domain point for an n -sided patch is represented by n dependent parameters. If the remainder of the parameters can be computed when any two parameters are independently chosen, it is called a *symmetric system of parameters*. The main results from multisided patch schemes obtained to date are summarized in Table 53.2.1.

TABLE 53.2.1 Multisided schemes.

TYPE	LIMITATIONS	PROPERTIES	DOMAIN POINTS
Sabin	$n=3,5$	C^1	constrained domain mapping, symmetric system of parameters
Gregory/Charrot	$n=3,5$	C^1	barycentric coordinates
Hosaka/Kimura	$n \leq 6$	C^1	constrained domain mapping, symmetric system of parameters
Varady		VC^1	$2n$ variables constrained along polygon sides
Base points	$n = 4, 5, 6$	rational Bézeir surfaces	base points in the parametric domain map to rational curves in $\mathbb{R}^3$
S-patches	multisided	G^1 rational bi-quadratic and bicubic	embed n -sided domain polygon into simplex of dimension $n - 1$
Multisided A-patches	“functional” bd curves	B-splines C^1, C^2 implicit Bezier surfaces	Hermite interpolation of boundary curves

TRIANGULAR RATIONAL PATCHES WITH BASE POINTS

Another approach to creating multisided patches is to introduce base points into rational parametric functions. Base points are parameter values for which the homogeneous coordinates (x, y, z, w) are mapped to $(0, 0, 0, 0)$ by the rational parametrization. Gregory’s patch [Gre83] is defined using a special collection of rational basis functions that evaluate to $0/0$ at vertices of the parametric domain, and thus introduce base points in the resulting parametrization. Warren [War92] uses base points to create parametrizations of four-, five-, and six-sided surface patches using rational Bézier surfaces defined over triangular domains. Setting a triangle of weights to zero at one corner of the domain triangle produces a four-sided patch that is the image of the domain triangle.

S-PATCHES

Loop and DeRose [LD89, LD90] present generalizations of biquadratic and bicubic B-spline surfaces that are capable of representing surfaces of arbitrary topology by placing restrictions on the connectivity of the control mesh, relaxing C^1 continuity to G^1 (geometric) continuity, and allowing n -sided finite elements. This generalized view considers the spline surface to be a collection of possibly rational polynomial maps from independent n -sided polygonal domains, whose union possesses continuity of some number of geometric invariants, such as tangent planes. This more

general view allows patches to be sewn together to describe free-form surfaces in more complex ways.

An n -sided S-patch S is constructed by embedding its n -sided domain polygon P into a simplex $\triangle$ whose dimension is one less than the number of sides of the polygon. The edges of the polygon map to edges of the simplex. A Bézier simplex B is then constructed using $\triangle$ as a domain. The patch representation S is obtained by restricting the Bézier simplex to the embedded domain polygon.

A-PATCHES

The A-patch technique provides simple ways to guarantee that a constructed implicit surface is single-sheeted and free of undesirable singularities. The technique uses the zero contouring surfaces of trivariate Bernstein-Bézier polynomials to construct a piecewise smooth surface. We call such iso-surfaces *A-patches*. Algorithms to fill an n -sided hole, using either a single multisided A-patch or a network of A-patches, are given in [BE95]. The blends may be C^0 , C^1 , or C^2 exact fits (interpolation), as well as C^1 or C^2 least squares fits (interpolation and approximation).

For degree-bounded patches, a triangular network of A-patches for the hole may be generated in two ways. First, the n -sided hole is projected onto a plane and the result of a planar triangulation is projected back onto the hole. Second, an initial multisided A-patch is created for the hole and then a coarse triangulation for the patch is generated using a rational spline approximation [BX94].

MULTIVARIATE BOX SPLINES AND SIMPLEX SPLINES

Multivariate splines are a generalization of univariate B-splines to a multivariate setting. Multivariate splines have applications in data fitting, computer-aided design, the finite element method, and image analysis. Work on splines has traditionally been for a given planar triangulation using a polynomial function basis. Box splines are multivariate generalizations of B-splines with uniform knots. Many of the basis functions used in finite element calculations on uniform triangles occur as special instances of box splines. In general a box spline is a locally supported piecewise polynomial. One can define translates of box splines that form a negative partition of unity.

In the bivariate case, box splines correspond to surfaces defined over a regular tessellation of the plane. If the tessellation is composed of triangles, it is possible to represent the surface as a collection of Bernstein-Bézier patches. The two most commonly used special tessellations arise from a rectangular grid by drawing in lines in north-easterly diagonals in each subrectangle or by drawing in both diagonals for each subrectangle. For these special triangulations there is an elegant way to construct locally supported splines.

Multivariate splines defined as projections of simplices are called *simplex splines*. Auerbach [AMNS91] constructs approximations with simplex splines over irregular triangles. Bivariate quadratic simplicial B-splines defined by their corresponding sets of knots derived from a (suboptimal) constrained Delaunayi triangulation of the domain are employed to obtain a C^1 surface. This approach is well suited for scattered data.

Fong and Seidel [FS86, FS92] construct multivariate B-splines for quadratics and cubics by matching B-patches with simplex splines. The surface scheme is an

approximation scheme based on blending functions and control points and allows the modeling of C^{k-1} continuous piecewise polynomial surfaces of degree k over arbitrary triangulations of the parameter plane. The resulting surfaces are defined as linear combinations of the blending functions, and are parametric piecewise polynomials over a triangulation of the parameter plane whose shape is determined by their control points.

53.3 FREE-FORM SURFACES

The representation of free-form surfaces is one of the major issues in geometric modeling. These surfaces are generally defined in a piecewise manner by smoothly joining several, mostly four-sided, patches. Common approaches to constructing surfaces over irregular meshes are local construction, blending polynomial pieces, and splitting.

GLOSSARY

Blending polynomial pieces: Constructing k pieces for a k -sided mesh facet such that each piece matches a part of the facet data, and a convex combination of the pieces matches the whole.

Vertex enclosure constraint: Not every mesh of polynomial curves with a well-defined tangent plane at the mesh points can be interpolated by a smooth regularly parameterized surface with one polynomial piece per facet. This constraint on the mesh is a necessary and sufficient condition to guarantee the existence of such an interpolant [Pet91]. Rational patches, singular parametrizations, and the splitting of patches are techniques to enforce the vertex enclosure constraint.

MAIN RESULTS

Blending approaches prescribe a mesh of boundary curves and their normal derivatives. For this approach, however, the existence of a well-defined tangent plane at the data points is not sufficient to guarantee the existence of a C^1 mesh interpolant, because the mixed derivatives p_{uv} and p_{vu} are given independently at any point p . Splitting approaches, on the other hand, expect to be given at least tangent vectors at the data points, and sometimes the complete boundary. Mann et al. [MLL⁺92] conclude that local polynomial interpolants generally produce unsatisfactory shapes.

With splitting schemes, every triangle in the triangulation of the data points (also called a *macro-triangle*) is split into several *mini-triangles*. Split-triangle interpolants do not require derivative information of higher order than the continuity of the desired interpolant. The simplest of the split-triangle interpolants is the C^1 Clough-Tocher interpolant. Each vertex is joined to the centroid, and the macro-triangle is split into three mini-triangles. The first-order data that this interpolant requires are position and gradient value at the macro-triangle vertices, plus some cross-boundary derivative at the midpoint of each edge. There are twelve data per

macro-triangle, and cubic polynomials are used over each mini-triangle. The C^1 Powell-Sabin interpolants produce C^1 piecewise quadratic interpolants to C^1 data at the vertices of a triangulated data set. Each macro-triangle is split into six or twelve mini-triangles.

PARAMETRIC PATCH SCHEMES

These patches are given in vector valued parametric form, generally mapping a rectangular or triangular parametric domain into $\mathbb{R}^3$. Parametric free-form surface patch schemes are summarized in Table 53.3.1.

TABLE 53.3.1 Free-form parametric schemes.

DEGREE	SCHEME	INPUT	PROPERTIES
Piecewise biquartic	local interpolation	cubic curve mesh	C^1 , interpolate second-order data at mesh points
Piecewise biquadratic	G-edges	control points on a mesh with arbitrary topology	G^1 , system of linear eqns for smoothness conditions around singular vertices
Sextic triangular pieces	approximation, no local splitting	triangular control mesh	G^1
Quadratic/cubic triangular pieces	splitting, subdivision	irregular mesh of points	C^1 , refine mesh by Doo-Sabin to isolate regions of irregular points

IMPLICIT PATCH SCHEMES

While it is possible to model a general closed surface of arbitrary genus as a single implicit surface patch, the geometry of such a global surface is difficult to specify, interactively control, and polygonize. The main difficulties stem from the fact that implicit representations are iso-contours which generally have multiple real sheets, self-intersections, and several other undesirable singularities. Looking on the bright side, implicit polynomial splines of the same geometric degree have more degrees of freedom compared with parametric splines, and hence potentially are more flexible for approximating a complicated surface with fewer pieces and for achieving a higher order of smoothness. The potential of implicits remains largely latent: virtually all commercial and many research modeling systems are based on the parametric representation. An exception is SHASTRAS, which allows modeling with both implicit and parametric splines [Baj93]. Implicit free-form surface schemes are summarized in Table 53.3.2.

A-SPLINES

An *A-spline* is a piecewise G^k -continuous chain of real algebraic curve segments, such that each curve segment is a smooth and single-sheeted zero contour of a bivariate Bernstein-Bézier polynomial (called a regular curve segment). A-splines are

TABLE 53.3.2 Free-form implicit schemes.

DEGREE	SCHEME	INPUT	PROPERTIES
5, 7	local interpolation, no splitting	curve mesh from spatial triang	C^1 interpolate or approximate

3	simplicial hull construction, Clough-Tocher split	spatial triangulation	
3	simplicial hull construction, Clough-Tocher split of coplanar faces	spatial triangulation	
5	simplicial hull construction, Clough-Tocher split of coplanar faces	spatial triangulation	C^2 A-patches

a suitable polynomial form for working with piecewise implicit polynomial curves. A characterization of A-splines defined over triangles or quadrilaterals is available [BX99, XB00], as is a detailing of their applications in curve design and fitting [BX01].

CURVILINEAR MESH SCHEMES

Bajaj and Ihm [Baj92, BI92a] construct implicit surfaces to solve the scattered data-fitting problem. The resulting surfaces approximate or contain with C^1 continuity any collection of points and algebraic space curves with derivative information. Their Hermite interpolation algorithm solves a homogeneous linear system of equations to compute the coefficients of the polynomial defining the algebraic surface. This idea has been extended to C^k (rescaling continuity) interpolate or least squares approximate implicit or parametric curves in space [BIW93]. This problem is formulated as a constrained quadratic minimization problem, where the algebraic distance is minimized instead of the geometric distance.

In a *curvilinear-mesh-based* scheme, Bajaj and Ihm [BI92b] construct low-degree implicit polynomial spline surfaces by interpolating a mesh of curves in space using the techniques of [Baj92, BI92a, BIW93]. They consider an arbitrary spatial triangulation $\mathcal{T}$ consisting of vertices in $\mathbb{R}^3$ (or more generally, a simplicial polyhedron $\mathcal{P}$ when the triangulation is closed), with possibly normal vectors at the vertex points. Their algorithm constructs a C^1 mesh of real implicit algebraic surface patches over $\mathcal{T}$ or $\mathcal{P}$. The scheme is local (each patch has independent free parameters) and there is no local splitting. The algorithm first converts the given triangulation or polyhedron into a curvilinear wire frame, with at most cubic parametric curves which C^1 interpolate all the vertices. The curvilinear wire frame is then fleshed to produce a single implicit surface patch of degree at most 7 for each triangular face $\mathcal{T}$ of $\mathcal{P}$. If the triangulation is convex then the degree is at most 5. Similar techniques exist for parametrics [Pet91, Far86, Sar87]; however, the geometric degrees of the solution surfaces tend to be prohibitively high.

SIMPLEX- AND BOX-BASED SCHEMES

In a *simplex-based* approach, one first constructs a tetrahedral mesh (called the simplicial hull) conforming to a surface triangulation $\mathcal{T}$ of a polyhedron $\mathcal{P}$. The implicit piecewise polynomial surface consists of the zero set of a Bernstein-Bézier polynomial, defined within each tetrahedron (simplex) of the simplicial hull. A

simplex-based approach enforces continuity between adjacent patches by enforcing that vertex/edge/face-adjacent trivariate polynomials are continuous with one another.

Similar to the trivariate interpolation case, Powell-Sabin or Clough-Tocher splits are used to introduce degree-bounded vertices to prevent the continuity system from propagating globally. Such splitting, however, could result in a large number of patches. However, as only the zero set of the polynomial is of interest, one does not need a complete mesh covering the entire space.

Sederberg [Sed85] showed how various smooth implicit algebraic surfaces, represented in trivariate Bernstein basis form, can be manipulated as functions in Bézier control tetrahedra with finite weights. He showed that if the coefficients of the Bernstein-Bézier form of the trivariate polynomial on the lines that parallel one edge, say L , of the tetrahedron all increase (or decrease) monotonically in the same direction, then any line parallel to L will intersect the zero contour algebraic surface patch at most once.

Guo [Guo91] used cubics to create free-form geometric models and enforced monotonicity conditions on a cubic polynomial along the direction from one vertex to a point of the face opposite the vertex. A Clough-Tocher split is used to subdivide each tetrahedron of the simplicial hull. Dahmen and Thamm-Scharr [DTS93] utilize a single cubic patch per tetrahedron, except for tetrahedra on coplanar faces.

Lodha [Lod92] constructed low degree surfaces with both parametric and implicit representations and investigated their properties. A method is described for creating quadratic triangular Bézier surface patches that lie on implicit quadric surfaces. Another method is described for creating biquadratic tensor product Bézier surface patches that lie on implicit cubic surfaces. The resulting patches satisfy all the standard properties of parametric Bézier surfaces, including interpolation of the corners of the control polyhedron and the convex hull property.

Bajaj and Ihm, Guo, and Dahmen [BI92b, Guo91, Guo93, Dah89] provide heuristics based on monotonicity and least square approximation to circumvent the multiple-sheeted and singularity problems of implicit patches.

Bajaj, Chen, and Xu [BCX95] construct 3- and 4-sided A-patches that are implicit surfaces in Bernstein-Bézier (BB) form and that are smooth and single-sheeted. They give sufficiency conditions for the BB form of a trivariate polynomial within a tetrahedron, such that the zero contour of the polynomial is a single-sheeted nonsingular surface within the tetrahedron, and its cubic-mesh complex for the polyhedron $\mathcal{P}$ is guaranteed to be both nonsingular and single-sheeted. They distinguish between convex and nonconvex facets and edges of the triangulation. A double-sided tetrahedron is built for nonconvex facets and edges, and single-sided tetrahedra are built for convex facets and edges. A generalization of Sederberg's condition is given for a three-sided j -patch where any line segment passing through the j th vertex of the tetrahedron and its opposite face intersects the patch only once. Instead of having coefficients be monotonically increasing or decreasing there is a single sign change condition. There are also free parameters for both local and global shape control.

Reconstructing surfaces and scalar fields defined over the surface from scattered data using implicit Bézier splines is described in [BBX95, BX97, CX01]. See also [Chapter 30](#).

53.4 MULTIREOLUTION SPLINE SURFACES

SUBDIVISION SURFACES

Subdivision techniques can be used to produce generally pleasing surfaces from arbitrary control meshes. The faces of the mesh need not be planar, nor need the vertices lie on a topologically regular mesh. Subdivision consists of splitting and averaging. Each edge or face is split, and each new vertex introduced by the splitting is positioned at a fixed affine combination of its neighbor's weights. Subdivision schemes are summarized in Table 53.4.1.

TABLE 53.4.1 Subdivision schemes.

TYPE	PROPERTIES
Doo-Sabin; Catmull-Clark	C^1 , interpolate centroids of all faces at each step
Nasri	interpolate points/normals on irregular networks
Loop	C^1 , split each triangle of a triangular mesh into 4 triangles
Hoppe et al.	extends Loop's method to incorporate shape edges in limit surfaces; initial vertices belong to vertex, edge, or face of limit surface
Storry and Ball	C^1 n -sided B-spline patch to fit in bicubic surface, one dof
Yn, Levin, and Gregory	interpolatory butterfly subdivision, modify set of deterministic rules for subdivision
Bajaj, Chen, and Xu	approximation, one step subdivision to build simplicial hull, C^1 cubic and C^2 quintic A-patches
Reif	regularity conditions

MAIN ALGORITHMS

Subdivision algorithms start with a polyhedral configuration of points, edges, and faces. The control mesh will in general consist of large regular regions and isolated singular regions. Subdivision enlarges the regular regions of the control net and shrinks the singular regions. Each application of the subdivision algorithm constructs a refined polyhedron, consisting of more points and smaller faces, tending in the limit to a smooth surface. In general the new control points are computed as linear combinations of old control points. The associated matrix is called the **subdivision matrix**. Except for some special cases, the limiting surface does not have an explicit analytic representation. If each face of the polyhedron is a rectangle, the Doo-Sabin subdivision rules generate biquadratic tensor product B-splines, and the Catmull-Clark subdivision rules generate bicubic tensor product B-splines. Also, the subdivision technique of Loop generates three-direction box splines.

Reif [Rei92] presents a unified approach to subdivision algorithms for meshes with arbitrary topology and gives a sufficient condition for the regularity of the surface. The existence of a smooth regular parametrization for the generated surface

near the point is determined from the leading eigenvalues of the subdivision matrix and an associated characteristic map. Details and further discussion of recent subdivision schemes are available from [WW02].

APPROXIMATING SCHEMES

Bajaj, Chen, and Xu [BCX94] construct an “inner” simplicial hull after one step of subdivision of the input polyhedron $\mathcal{P}$. As in traditional subdivision schemes, $\mathcal{P}$ is used as a control mesh for free-form modeling, while an inner surface triangulation $\mathcal{T}$ of the hull can be considered as the second level mesh. Both a C^1 mesh with cubic A-patches and a C^2 mesh with quintic patches can be constructed to approximate the polyhedron $\mathcal{P}$ [XBE01].

INTERPOLATING SCHEMES

There are two key approaches to constructing interpolating subdivision surfaces. One approach is to first compute a new configuration of vertices, edges, and faces with the same topology such that the vertices of the new configuration converge to the given vertices in the limit. The subdivision technique is then applied to this new configuration. The other approach is to modify the deterministic subdivision rules so that the limiting surface interpolates the vertices.

HIERARCHICAL SPLINES

Hierarchical splines are a multiresolution approach to the representation and manipulation of free-form surfaces. A hierarchical B-spline is constructed from a base surface (level 0) and a series of overlays are derived from the immediate parent in the hierarchy. Forsey and Bartels [FB88] present a refinement scheme that uses a hierarchy of rectangular B-spline overlays to produce C^2 surfaces. Overlays can be added manually to add detail to the surface, and local or global changes to the surface can be made by manipulating control points at different levels.

Forsey and Wang [FW93] create hierarchical bicubic B-spline approximations to scanned cylindrical data. The resulting hierarchical spline surface is interactively modifiable using editing capabilities of the hierarchical surface representation, allowing either local or global changes to surface shape while retaining the details of the scanned data. Oscillations occur, however, when the data have high-amplitude or high-frequency regions. Forsey and Bartels use a hierarchical wavelet-based representation for fitting tensor product parametric spline surfaces to gridded data in [FB95]. The multiresolution representation is extended to include arbitrary meshes in [EDD⁺95]. The method is based on approximating an arbitrary mesh by a special type of mesh and using a continuous parametrization of the arbitrary mesh over a simple domain mesh.

Further discussion of wavelet based multiresolution schemes and some of their applications is available from [SDS96].

53.5 PHYSICALLY BASED APPROACHES TO SURFACE MODELING

ENERGY-BASED SPLINES

A group of researchers [TF88, PB88, PTBK87, WFB87, BHN99] have presented discrete models which are based extensively on the theory of elasticity and plasticity, using energy fields to define and enforce constraints. Haumann [Hau87] used the same approach but used a triangulated model and a simpler physical model based on points, springs, and hinges. Thingvold and Cohen [TC90] defined a model of elastic and plastic B-spline surfaces which supports both animation and design operations. The basis for the physical model is a generalized point-mass/spring/hinge model that has been adapted into a simultaneous refinement of the geometric/physical model. Always having a sculptured surface representation as well as the physical hinge/spring/mesh model allows the user to intertwine physical-based operations, such as force application, with geometrical modeling. Refinement operations for spring and hinge B-spline models are compatible with the physics and mathematics of B-spline models. The models of elasticity and plasticity are written in terms of springs and hinges, and can be implemented with standard integration techniques to model realistic motions of elastic and plastic surfaces. These motions are controlled by the physical properties assigned and by kinematic constraints on various portions of the surface. Terzopoulos and Qin [TQ94] develop a dynamic generalization of the nonuniform rational B-spline (NURBS) model. They present a physics-based model that incorporates mass distributions, internal deformation energies, and other physical quantities into the NURBS geometric substrate. These dynamic NURBS can be used in applications such as rounding of solids, optimal surface fitting to unstructured data, surface design from cross-sections, and free-form deformations.

DIFFERENTIAL EQUATIONS AND SURFACE SPLINES

Early research on using partial differential equations (PDEs) to handle surface modeling problems trace back to Bloor et al.'s work at the end of the 1980s ([BW89a, BW89b, BW90]). The basic idea of these papers is the use of biharmonic equations on a rectangular domain to solve blending and hole filling problems. One of the advantages of using the biharmonic equation is that it is linear, and therefore easier to solve. However, the solution of the equation depends on the surface parametrization.

The evolution technique, based on the heat equation $\partial_t x - \Delta x = 0$, has been extensively used in the area of image processing (see [PM87, PR99, Wei98], where Δ is a 2D Laplace operator. This was extended later to smoothing or fairing noisy surfaces (see [CDR00, DMSB99, DMSB00]). For a surface M , the counterpart of the Laplacian Δ is the Laplace-Beltrami operator Δ_M (see [dC92]). One then obtains the geometric diffusion equation $\partial_t x - \Delta_M x = 0$ for a surface point $x(t)$ on the surface $M(t)$. Taubin [Tau95] discusses the discretized operator of the Laplacian and related approaches in the context of generalized frequencies on meshes. Kobbelt

[Kob96] considers discrete approximations of the Laplacian in the construction of fair interpolatory subdivision schemes. This work was extended in [KCVS98] to arbitrary connectivity for purposes of multi-resolution interactive editing. Desbrun et al. [DMSB99] used an implicit discretization of geometric diffusion to obtain a strongly stable numerical smoothing scheme. The same strategy of discretization is also adopted and analyzed by Deckelnick and Dziuk [DD02] with the conclusion that this scheme is unconditionally stable. Clarenz et al. [CDR00] introduced anisotropic geometric diffusion to enhance features while smoothing. Ohtake et al. [OBB00] combined an inner fairness mechanism in their fairing process to increase the mesh regularity. Bajaj and Xu [BX03] smooth both surfaces and functions on surfaces, in a C^2 smooth function space defined by the limit of triangular subdivision surfaces (quartic Box splines).

Similar to surface diffusion using the Laplacian, a more general class of PDE based methods called *flow surface techniques* have been developed which simulate different kinds of flows on surfaces (see [WJE00] for references) using the equation $\partial_t x - v(x, t) = 0$, where $v(x, t)$ represents the instantaneous stationary velocity field.

Level set methods were also used in surface fairing and surface reconstruction; see [BCO00, BSCO00, CS99, MBWB02, OF00, WB98, ZOF01, ZOMK00]. In these methods, surfaces are formulated as iso-surfaces (level surfaces) of 3D functions, which are usually defined from the signed distance over Cartesian grids of a volume. An evolution PDE on the volume governs the behavior of the level surface. These level-set methods have several attractive features including, ease of implementation, arbitrary topology [BW01] and a growing body of theoretical results. Often, fine surface structures are not captured by level sets, although it is possible to use adaptive [PR99] and triangulated grids as well as Hermite data [JLSW02, KBSS01]. To reduce the computational complexity, Bertalmio et al. [BCO00, BSCO00] solve the PDE in a narrow band for deforming vectorial functions on surfaces (with a fixed surface represented by the level surface).

Recently, surface diffusion flow has been used to solve the surface blending problem and free-form surface design problem. In [SK00], fair meshes with G^1 conditions are created in the special case where the meshes are assumed to have subdivision connectivity. In this work, local surface parametrization is still used to estimate the surface curvatures. A later paper [SK01] uses the same equation for smoothing meshes while satisfying G^1 boundary conditions. Outer fairness (the smoothness in the classical sense) and inner fairness (the regularity of the vertex distribution) criteria are used in their fairing process.

Another category of surface fairing research is based on utilizing optimization techniques. In this category, one constructs an optimization problem that minimizes certain objective functions [Gre94, HG00, MS92, Sap94, WW92], such as thin plate energy, membrane energy [KCVS98], total curvature [KHPS97, WW94], or sum of distances [Mal92]. Using local interpolation or fitting, or replacing differential operators with divided difference operators, the optimization problems are discretized to arrive at finite dimensional linear or nonlinear systems. Approximate solutions are then obtained by solving the constructed systems. In general, such an approach is quite computationally intensive.

54 SURFACE SIMPLIFICATION AND 3D GEOMETRY COMPRESSION

Jarek Rossignac

INTRODUCTION

Central to 3D modeling, graphics, and animation, *triangle meshes* are used in Computer Aided Design, Visualization, Graphics, and video games to represent polyhedra, control meshes of subdivision surfaces, or tessellations of parametric surfaces or level sets. A triangle mesh that accurately approximates the surface of a complex 3D shape may contain millions of triangles. This chapter discusses techniques for reducing the delays in transmitting it over the Internet. The *connectivity*, which typically dominates the storage cost of uncompressed meshes, may be compressed down to about one bit per triangle by compactly encoding the parameters of a triangle-graph construction process and by transmitting the vertices in the order in which they are used by this process. Vertex coordinates, i.e., the *geometry*, may often be compressed to less than 5 bits each through quantization, prediction, and entropy coding. Thus, *compression* reduces storage of triangle meshes to about a byte per triangle. When necessary, file size may be further reduced through *simplification*, which collapses edges or merges clusters of neighboring vertices to decrease the total triangle count. The application may select the appropriate level-of-detail; trading fidelity for transmission speed. In applications where preserving the exact geometry and connectivity of the mesh is not essential, the triangulated surface may be *re-sampled* to produce a mesh with a more regular connectivity and with vertices that are constrained to, each, lie on a specific curve, and thus may be fully specified by a single parameter. Re-sampling may improve compression significantly, without introducing noticeable distortions. Furthermore, when the accuracy of a simplified or re-sampled model received by a client is insufficient, compressed upgrades may be downloaded as needed to *refine* the model in a *progressive* fashion.

Due to space limitations, we focus primarily on triangle meshes that are homeomorphic to triangulation of a sphere. Strategies for extending the compression, simplification, and refinement techniques to more general meshes, which include polygonal meshes, manifold meshes with handles and boundaries, or nonmanifold models; to tetrahedral, higher dimensional, or animated meshes; and to models with texture or property maps, are discussed elsewhere.

GLOSSARY

Mesh: A set of triangles homeomorphic to the triangulation of a sphere.

Geometry (of a mesh): The positions of the vertices (possibly described by 3 coordinates each).

Incidence: The definition of the triangles of the mesh, each as 3 vertex Ids.

Connectivity: Incidence, combined with adjacency and order relations, which may be derived from the incidence.

Connectivity compression: Encoding the incidence, while ignoring the geometry.

Geometry compression: Encoding of the vertex locations, while assuming that the relevant connectivity information will be available to the decoder.

Simplification: The process of merging the vertices of a mesh to generate a new mesh that approximates the original one, but comprises fewer triangles.

Level-of-Detail (LOD): One of a series of increasingly simplified models that approximate an original shape by trading fidelity for a decrease in triangle count.

Re-sampling: The approximation of an original mesh by one with a new connectivity and a new set of vertices, selected to minimize error and maximize compression.

Progressive transmission: A protocol in which the client receives the lowest LOD, possibly followed by upgrades, if and when needed.

Single-rate compression: A compressed representation that does not support progressive transmission.

54.1 SIMPLE TRIANGLE MESHES

In this section, we introduce the terminology, properties, data structures, and operators used in this chapter. We assume that the mesh is simple, i.e., homeomorphic to the triangulation of a sphere.

GLOSSARY

Vertex and triangle count: A mesh with v vertices and t triangles satisfies $t = 2v - 4$.

Triangle: A node of the connectivity graph representing a closed point-set that is the convex hull of three noncollinear vertices.

Surface (of a mesh): The union of the point-sets of its triangles.

Edge: A link in the connectivity graph representing a relatively open line segment joining two vertices of a mesh, but not containing them.

Face: The relative interior of a triangle, i.e., the triangle minus the union of the point-sets of its edges and vertices.

Corner: A corner c associates a vertex $c.v$ with one of its incident triangles $c.t$.

Cascading corner operators: The notation $c.n.v$ stands for $(c.n).v$.

Next and previous corners: The two corners in $c.t$ other than c are denoted $c.n$ and $c.p$.

Incidence table: An array V of $3t$ entries, where $V[c]$ is denoted $c.v$ and contains a vertex Id. Entries for $c.p$, c , and $c.n$ are consecutive in V . Therefore, $c.t$ is the integer division $c.t \div 3$; $c.n$ is $c-2$, when $c \bmod 3$ is 2, and $c+1$ otherwise; and $c.p$ is $c.n.n$.

Opposite corner: Two corners c and b are opposite when $b.n.v=c.p.v$ and $b.p.v=c.n.v$. The opposite corner of c , denoted $c.o$, is a corner Id stored as the entry $O[c]$ in the O table.

Orientation: The orientation of a triangle $c.t$ is defined by the choice of $c.n$ amongst the other two corners of $c.t$. The mesh is globally oriented so that $c.n.v=c.o.p.v$ for all corners c .

Corner Table: The two arrays, V and O .

Left and right neighbors of a corner: For convenience, we define $c.l$ to be $c.n.o$ and $c.r$ to be $c.p.o$.

Vertex-Spanning Tree (VST): A subset of cycle-free edges connecting all of the vertices.

Cut-Edges: The edges contained in a given VST.

Cut: The union of the cut-edges with all of the vertices.

Hinge-Edges: Edges that are not cut edges.

Web: Union of all the faces and of all the hinge-edges.

Triangle-Spanning-Tree (TST): Rooted graph with hinge-edge links and triangle nodes.

54.1.1 TERMINOLOGY AND PROPERTIES

Consider a mesh with v vertices, e edges, and t triangles.

GEOMETRY AND INCIDENCE

A mesh is usually defined in terms of a set of *vertices* and its triangle-vertex *incidence*. The vertex description comprises *geometry* (three coordinates per vertex) and optionally *photometry* (surface normals, vertex colors, or texture coordinates), not discussed in this chapter. *Incidence* defines each triangle by three integer references identifying its vertices. Simple and regular data structures, such as the *Corner Table* described below, and formats, such as the *indexed face set* of VRML [VRML97] may be used for representing geometry and incidence.

An *uncompressed representation* uses $12v$ bytes for geometry and $12t$ bytes for incidence. Given that $t \approx 2v$, the total cost is $144t$ bits, of which two thirds are used for incidence.

CUT, WEB, AND SPANNING TREES

The vertices of a mesh that is homeomorphic to a sphere may always be placed on the plane so that the edges and vertices are mutually disjoint. The union of these edges and vertices partition the rest of the plane into *cells* that are each bounded by 3 edges and 3 vertices. One of the cells is unbounded. This mapping forms a *planar graph* of the mesh.

A *Vertex-Spanning Tree* (VST) of a triangle mesh is a subset of its edges, selected so that their union with all of the vertices forms a tree (connected cycle-free graph). We assume henceforth that a particular VST has been chosen for the mesh. The edges that it includes are called the *cut-edges*. The union of the cut-edges

with all the vertices is called a **cut**. Because the VST is a tree, there are $v - 1$ cut-edges.

We use the term **web** to denote the difference between the surface and the point-set of its cut. Edges that are not cut-edges are called **hinge-edges**. The web is composed of all of the faces and of all of the hinge-edges. Removing the loopless cut from the surface will leave a web that is a simply connected (relatively open), triangulated 2D point-set in $\mathbb{R}^3$. The web may be represented by an acyclic graph, whose nodes correspond to faces and whose links correspond to hinge edges. Thus there are $t - 1$ hinge edges.

Note that by selecting a leaf of this graph as root and orienting the links, we can always turn it into a binary tree, which we call the **Triangle-Spanning-Tree** (TST), and which is a spanning tree of the dual of the planar graph.

EULER EQUATION

Because an edge is either hinge or cut, the total number e of edges is $v - 1 + t - 1$. Each triangle uses 3 edges and each edge is used by 2 triangles. Thus the number e of edges is also equal to $3t/2$. Combining these two equations yields $t = 2v - 4$, a special case of Euler's formula $f - e + v = 2$.

54.1.2 CORNER TABLE REPRESENTATION

We present a simple data structure for meshes. We call it the Corner Table [RSS03] and use it to explain the details of connectivity compression.

DATA STRUCTURE AND OPERATORS

The corner table is composed of three arrays: G , V , and O .

The geometry is stored in the coordinate table, G , where $G[v]$, denoted v.g., contains the triplet of the coordinates of vertex number v . The order in which the vertices are listed in G is arbitrary, but defines the Id (integer) associated with each vertex.

Triangle-vertex incidence defines each triangle by the three Ids of its vertices, which are stored as consecutive entries in the **V-table**. Note that each one of the $3t$ entries in V represents a **corner** (association of a triangle with one of its vertices). Let c be such a corner. Let $c.t$ denote its triangle and $c.v$ its vertex. Recall that $c.v$ and $c.t$ are integers in $[0, v - 1]$ and $[0, t - 1]$, respectively. Let $c.p$ and $c.n$ refer to the **previous** and **next** corner in the cyclic order of vertices around $c.t$.

Although G and V suffice to completely specify the triangles and thus the surface they represent, they do not offer direct access to a neighboring triangle or

FIGURE 54.1.1

Corner operators for traversing and processing a corner table representation of a triangle mesh.

vertex. We chose to use the *opposite* corner Id , $c.o$, cached in the *O table* to accelerate mesh traversal from one triangle to its neighbors. For convenience, we introduce the operators $c.l$ and $c.r$, which return the *left* and *right* neighbors of c (Figure 54.1.1).

Given a corner c , the choice of which of the other two vertices of $c.t$ is $c.n$ defines one of two possible *orientations* for $c.t$. We assume that all triangles have been consistently *oriented*, so that $c.n.v = c.o.p.v$ for all corners c .

MESH TRAVERSAL ON A CORNER TABLE

Assume that the Boolean $c.t.m$ is set to TRUE when the triangle $c.t$ has been visited. The procedure: $visit(c) \{ \text{if } !c.t.m \text{ then } \{ c.t.m = \text{TRUE}; visit(c.r); visit(c.l) \} \}$ will visit all the triangles in a depth-first order of a TST.

THE COMPUTATION OF THE O-TABLE FROM V

Given the V-table, the entries in O may be computed by a double loop over corners, identifying the opposite corners. A faster approach sorts the triplets $\{\min(c.n.v, c.p.v), \max(c.n.v, c.p.v), c\}$ into bins. All entries in a bin have the same first record: $\min(c.n.v, c.p.v)$, an integer in $[0, v - 1]$. There are rarely more than 20 entries in a bin. Then, we sort the entries in each bin by the second record: $\max(c.n.v, c.p.v)$. Now, pairs with identical first two records are consecutive and correspond to opposite corners, identified by the third record in each triplet. Thus, if a sorted bin contains consecutive entries (a, b, c) and (a, b, d) , we set $c.o := d$ and $d.o := c$.

54.1.3 REDUCTIONS OF THE TRANSMISSION COST

Because it can be easily recreated, the O-table needs not be transmitted. Furthermore, the $31 - \log_2 v$ leading zeros of each entry in the V table need not be transmitted. Thus, a compact, but uncompressed representation of a triangle mesh requires $48t$ bits for the coordinates and $3t \log_2 t - 3t$ bits for the V-table.

54.2 GEOMETRY COMPRESSION

The compression of vertex coordinates usually combines three steps: quantization, prediction, and statistical coding. The combined three stages usually yield a 7-to-1 compression of geometry.

GLOSSARY

Normalization: Linear transformation of coordinates so that their range spans $[0, 2^B - 1]$.

Quantization: Rounding of each normalized vertex coordinate to the nearest integer.

Prediction: The prediction of the quantized location of a new vertex from its neighbors.

Parallelogram prediction: Using $\text{c.n.v.g} + \text{c.p.v.g} - \text{c.v.g}$ as a prediction for c.o.v.g.

Residues: The differences between the actual quantized coordinates and their prediction.

Statistical coding: A bit-efficient encoding of the residues, exploiting the bound on their magnitude and the statistics of the nonuniform distribution of their frequencies.

54.2.1 QUANTIZATION

The common use of *Floats* for vertex coordinates has three major drawbacks. First, the range of values that can be represented may significantly exceed the actual range covered by the vertex coordinates, and thus bit-combinations are “wasted on” impossible coordinates. Second, the distance between two consecutive coordinate values, i.e., the **round-off error**, is not uniformly distributed, but depends on the distance to the origin, thus providing more accuracy for some portion of the model than for others. Third, the **resolution** of the representation may significantly exceed what is required by the application.

Quantization addresses these three drawbacks. It truncates the vertex coordinates to a fixed accuracy, thus, by itself, reducing storage size while preserving an acceptable geometric accuracy. It starts with a **normalization** process, which computes a tight, axis-aligned bounding box. Then the longest dimension of the box is divided into 2^B segments or equal size, s . The other dimensions are also divided into cells of size s , possibly enlarging the box to have uniform cells. Thus, the normalization process divides the (enlarged) bounding box into cubic cells of size s . The vertices that fall inside a given cells are snapped to the cell center. Thus, the corresponding error is bounded by half of the diagonal of the cell. The number of bits required to encode each coordinate is less than B . Choosing $B = 12$ ensures a sufficient geometric fidelity for most applications and most models. Thus, this lossy quantization step, by itself, reduces the storage cost of geometry from $96v$ bits to $36v$ bits.

54.2.2 PREDICTION

The next and most crucial geometry compression step involves **vertex prediction**. Both the encoder and the decoder use the same predictor. Thus, only the **residues** between the predicted and the correct coordinates need to be transmitted. The **coherence** between neighboring vertices in meshes of finely sampled smooth surfaces limits the magnitude of the residues. For example, if the magnitude of the largest residue is less than 63 (quantized units), then the total cost for geometry drops to $21v$ bits (a sign bit and a 6-bit magnitude per coordinate). We describe below several predictors.

Because most edges are short with respect to the size of the model, adjacent vertices are in general close to each other and the differences between their coordinates are small. Thus a new vertex may be predicted by a previously transmitted **neighbor** [Dee95]. Instead of using a single neighbor, when vertices are transmitted in VST top-down order, a linear combination of the four ancestors in the VST

may be used [TR98]. The four coefficients of this combination are computed to minimize the magnitude of the residues over the entire mesh and transmitted as part of the compressed stream.

The most popular predictor for *single-rate compression* is based on the *parallelogram* construction [TG89]. Assume that the vertices of *c.t* have been decoded. We predict *c.o.v.g* using $\text{c.n.v.g} + \text{c.p.v.g} - \text{c.v.g}$. The parallelogram prediction may sometimes be improved by predicting the angle between *c.t* and *c.o.t* from the angles of previously encountered triangles.

54.2.3 STATISTICAL CODING

Some of the residues may be large. Thus, good prediction by itself may not lead to compression. For example, if the coordinates have been quantized to B -bit integers, some of the coordinates of the corrective vector, $\text{c.o.v.g} - \text{c.n.v.g} - \text{c.p.v.g} + \text{c.v.g}$ may require $B + 2$ bits of storage. Thus, parallelogram prediction may expand storage rather than compress it. However, the distribution of the residues is usually biased toward zero, which makes them suitable for statistical compression [Sal00].

For instance, assume that all residues are integers in $[-63, +63]$. Furthermore suppose that in 99% of the cases, the most significant bit of the magnitude of the residue is 0. The entropy of this bit is $-0.99 \log_2(0.99) - 0.01 \log_2(0.01)$, which amounts to 0.05 bit per coordinate. Arithmetic coding compression may be used to reduce the total storage size of these most significant bits close to its theoretical *entropy*. Furthermore, if in 95% of the cases the second most-significant bit of the residue magnitude is 0, its cost per coordinate may be reduced to 0.15 bits. If the third and fourth bits have respective probabilities of 90% and 80% of being zero, their respective costs are 0.50 and 0.72 bits per coordinates. Even if we assume no statistical compression of the sign and of the two least significant bits, the total cost per coordinate will be 4.42 bits per coordinate, or equivalently $13.3v$ bits.

54.3 CONNECTIVITY COMPRESSION

As discussed above, typically geometry may be encoded with $< 14t$ bits, i.e., $7t$ bits, provided that connectivity information is available during geometry decompression to locate previously decoded neighbors of each vertex along the surface. This section presents techniques for compressing the connectivity information from $3t(2v - 4) \log_2 v$ bits to bt bits, where b is guaranteed never to exceed 1.80 and in practice is usually close to 1.0. As a result, many meshes may be encoded with a total of less than $8t$ bits ($7t$ for geometry, $1t$ for connectivity) with a small error due to quantization.

Two observations could lead to misjudgement of the importance of incidence compression. (1) Some applications [ABK98] produce unorganized clouds of 3D point samples for which the incidence is derived algorithmically, and thus needs not be transmitted. (2) Recently developed graphic techniques for producing images of 3D surfaces directly from clouds of unstructured 3D samples [LW85] eliminate altogether the need for computing and transmitting the incidence information. Thus, one may conclude that it is not only unnecessary to transmit the incidence, but also unadvisable, considering that uncompressed, it is more expensive than geometry.

However, capturing and transmitting the incidence information has several important benefits. (1) Its reconstruction is a computationally expensive and delicate process; thus it is usually faster to transmit and decompress the incidence than to recompute it. (2) To correctly render a cloud of unstructured samples as a continuous surface, the samples must be uniformly distributed over the surface and the density of their distribution must ensure that the distance between neighboring samples along the surface is smaller than the size of the smallest feature. Incidence information permits significant reduction in the density of samples in low-curvature portions of the surface. Thus, the samples in nearly flat regions need not be transmitted, since their approximation will be reproduced automatically by the graphics rasterization at rendering time. (3) The most effective *geometry compression* techniques are based on the prediction of the location of the next vertex from the locations of its previously decompressed neighbors. Transmitting information describing who the previously decoded neighbors of each vertex are and how they are organized around a new vertex is equivalent to transmitting the incidence graph. (4) The incidence may be compressed to about a bit per triangle and thus the overhead of transmitting it is negligible when compared to the savings in geometry storage to which it leads.

GLOSSARY

Border edge: An edge of the recovered portion of the triangle mesh during decompression that has, so far, only one incident triangle. The natural orientation of a border edge is consistent with the orientation of the incident triangle.

Hole: A maximally connected component of the relative interior of the not-yet-recovered portion of the mesh.

Loop: A chain of border edges forming a closed manifold boundary of a hole.

Gate: The border edge where the next new triangle will be attached during decompression.

Active loop: The loop containing the gate.

Tip corner: The corner c of the new triangle, where $c.n.v$ and $c.p.v$ bound the gate.

Tip vertex: The vertex, $c.v$, associated with the tip corner, c .

Right edge: The edge joining $c.v$ and $c.n.v$, where c is the tip corner.

Left edge: The edge joining $c.p.v$ and $c.v$, where c is the tip corner.

Offset: The number of vertices in the active loop from the gate to the tip vertex of an S-triangle.

clers string: Connectivity encoding as a sequence of labels in C,L,E,R,S.

Valence (or degree): The number of triangles incident upon a given vertex.

54.3.1 EDGEBREAKER

Instead of retracing the chronological evolution of research results in the field of single-rate incidence compression, we first describe in detail Edgebreaker [Ros99],

one of the simplest and most effective single-rate compression approaches. The source code for Edgebreaker is publicly available.¹

Then, we briefly review several variants and other approaches, using Edgebreaker's terminology to characterize their differences and respective advantages.

The Edgebreaker compression visits the triangles in a spiraling (depth-first) TST order and generates the *clers string* of labels, one label per triangle, which indicate to the decompression how the connectivity of the mesh can be rebuilt by attaching new triangles to previously reconstructed ones. We first describe the Edgebreaker decompression process.

EDGEBREAKER DECOMPRESSION

During decompression, the reconstructed portion of the mesh is a surface with one or more holes, bounded by *loops* of oriented *border edges*. Each decompression step attaches a new triangle to a border edge, called the *gate*, in the active loop (Figure 54.3.1).

The labels in the *clers* string define where the tip of the new triangle is. Edgebreaker uses only five labels: C, L, E, R, and S. Label C indicates that the new triangle will have as tip a new vertex. We say that this triangle is of type C. Note that the three vertices of the triangle incident upon the gate have been previously decoded and may be used in a parallelogram prediction of the new vertex. The numbering of the vertices and hence their order in the G-table of the reconstructed mesh reflects the order in which the vertices are instantiated as tips of C-triangles.

L indicates that the tip vertex is the first border vertex on the left of the gate in the current loop (Figure 54.3.1). R indicates that the tip is the first border vertex on the right of the gate in the current loop. E indicates that the new triangle will close a hole bounded by the current loop, which therefore must have only three vertices. S indicates that the tip of the new triangle is elsewhere in the current loop. An S-triangle splits the current loop in two loops, as well as splitting the hole bounded by that loop into two holes. The one bounded by the right edge of the new triangle is the *right hole*. The other one is the *left hole* (Figure 54.3.2).

After the new triangle is attached, the gate is moved to the right edge of the new triangle for cases C and L. It is moved to the left edge for case R. When an

¹www.gvu.gatech.edu/~jarek/edgebreaker/eb

FIGURE 54.3.1

The terminology used to describe the Edgebreaker decompression.

S-triangle is attached, the gate is first moved to the right edge and the right hole is filled through a recursive call to decompression. Then the gate is moved to the left edge and the process resumes as if the S-triangle had been an R-triangle.

The reconstruction of the connectivity graph from the *clers* string is trivial, except for the S-triangles. Indeed, a C-triangle is attached to the gate and a new vertex is used for its tip. The tips of the L, R, and E triangles are known. The Id of the tip of each S-triangle could be encoded using $\log_2(k)$ bits, where k is the number of previously decoded vertices. A more economical approach is to encode an *offset* o indicating the number of vertices that separate the gate from the tip in the current loop (Figure 54.3.2). Because the current loop may include a large fraction of the vertices, one may still need up to $\log_2(k)$ bits to encode the offset. Although one may prove that the total cost of encoding the offsets is linear in the number of triangles [Gum99], the encoding of the offsets constitutes a significant fraction of the total size of the compressed connectivity. Hence, several authors strived to minimize the number of offsets [AD01b].

The author has observed [Ros99] that the *offsets need not be transmitted* at all, because they can be recomputed by the decompression algorithm from the *clers* string. The observation is based on the fact that the attachment of a triangle of each type changes the number of edges in the current loop by specific amounts (Figure 54.3.2). C increments the edge-count. R and L decrement it. E removes a loop of three edges and thus decreases the edge-count by 3. S splits the current loop in two parts, but if we count the edges in both parts, it increments the total edge count. Each S label starts a recursive call that fills in the hole bounded by the right loop and terminates with the corresponding E label. Thus **S and E** labels work as pairs of *parentheses*. Combining all these observations, we can compute the offset by identifying the substring of the *clers* string between an S and the corresponding E, and by summing the edge-count changes for each label in that substring. To avoid the multiple traversals of the *clers* string, all offsets may be precomputed by reading the *clers* string once and using a stack for each S.

The elegant *Spirale Reversi* approach [IS99] for decompressing *clers* strings that have been created by the Edgebreaker compression avoids this preprocessing by reading the *clers* string backwards and building the triangle mesh in reverse order.

A third approach, **Wrap&Zip** [RS99], also avoids the preprocessing and directly builds a Corner Table as it reads the *clers* string. It does not require maintaining a linked list of border vertices. For each symbol, as a new triangle is attached to the gate, Wrap&Zip fills in the known entries to the V and O-tables. Specifically, it fills in c.o for the tip corner c of the new triangle and for its opposite, c.o. It assigns vertex Ids for the tips of C-triangles as they are created, by simply incrementing a vertex Id counter. It defers assigning the Ids of other vertices until a Zip process matches them with vertices that already have an Id. Thus, it produces a *web*, as defined earlier. The border edges of the web must be matched into pairs. The correct matching could be specified by encoding the structure of the cut [Tur84] [TR98]. However, as discovered in [RS99], the information may be trivially extracted from the *clers* string by orienting the border edges of the web as shown in Figure 54.3.3. Note that these border-edge orientations are consistent with an upward orientation of the cut-edges toward the root of the VST.

The zipping part of Wrap&Zip matches pairs of adjacent border edges that are oriented away from their shared vertex. Only L and E triangles open new zipping opportunities. Zipping the borders of an E triangle may start a chain of zipping

operations (Figure 54.3.4). The cost of the zipping process is linear, since there are as many zipping operations as edges in the VST and the number of failed zipping tests equals the number of E or L-triangles.

GUARANTEED ENCODING OF THE CLERS STRING

Except for the first two triangles, there is a one-to-one mapping between each C-triangle and each vertex. Consequently, the number of C-triangles is $v - 2$, and the number of non-C-triangles is $t - (v - 2) = v - 2$. Thus exactly half of the triangles are of type C, and Edgebreaker guarantees a compression of not more than 2.0 bits per triangle [Ros99] using a trivial code, where the first bit is used to distinguish C-triangles from non-C-triangles.

Given that the subsequences CE and CL are impossible, a slightly more complex code [KR99] may be used to guarantee that the compressed file will not exceed $1.83t$ bits.

Further constraints exist on the *clers* string. For example, CCRE is impossible,

FIGURE 54.3.2

The five Edgebreaker mesh reconstruction operations attach a new triangle to the gate (indicated by a red line on the left column) in the active border loop around a hole in the partly reconstructed mesh. The C operation (top) creates a new vertex (v). The tip of the S-triangle (bottom) may be identified by an offset o . The S operation first puts the gate on the right edge of the new triangle and proceeds to fill the right hole using a recursive call. Then it sets the gate to the left edge of the new triangles and resumes the process. Note that C and S increment the edge count, L and R decrement it, and E reduces it by 3.

FIGURE 54.3.3

The borders of the web are oriented clockwise, except for the seed and the C triangles.

because CCR increments the length of the loop, which must have been at least 3. By exploiting such constraints to better estimate the probability of the next symbol, a more elaborate code was developed [Gum00], which guarantees $1.778t$ bits when using a forward decoding [RS99], and $1.776t$ bits when using a reverse decoding scheme [IS99]. Hence, the Edgebreaker encoding of the connectivity of any mesh (homeomorphic to a sphere) may be compressed down to $1.78t$ bits. This brings it within 10% of the proven $1.62t$ theoretical lower bound for encoding planar triangular graphs, as established by [Tut62], who by counting all possible planar triangulations of v vertices proved that an optimal encoding uses at least $v \log_2(256/7) \approx 3.245v$ bits, for a sufficiently large v .

STATISTICAL ENCODING

Recent developments in the guaranteed compression ratios discussed above not only have a theoretical importance, but ensure excellent and fast compression and decompression for meshes with irregular connectivity and for large collections of small meshes.

In practice, however, better compression ratios may often be obtained. For example, one may encode CC, CS, and CR pairs as single symbols. Each odd C symbol will be paired with the next symbol. After an even number of C symbols, special codes lead to a guaranteed $2.0t$ -bit encoding [RS99].

Furthermore, by arranging symbols into words that each start with a sequence of consecutive Cs and by using a *Huffman* code, we often reduce storage to less than $1.0t$ bits. For example, $0.85t$ bits suffice for the Huffman codes of the Stanford Bunny. Including the cost of transmitting the associated 173 word dictionary brings the total cost to $0.91t$ bits. A *gzip* compression on the resulting bit stream improves it only by 2%.

FIGURE 54.3.4

We assume that the part of the mesh not shown here has already been decoded into a web with properly oriented borders (exterior arrows). Building the TST (shown by the labeled triangles) for the substring CRSRLECRRRLE produces a web whose free borders are oriented clockwise for all non-C-triangles and counterclockwise for C triangles (left). Each time Wrap&Zip finds a pair of edges oriented away from their common vertex, it matches them. The result of the first zip operation (center) enables another zip. Repeating the process zips all the borders and restores the desired connectivity (right).

CONNECTIVITY PREDICTION

In addition to vertex location prediction, the connectivity of the next vertex may also be predicted using the same information. The *Delphi* connectivity prediction scheme [CR02] works as follows. The triangle connectivity, and its *clers* string produced by the Edgebreaker compression, is estimated by *snapping* the tip-vertex to the nearest bounding vertex of the active loop, if one lies sufficiently close. If no bounding vertex lies nearby, the next *clers* symbol is estimated to be a C. If the guess is correct, a single confirmation bit is sufficient. Otherwise, an entropy-based code is received and used to select the correct CLERS symbol from the other four possible ones (or the correct tip of an S-triangle). Experiments indicate that, depending on the model, up to 97% of Dephi's guesses are correct, compressing the connectivity down to $0.19t$ bits. When the probability of a wrong guess exceeds 40% the Delphi encoding ceases to be advantageous.

54.3.2 OTHER CONNECTIVITY COMPRESSION APPROACHES

CUT-BORDER MACHINE

Although invented independently, the *cut-border machine* [GS98] has strong similarities with Edgebreaker. Because it requires encoding the offset of S-triangles and because it was designed to support manifold meshes with boundaries, cut-border is slightly less effective than Edgebreaker. Reported connectivity compression results range from $1.7t$ to $2.5t$ bits. A context-based arithmetic coder further improves them to $0.95t$ bits [Gum99]. Gumhold proposes [Gum00] a custom variable length scheme that guarantees a total of less than $0.94t$ bits for encoding the offsets, thus proving that the cut-border machine has linear complexity.

TOPOLOGICAL SURGERY AND MPEG-4

Turan [Tur84] noted that the connectivity of a planar triangle graph can be recovered from the structure of its VST and TST, which he proposed to encode using a total of roughly $12v$ bits. There is a simple way to reduce this total cost to $6v$ bits by combining two observations: (1) The binary TST may be encoded with $2t$ bits, using two bits to indicate the presence or absence of left and right children. (2) The corresponding (dual) VST may be encoded with $1t$ bits, one bit per vertex indicating whether the node is a leaf and one bit indicating whether it is the last child of its parent. (Recall that $2v = t + 2$.) This scheme does not impose any restriction on the TST. Note that for less than the $2t$ bits budget needed for encoding the TST alone, Edgebreaker encodes the *clers* string, which not only describes how to reconstruct the TST, but also how to orient the borders of the resulting web, so as to define the VST, and hence the complete incidence. This economy comes from the fact that it uses a *spiraling* TST.

Taubin and Rossignac have noticed that a spiraling VST, formed by linking concentric loops into a tree, has relatively few branches. Furthermore, the corresponding dual TST, which happens to be identical to the TST produced by Edgebreaker, has also few branches (Figure 54.3.5). They have exploited this regularity by *Run Length Encoding* the *TST* and the *TST*. The resulting *Topological Surgery* compression technique [TR98] encodes the length of each run, the struc-

ture of the trees of runs, and a marching pattern, which encodes each triangle run as a generalized *triangle strip* [ESV96], using one bit per triangle to indicate whether the next triangle of the run is attached to the right or left.

An IBM implementation of the Topological Surgery compression has been developed for the VRML standard [THLR98] for the transmission of 3D models across the Internet, thus providing a compressed binary alternative to the original VRML ASCII format [VRML97], resulting in a 50-to-1 compression ratio. Subsequently, the Topological Surgery approach has been selected as the core of Three Dimensional Mesh Coding (3DMC) algorithm in *MPEG-4*, the ISO/IEC multimedia standard developed by the Moving Picture Experts Group for digital television, interactive graphics, and interactive multimedia applications.

Instead of linking the concentric rings of triangles into a single TST, the *layered structure* shown in Figure 54.3.5 (left) may be preserved [BPZ99]. The incidence is represented by the total number of vertex layers, and by the triangulation of each layer. When the triangle layer is a simpler closed strip, its triangulation may be encoded as a triangle strip, using one marching bit per triangle. However, in practice, a significant number of overhead bits are needed to encode the connectivity of more complex layers.

HARDWARE DECOMPRESSION IN JAVA 3D

Focusing on hardware decompression, Deering [Dee95] encodes generalized triangle strips using a buffer of 16 vertices. One bit identifies whether the next triangle is attached to the left or right border edge of the previous triangle. Another bit indicates whether the tip of the new triangle is a new vertex, whose location must be encoded in the stream, or a previously processed vertex that is still in the buffer and can hence be identified with 4 bits. Additional bits are used to manage the buffer and to indicate when a new triangle strips must be started. This compressed format is supported by the Java 3D's Compressed Object node.

Chow [Cho97] has provided an algorithm for compressing a mesh into Deering's format by extending the border of the previously visited part of the mesh by a fan of not-yet-visited triangles around a border vertex. When the tip of the new triangle is a previously decoded vertex no longer in the cache, its coordinates, or an absolute or relative reference to them, must be included in the vertex stream, significantly

FIGURE 54.3.5

The Topological Surgery approach merges concentric circles of triangles into a single TST (left). That TST and its dual VST have relatively few runs (right).

increasing the overall transmission cost. Therefore, the optimal encoding traverses a TST differently from the spiraling TST of Edgebreaker, so as to reduce cache misses.

VALENCE-BASED INCIDENCE COMPRESSION

A consequence of Euler's theorem is that the average vertex valence is 6. In fact, in most models, the valence distribution is highly concentrated around 6. For example, in a subdivision mesh, all vertices that do not correspond to vertices of the original mesh have valence 6. To exploit these statistics, Touma and Gotsman [TG89] have developed a valence-based encoding, which visits the triangles in the same order as Edgebreaker. They encode the distinction between the C- and the S-triangles as in Edgebreaker, but instead of encoding the symbols for L, R, and E, they encode the valence of each vertex and the offset for each S-triangle. When the number of incident triangles around a vertex is one less than its valence, the missing L, R, or E triangle may be completed automatically. For this scheme to work, the offset must not only encode the number of vertices separating the gate from the tip of the new S-triangle along the border, but also the number of incident triangles on the tip that are part of the right hole.

Only one bit is needed to distinguish a C from an S. Given that 50% of the triangles are of type C and usually about 5% of the triangles are of type S, the amortized entropy cost of that bit is around $0.22t$ bits. Therefore, about 80% of the encoding cost lies in the valence, which has a low entropy for regular and finely tessellated meshes, and in the encoding of the offsets. To fix ideas, consider the example where 80% of the vertices have valence 6. A bit used to distinguish them from the other vertices may be encoded using $0.36t$ bits. The amortized cost of encoding the valence of the other 20% vertices with 2 bits each is $0.40t$ bits. Thus, the valence of reasonably regular meshes may be encoded with $0.76t$ bits. If 5% of the triangles are of type S and each offset is encoded with an average of 5 bits, the amortized cost of the offsets reaches $0.25t$ bits. Thus, offsets add about 25% to the cost of encoding the C/S bits and the valence.

Alliez and Desbrun [AD01a] managed to significantly reduce the number of S-triangles, and thus the cost of encoding the offsets, by using a heuristic that selects a gate with a low probability of producing an S-triangle. They also show that if one could eliminate the S-triangles completely, the valence-based approach would guarantee to compress the mesh with less than $1.62t$ bits, which happens to be Tutte's lower bound [Tut62].

An improved Edgebreaker compression approach was proposed [SKR00] for sufficiently large and regular meshes. It is based on a specially designed context-based coding of the *clers* string and uses the Spirale Reversi decompression. For a sufficiently large ratio of degree-6 vertices and sufficiently large t , this approach guarantees a worst-case storage of $0.81t$ bits.

54.4 SURFACE SIMPLIFICATION

Most of the details are usually far from the viewer. Their perspective projections on the screen appear small and thus need not be displayed at full resolution. Therefore, to avoid transmission delays, only crude approximations (called **Levels-**

of-Detail) will be transmitted initially. They are produced by single-resolution *simplification* processes discussed in this section. The use of LODs as a technique for accelerating graphics is supported in graphics libraries, such as OpenGL. We do not discuss here the image-based techniques that replace such distant models with *imposters* [DSSD99] made by pasting, as textures, low-resolution images of them onto simple polygons. Instead, we focus on techniques that reduce the triangle count while striving to minimize the error introduced by the simplification. The connectivity and geometry of these simplified models may be compressed using the single-rate compression techniques discussed above. Refinements that upgrade their fidelity may be transmitted later, if at all needed.

We can simplify the mesh by moving one or more vertices to *collapse* one or more triangles, which may then be identified and discarded. Removing a collapsed triangle from the new mesh will not affect the surface, but may create a hole in the connectivity graph. For example, removing a single triangle that has been collapsed by displacing one of its vertices to the mid-point of the opposite edge will create a topological hole sometimes called a “T-junction.” Therefore, we will only remove triangles that have 2 or 3 coincident vertices. The two main simplification approaches, *vertex clustering* and *edge collapse*, are discussed below.

GLOSSARY

Uniform LOD: A simplified model constructed by striving to maintain a uniform distribution of error between the original and the simplified model.

View-dependent LOD: A simplified model created by adjusting the tolerance to a particular set of view parameters, e.g., increasing the accuracy of the approximation close to the viewer and to the visible silhouettes of the model.

Multi-Resolution Model (MRM): A representation from which view-dependent LODs may be efficiently extracted as the viewpoint is displaced.

Vertex-Clustering Simplification: A mesh simplification process that collapses clusters of vertices with identical quantized coordinates to one representative vertex and removes collapsed triangles when redundant.

Edge-collapse: A simplification step that collapses pairs of edge-connected vertices along nearly straight edges or nearly flat regions. Each edge-collapse also collapses two triangles, which may be removed.

Silhouette: The union of the edges of a mesh that are bounded by a front and a back-facing triangles.

Hausdorff distance: The Hausdorff deviation $H(A, B)$, between two sets, A and B , is the largest distance between a point in one of the sets and the other set.

Quadric error: The sum of the squares of the distances between a new position of a vertex v and planes that contain the triangles incident upon v in the original mesh.

54.4.1 VERTEX CLUSTERING

Vertex clustering [RB93], among the simplest simplification techniques, is based on a crude vertex *quantization*, obtained by imposing a uniform, axis-aligned grid

(Figure 54.4.1) and clustering all vertices that fall in the same grid cell. The simplest implementation of vertex clustering associates each vertex v with a cell number $v.cell$ computed by concatenating its three quantized coordinates. The quantized version, x' of the x coordinate is the integer part of $s_x(x - x_{min})/(x_{max} - x_{min})$, where s_x is the number of cells in the x direction. Similar expressions are used for quantizing the y and z coordinates. If one wishes to guarantee a uniform error, $\{s_x, s_y, s_z\}$ are chosen so that the $\{x, y, z\}$ dimensions of each cell are nearly identical. The computational cost of this quantization pass is linear and does not require accessing any connectivity or incidence information. One may think of $v.cell$ as the *cluster name* for the vertices in it.

A second pass selects a *representative vertex* for each cluster. It is often preferable to use one of the vertices of the cluster, rather than to create a new location for the representative vertex. Picking the vertex closest to the average of the cluster vertices has a tendency to shrink the objects. Rossignac and Borrel [RB93] found that the vertex furthest from the center of the model's bounding box is a better choice (Figure 54.4.1). Even better choices may be obtained by using more expensive schemes, which weigh vertices based on the local curvature or on the probability that they would be on a *silhouette* of the object, when seen from a random direction, and then select the closest vertex to the weighted average in each cluster.

Rendering all of the triangles of the original mesh with each vertex replaced by its cluster representative will produce an image of the simplified model; see Figure 54.4.1. To reduce the redundancy of this representation, one may choose to identify and eliminate all degenerate triangles, which may be done in a single pass over all triangles. Note, however, that groups of triangles that model thin branches or small shells may collapse to dangling edges or to isolated points. It would be simple to remove them by not drawing zero-area triangles. However, this option would result in a loss of information about the presence of the object along these thin branches or in the small isolated components. Therefore, these dangling edges and vertices are usually identified and preserved. Consequently, a third step of vertex clustering removes all degenerate triangles that have 2 or 3 vertices in the same cluster, but also creates a list of dangling edges and isolated vertices.

To identify dangling edges and vertices, one can construct a list of six triplets, one per triangle, using the three cluster names of its vertices in all possible permutations. This list may be sorted efficiently by using hashing on the first cluster name in each triplet. All entries $\{a, b, c\}$ that start with $\{a, b\}$ are consecutive. If the third element c in all of them is either a or b , then (a, b) is a dangling edge. Similarly, if all entries that start with $\{a\}$ are of the form $\{a, a, a\}$, then a is an isolated vertex.

This vertex clustering approach has been used in several commercial systems as a simplification tool for accelerating the rendering of 3D models (such as IBM's 3DIX and OpenGL), not only because of its simplicity and speed, but also because it does not use adjacency information beyond the triangle/vertex incidence table, and because it may be applied to arbitrary collections of triangles, edges, and vertices, with no topological restrictions. For example, it may, in a single process, simplify 3D models of solids and 2D models of their drawings, including vector-based text and mark-up.

A second vertex clustering phase with a coarser grid may be applied to the LOD produced by a first pass. Repeating this process produces a series of LODs that all use the same initial vertex set. When, for each LOD, the cell size is reduced by two

in each dimension, the vertex clusters correspond to a hierarchy of clusters, which may be stored in an octree [Sam90]. Luebke [LE97] has used vertex clustering with such an octree to support view-dependent simplification.

Clearly, no vertex has moved by more than the length of the diagonal of a cell, and thus this length offers a bound on the maximum geometric error between the original shape and the simplified one. This is a tight bound on the Hausdorff distance between the two shapes, which may be of considerable importance to manufacturing, robotics, and animation applications where computing clearance and detecting interferences and collisions is important.

Unfortunately, vertex clustering rarely offers the most accurate simplification for a given triangle-count reduction. One of its problems lies in the fact that the result is affected by the grid alignment, which may split nearby vertices into separate clusters, and replace them with distant representatives. Allowing the cells to float a bit [LT97] considerably improves the quality of some models, although at the expense of a slightly higher computational cost.

A more delicate problem may be illustrated by considering the 3D triangulated model of a scanned shape whose vertices have been sampled on a regular grid. If we use a large cell size, important features of the mesh will be simplified. If we use a small cell size, the triangulations of flat or nearly flat portions of the surface will retain an excessive triangle count, because their vertices are not allowed to slide along the surface past their cell boundaries. To overcome this constraint, we would like to have cluster cells that form *slabs* around the surface, with a small thickness in the normal direction that captures the tolerance, but with a wide tangential spread over flat areas. Clearly, if a manifold vertex has all its neighbors in such a slab, then moving it to one of its neighbors will not result in an error that exceeds the tolerance. By progressively adjusting the slab, several techniques identify simply connected groups of coplanar or nearly coplanar triangles and then retriangulate their surface to eliminate interior vertices [KT96]. Instead of local slabs, Cohen et al. [Co⁺96] compute offset surfaces, called *envelopes*, that bound a tolerance zone around the surface, which is used to constrain vertex merging operations.

54.4.2 EDGE COLLAPSING

Collapsed triangles may be created by edge-collapse operations (Figure 54.4.2), which each merge two vertices and collapse two triangles. These collapsed triangles may be easily removed from the connectivity graph. For example, to update a Corner Table, we identify the collapsed edge by a corner *c* (Figure 54.4.2) and use it to access the corners of the neighboring triangles. We mark the corners of the collapsed triangles as “unused.” Then the V- and O-tables are updated in the natural way. See Figure 54.4.3 for an example.

Note that these updates assume that we have a manifold representation. Hence, most simplification techniques preclude topology-changing edge-collapses, which for example would create dangling edges or nonmanifold vertices. Many of the algorithms also assume that each vertex of the mesh has at least three incident triangles, and that no two edges have identical endpoints. Edge-collapses that violate these restrictions may be easily detected and prevented. Thus, the triangle-count reduction capacity of the restricted simplification may be reduced for objects with many holes or thin branches, such as the chair of Figure 54.4.1.

A simplified mesh may be produced by a sequence of edge-collapse opera-

tions [Hop96]. Most simplification techniques strive to select at each stage the edge whose collapse will have the smallest impact on the total error between the resulting simplified mesh and the original surface. Deciding how the error should be measured is delicate and computing it precisely is time consuming. Therefore, most simplification approaches are based on a compromise where the error is estimated, as discussed below. These estimates are used to select the best candidate for the next edge-collapse. Error estimates for portions of the mesh that have been affected by prior collapses must be updated. A priority queue is used to maintain a sorted list of candidates.

54.4.3 MIXED APPROACHES

FIGURE 54.4.1

Left: vertex clustering simplification on a 2D mesh. Top left: grouping vertices; top right: cluster representative vertex. Bottom left: degenerate triangles removed; bottom right: all vertices replaced by cluster representative, dangling edges and isolated vertices added. Right: simplified coarse approximation.

FIGURE 54.4.2

Collapsing the fat edge (left) to one of its vertices collapses its two incident triangles (center). The corner table of the collapsed mesh may be updated using the corner c (right). The reverse of an edge-collapse is a vertex-split.

It is also possible to combine vertex-clustering and edge-collapse approaches. For example, vertex-clustering may be used as a geometric and topological filter to remove small features, such as holes or bumps. Then, the result may be simplified through an edge-collapse process, which is better suited for removing redundant samples along flat portions of the surface and along nearly linear edges. The error resulting from this combination is bounded by the sum of the cell diagonal used in vertex clustering plus the estimate of the worst case error produced by edge collapsing.

In order to prevent topology changes and still exploit the speed and simplicity benefits of vertex clustering, one may split the cluster of vertices within a given cell into edge-connected sub-clusters. Collapsing each sub-cluster into a separate representative vertex will not merge disconnected components, but can still create nonmanifold singularities and dangling faces and edges. A local topology analysis may be conducted to detect and prevent these collapses. Such a combination of vertex clustering and edge-collapse was exploited for performing out-of-core simplification [Lin00] of datasets that are too large to fit in memory and thus would make the random access to the vertex data and connectivity tables, which are performed by edge-collapsing operations, too expensive.

Finally, several authors [PH97] [Lue98] have extended edge-collapsing simplifications by adding *virtual edges*, which are computed using vertex clustering and make it possible to merge components and to deal with nonmanifold meshes.

54.4.4 ERROR MEASURES

The error between two shapes could be measured in *image space*, as the discrepancy between the colors of the pixels for a particular set of views [LRC⁺02] [Lin00]. However, such error measures rely on assumptions as to how a particular color change or displacement of the projection of a highlight or color discontinuity on the screen impact the perceived fidelity of the image. They also require a fine sampling of the higher dimensional space of view parameters, and are thus expensive to compute.

The geometric error between the projection of the two shapes on the screen

FIGURE 54.4.3

The 3D model (left) has been simplified by a sequence of edge-collapses to a model with a much lower triangle count (right).

can be formulated more objectively, but is also view-dependent. For example, it may be formulated as the discrepancy between the projections of the silhouettes and sharp edges of both shapes.

Thus, most simplification techniques are based on a view-independent error formulation. The error, $E(A, B)$, between a shape A and a shape B may be formulated as the maximum of the distance, $d(p, S)$, from all points p on A or B , to S , the other shape, (B or A , respectively). This formulation is equivalent to the **Hausdorff** distance $H(A, B)$, which may also be formulated as the smallest radius r , such that $A \subset B \uparrow r$ and $B \subset A \uparrow r$, where $S \uparrow r$ denotes the expanded set S obtained by replacing each point q of S by a ball of center q and radius r . The distance $d(p, S)$ may be computed as the minimum of distances between p and the vertices of S , the normal projections of p onto the edges of S , and the normal projections of p onto the interiors of the triangles of S .

The difficulty in computing $H(A, B)$ lies primarily in the fact that it is not sufficient to test $d(p, S)$ for all vertices p of A and B , because the maximum error may occur at points inside faces, not at vertices or edges. Consequently, the exact Hausdorff measure is often approximated by **super-sampling** the two surfaces and computing the Hausdorff distance between the two dense sets of samples. The popular **Metro** tool [CRS98] super-samples one surface only and computes the maximum of the distance between the samples and the other surface.

Another drawback of the Hausdorff distance is that it does not require a good mapping from one shape to the other and fails to identify for example the fact that nearby and parallel portions of the two surfaces may have opposite orientation.

Thus, most simplification algorithms use a local error estimation. Consider a vertex that has moved from its initial position v to a new position v' , as a result of a vertex clustering step or of a series of edge-collapses. The distance $\|vv'\|$, which is bounded by the cell diagonal in the vertex clustering approach, provides a conservative bound on the Hausdorff error resulting from this displacement. However, it is too conservative when the mesh was nearly planar in the vicinity of v and when the vector vv' is tangent to the surface. Clearly, we want to measure the component of the displacement of that vertex along the normal to the surface.

The error resulting from the collapse of a vertex v_1 to its neighbor v_2 , can be estimated by the dot-product $v_1 v_2 \cdot N_1$, where N_1 is the surface normal computed at v_1 . Although simple, this formulation does not guarantee a conservative error bound.

Ronfard and Rossignac [RR96] used the maximum of the distance between the new position of v' and the planes that contain the original triangles incident upon v . The distance between v' and the plane containing vertices (v, a, b) is $vv' \cdot (va \times vb) / \|va \times vb\|$. The right term may be pre-computed and cached for each triangle in the original mesh using its vertices v , a , and b . Note that for very sharp edges and vertices, an additional plane is necessary to measure excursions of v' that would be tangential to all the faces incident upon v and yet would move away from the surface. That normal to that additional plane may be estimated using the surface normal estimation at v . The cost of this approach lies in the fact that, as vertices are merged through series of edge collapses, one needs to keep track of the list of all the planes that contain the triangles incident to these vertices in the original model. Furthermore, for each new edge-collapse candidate, the distance between the new position v' must be computed to all these planes. If the edge collapse is executed, the lists of planes must be merged.

By trading the conservative maximum error bound of [RR96] for a quadratic

error measure, Garland and Heckbert [GH98] have considerably reduced the computational cost of error estimation. The square of the distance $D_1(P)$ between a point P and the plane $\text{Plane}(Q_1, N_1)$ through a point Q_1 with unit normal N_1 , is $(N_1 \cdot Q_1 P)^2$. It is a quadratic polynomial in the coordinates (x, y, z) of P .

Based on this observation, in a preprocessing stage, we pre-compute the 10 coefficients of $D_1(P)$ for each corner c_k , considering Plane $(c_k.v.g, N_k)$, where the normal N_k is computed as $(c_k.p.v.g - c_k.v.g) \times (c_k.p.v.g - c_k.v.g)$. Note that N_k is not a unit vector. Its length is proportional to the area of c.t. Then for each vertex v_m , we compute the coefficients by adding the respective coefficients of its corners. They define the function D_m associated with that vertex.

During simplification, we estimate the cost of an edge collapse that would move a vertex v_1 to a vertex v_2 , by $D_1(v_2)$. We perform the collapse with the lowest estimate and add to each coefficients of D_2 the corresponding coefficient of D_1 .

54.4.5 OPTIMAL QUANTIZATION FOR EACH LOD

Assume that simplification produces a mesh A that approximates the original mesh O within a conservative sampling error estimate e_S . The vertex quantization performed during the compression of A will produce a mesh C with a quantization error e_Q with respect to A. Thus, the conservative bound on the total error is $e_S + e_Q$. How should we choose the optimal combination of a triangle count t for A and of the number B of bits used by the quantization? Assume for instance that we have a fixed bit budget. If we use a LOD with too many triangles, we will have very few bits per coordinate, and thus will need to quantize them drastically. Given the magnitude of the resulting quantization error, we may decide that the model is over-sampled, and that we are better off by increasing B and using a lower LOD. Setting $e_S = e_Q$ yields a solution that is in general significantly suboptimal. An approximate solution to this optimization problem has been derived [KRS99] by formulating e_S as $K(t)/t$, and by approximating the shape complexity function $K(t)$ by a constant K , which may be estimated from a curvature integral over the model. In fact, for a sphere, $K(t)$ is constant.

54.5 RE-SAMPLING

The simplification approaches described above reduce the sampling of the mesh, while decreasing its accuracy. They strive to minimize the estimated error for a given vertex count reduction. In contrast, the re-sampling techniques described in this section strive to reduce storage cost while maintaining an acceptable accuracy. They are based on two strategies: (1) increase the regularity of the connectivity of the mesh, so as to increase connectivity compression; (2) constrain each new vertex to lie on a specific curve, so as to reduce to one the number of coordinates that must be specified per vertex.

GLOSSARY

Regular subdivision: A sequence of mesh refinement steps, each of which in-

serts new vertices in the middle of the edges and splits triangles into four. The positions of the new and old vertices are adjusted by a vector computed from the neighboring vertices.

Wavelet compression: A hierarchical encoding of regularly spaced data as a series of residues to values predicted by interpolation from a coarser model.

Normal meshes: The interleaving of mesh refinement steps with displacement steps, which adjust the inserted vertices along estimated surface normal. Statistical properties of the adjustments make them suitable for wavelet compression and progressive transmission.

54.5.1 REPULSION-BASED RETILING

An early simplification technique based on re-sampling [Tur92] first places *samples* on the surface of the mesh and distributes them evenly through an iterative process using *repulsive forces* computed from estimates of the geodesic distances [PS99] between samples. The repulsive forces may be adjusted taking local curvature into account so as to increase sample density in high curvature areas. Then it refines the mesh by inserting these samples as new vertices and hence splitting the triangles that contain them. Finally, the old vertices are removed through edge-collapse operations that preserve topology. This elegant process acts as a low pass filter and produces pleasing simplifications for smooth surfaces. Unfortunately, it may produce unnecessarily large errors near sharp features and does not reduce the cost of encoding the vertices.

54.5.2 NORMAL MESHES

Another approach [KSS00] uses the MAPS algorithm [LSS⁺98] to compute a crude LOD, which can be compressed using any of the single-rate compression schemes discussed above. Once received and restored by the decompression module, the crude LOD is used as the coarse mesh of a subdivision process. Each subdivision stage splits each edge of the mesh into two and each triangle into four, by the insertion of one new vertex per edge. They use the **Loop** subdivision (Chapter 53), which splits edge $(c.n.v, c.p.v)$ by inserting point $(c.v.g + c.o.v.g + 3c.n.v.g + 3c.o.v.g)/8$ and then moves the old vertices by a fraction toward the average of their old neighbors.

After each subdivision stage, they download a displacement field of corrective vectors and use them to adjust the vertices, to bring the current level subdivision surface closer to the desired surface. The distribution of the coefficients of the corrective vectors is concentrated around zero and their magnitude diminishes as subdivision progresses. They are encoded using a wavelet transform and compressed using a modified version of the SPIHT algorithm [SP96] originally developed for image compression.

Instead of encoding corrective 3D vectors, the **Normal Mesh** approach [GVSS00] restricts each offset vector to be parallel to the surface normal estimated at the vertex. Only one corrective displacement value needs to be encoded per vertex, instead of three coordinates. They use the **Butterfly subdivision** [DLG90], which preserves the old vertices, and for each pair of opposite corners c and $c.o$ splits the edge $(c.n.v, c.p.v)$ by inserting a point computed from 8 vertices.

They encode the corrective displacement values of each new vertex using the unlifted version of Butterfly wavelet transform [DLG90] [ZSS96]. Further subdivision stages will generate a smoother mesh that interpolates these displaced vertices. The difficulty of this approach lies in the computation of a suitable crude LOD and in handling situations where no suitable displacement may be found for a new vertex along the estimated surface normal, because for example the normal does not intersect the original mesh. Furthermore, that original mesh and the connectivity constraint imposed by the regular subdivision process limit the way in which the retiling can adapt to the local shape characteristics, and thus may result in less effective compression ratios. For example, regular meshes may lead to sub-optimal triangulations for surfaces with high curvature regions and saddle points, where vertices of valence different than 6 are more appropriate.

54.5.3 PIECEWISE REGULAR MESHES

The surface of the mesh may be algorithmically decomposed into *reliefs* [SRK02]. Each relief may be re-sampled by a regular grid of parallel rays. Triangles are formed between samples on adjacent rays and also, to ensure the proper connectivity, at the junction of adjacent reliefs.

The sampling rate (i.e., the density of the rays) may be chosen so that the resulting Piecewise Regular Mesh (PRM) has roughly the same number of vertices as the original mesh. In these situations, the PRM typically approximates the original mesh with the mean square error of less than 0.02% of the diameter of the bounding box. Because of the regularity of the sampling for each relief, the PRM may be compressed for both connectivity and geometry down to about $2t$ bits.

The PRM compression algorithm uses a modified version of the Edgebreaker compression and of the Spirale Reversi decompression to encode the global relief connectivity and the triangles which do not belong to the regular regions. First, Edgebreaker compression is used to convert the mesh to be encoded into a CLERS string. Then, the CLERS string is turned into a binary string using the context-based range, which reduces the uncertainty about the next symbol for a highly regular mesh.

The geometry of the reliefs is compressed using an iterated two-dimensional variant of the differential coding [Sal00]. The regular resampling causes the entropy of the parallelogram rule residues to decrease by about 40% when compared to the entropy for the original models, because on reliefs, two out of three coordinates of the residual vectors become zero.

Since this approach does not require global parametrization, it may be used for models with complex topologies. It is faster than the combination of the MAPS algorithm [LSS⁺98] and the wavelet mesh compression algorithm of [GVSS00] [KSS00], while offering comparable compression rates.

54.5.4 SWINGWRAPPER

The *SwingWrapper* approach [AFSR03], shown in Figure 54.5.1, partitions the surface of an original mesh M into simply connected regions, called *triangloids*. From these, it generate a new mesh M' . Each triangle of M' is a linear approximation of a triangloid of M . By construction, the connectivity of M' is fairly regular,

and can be compressed to less than a bit per triangle using EdgeBreaker. The locations of the vertices of M' are compactly encoded with a prediction technique that uses a single correction parameter per vertex. Instead of using displacements along the surface normal or heights on a grid of parallel rays, SwingWrapper requires that all C-triangles be isosceles, with left and right edges having a prescribed length L . SwingWrapper strives to reach a user-defined output file size rather than to guarantee a given error bound. For a variety of popular models, a rate of $0.4t$ bits yields a mean square error of about 0.01% of the bounding box diagonal.

54.6 PROGRESSIVE TRANSMISSION

When the full resolution model of a mesh is unnecessary or when immediate graphic feedback is needed, a compressed crude model obtained through simplification or resampling is downloaded first. Then, later, if a higher resolution is required, the full-resolution mesh could be downloaded using a compact encoding produced by a single-rate compression. When the storage size of the compressed crude model is small compared to the storage size of the full mesh, the overhead of transmitting both, instead of the full mesh only, is small. Yet, the benefits are considerable if the full model never becomes necessary or if the user is not willing to wait for the full resolution model. However, in this binary mode scenario, when the accuracy of the crude model is no longer sufficient, the delay associated with downloading the full resolution mesh could be avoided if an intermediate resolution model could be downloaded instead and would provide sufficient accuracy. In fact, it may be desired to offer a series of intermediate LODs. Each one could be compressed independently using a single-rate compression scheme.

FIGURE 54.5.1

The original mesh (left) containing 134,074 triangles requires 4,100,000 bytes, when stored in the WRL format. A dense partitioning of its surface into triangloids (2nd) yields a retiled mesh (3rd) which deviates from the original by less than 0.6% of the radius of the smallest ball bounding the model. Its 13642 triangles are encoded with $3.5t$ bits. The resulting total of 6042 bytes represents a 678-to-1 compression ratio. A coarser partitioning (4th) decomposes the original surface into 1505 triangloids. The corresponding retiled triangle mesh (last) approximating the original model within 4% is encoded with 980 bytes: A 4000-to-1 compression.

The shortcoming of this “independent” approach lies in the fact that the transmission does not take advantage of the information already available at the client side. For example, if the accuracy requirements increase progressively, and the client ends up downloading 10 different LODs, each having twice more vertices than the previous one, the total cost for a mesh will be about $(1+2+4+8+\dots+1024)t/1024$ bytes, which is $2t$ bytes, or twice the cost of transmitting the full-resolution mesh. In fact the total cost will be somewhat higher, because the geometry and connectivity of crude models is less regular and will in general not compress to a byte per triangle.

This shortcoming may be addressed by using a *progressive transmission* approach where the connectivity and geometry of previously decoded LODs is exploited to reduce the transmission cost of the next LOD. Most progressive approaches compress the upgrade, which contains the description of where new vertices should be inserted, i.e., their location and the associated connectivity changes.

GLOSSARY

Vertex split: The inverse of an edge-collapse operation. It is specified by selecting a vertex v and two of its incident edges.

Upgrade: The information permitting to refine an LOD to a higher accuracy LOD.

Compressed Progressive Meshes: A representation combining a single-rate compression of the lowest LOD with compressed encodings of the successive upgrades.

54.6.1 PROGRESSIVE MESHES

The progressive transmission of compressed meshes started with Hoppe’s *Progressive Meshes (PM)* [Hop96]. It encoded the coarsest LOD and a series of vertex-split operations, which when applied to the coarse mesh reverses the sequence of simplifying edge-collapse operations that were used to create it. The advantage of PM is its ability to stop transmission at any desired accuracy, thus offering the finest granularity of upgrades, each one being a vertex-split. The compression effectiveness of PM is limited by its need to encode the absolute index of the vertex at which the vertex-split occurs. That index requires $\log_2(n)$ bits, where n is the number of vertices decoded so far.

54.6.2 COMPRESSED PROGRESSIVE MESHES

By grouping the vertex splits into batches, the *Compressed Progressive Mesh (CPM)* [PR00] eliminates the $\log_2(v)$ cost replacing the vertex indexing by a one-bit-per-vertex mask. When combined with a modified Butterfly geometry predictor estimating the location of each new vertex from its neighbors, it achieves about $11t$ bits for a combined transmission code of the complete geometry ($7.5t$ bits) and connectivity ($3.5t$ bits), while offering between 7 and 12 intermediate LODs for common meshes.

The approach is illustrated in Figure 54.6.1.

54.6.3 EDGE-MASKS

The Wavemesh of Valette and Prost uses a batch strategy similar to CPM, but uses the mask to mark the edges that must be split [VP04]. They use a new simplification algorithm, which removes vertices in an order that permits recreation of the original connectivity with a small number of additional bits (above the cost of the mask). Experimental results suggest that the average cost for encoding the complete connectivity of the progressive mesh ranges from $1.0t$ bits to $2.5t$ bits for commonly used meshes.

54.6.4 KD-TREES

Gandoin and Devillers [GD02] use a hierarchy of vertex clustering [RB93]. However, instead of an octree, as in [Lue98] they use a k -d-tree. At an x -split node they split the parent's area in two equal parts by a plane orthogonal to the x -axis and store the number of vertices in the left child. This adaptive organization of the vertices leads to the factorization of the most significant bits of the x -coordinate. The alternating y -split and z -split nodes perform a similar split, but with a different orientation of the splitting plane.

Thus, the coordinates of the centers of the leaves of the k -d-tree are defined implicitly by their position in the tree. The cost of storing them lies in the cost of encoding the numbers of vertices in the left child of each node. When only one vertex lies in a node, its least significant bits that have not been factored in the structure of the tree must be encoded.

When moving down the tree, each parent vertex is split into two vertices, which may, but need not, be connected. Thus, the connectivity may be encoded as a series of possibly nonmanifold vertex-splits, as proposed in [PH97]. The total cost of

FIGURE 54.6.1

The coarse mesh (left) produced by an edge-collapsing simplification is refined by a CPM upgrade which inserts new vertices and new triangles (center). The higher LOD is shown (right).

transmitting a progressive mesh compressed with this approach comprises $1.8t$ bits for the connectivity and about $7.8t$ bits for the geometry, when the original vertex coordinates have been quantified to 12 bits each.

54.6.5 VALENCE DRIVEN CONQUEST

To exploit the regularity of distribution of vertex degrees (or valences), which are concentrated around 6, Alliez and Desbrun [AD01a] use a series of passes to produce decreasing LODs. Each pass reduces the number of triangles by 3 by combining three steps that each traverses the mesh in a breadth-first order. The first one removes the tip vertices of triangles that have a valence of less than 7, leaving polygonal holes in the mesh. It also tags the remaining vertices. The second phase uses these tags to retriangulate the holes, striving to create vertices with valence 3 or 9. The third one removes valence-3 vertices. Because the decimation follows a systematic traversal, it can be reversed by decompression. The upgrade information for each pass contains the degree of the vertices removed during the first step (which must be 3, 4, 5, or 6) and an encoding of the traversal irregularities. These connectivity upgrades may be compressed to an average of $1.9t$ bits, which corresponds to a 40% improvement over CPM [PR00]. However, the selection of which vertices are removed at each phase is only dictated by the connectivity and cannot take into account the geometry, and thus cannot favor vertices whose removal will have the lowest impact on the geometric error. Consequently, this approach will produce intermediate models which for the same triangle count will be less accurate than those produced by CPM.

54.6.6 PROGRESSIVE NORMAL MESHES

By exploiting the hierarchical nature of the wavelet formulation, the normal meshes provide an effective progressive transmission scheme, in which the bits of the coefficients are transmitted in the order of their importance [SP96] [Sha93]. For the same transmission cost, this approach yields fourfold better accuracy than CPM [PR00]. In fact, the total cost of transmitting the highest accuracy mesh is often lower than one offered by the best single-rate compression schemes [TG89]. However, this approach is not capable of restoring the original mesh for two reasons: (1) it has the semiregular connectivity of a subdivision mesh and (2) the constraints on vertex locations make it impossible to restore the original surface.

54.7 SOURCES AND RELATED MATERIAL

SURVEYS

Simplification techniques have been surveyed in [HG97] [PS97] and more recently in [LRC⁺02]. Compression and progressive transmission techniques have been surveyed in [Ros99b].

Topological extensions of simplification and compression not covered here are

discussed in [GBTS99] [RC99] [PH97] for nonmanifold models, in [Ros99] [Lo+02] for handles, in [TG89] for holes, and in [KRS99] [IS00] for quadrilateral and polygonal meshes [KRS99] [IS00]. Simplification and compression of meshes with properties are discussed in [GH98] [BPZ99] [IS00]. Compression and progressive transmission of tetrahedral meshes have been addressed in [PRS99] [SR00]. Error correction strategies for progressive transmission are addressed in [AAR02].

55 MANUFACTURING PROCESSES

Ravi Janardan and Tony C. Woo

INTRODUCTION

This chapter surveys some recent work on the application of techniques from computational geometry to geometric problems arising in manufacturing processes such as layered manufacturing, mold design, and numerically controlled machining. Within each topic, we discuss problems that have benefited from the application of geometric techniques, and mention several other problems where such techniques could be used to advantage.

55.1 LAYERED MANUFACTURING

Layered Manufacturing (LM) is a relatively new technology which allows physical prototypes of 3D models to be built directly from their digital representations, using a “3D printer” attached to a computer [Jac92]. LM provides the designer with an additional level of physical verification and facilitates the early detection and correction of design flaws that may have gone unnoticed otherwise. The use of LM has proliferated into a wide variety of areas, including, among others, engineering (e.g., automotive and aerospace design), ergonomic product design (e.g., hand-held devices such as cell phones), medicine (e.g., prosthetics design and tissue engineering), and art (e.g., sculpture) [Cad02, Har01, KF97, Lev02, NLG02].

The basic principle underlying LM is simple: The digital model is oriented suitably and sliced into horizontal layers by a plane. The layers are transmitted over a network to a fabrication device, which “prints” them successively in the vertical direction, each layer on top of the previous one; thus the physical prototype is realized as a vertical stack of two-dimensional layers. The efficiency and accuracy of LM depends, in part, on the efficient solution of a number of geometric problems. For instance, the choice of the model’s orientation determines the number of layers, the surface finish, and the quantity and location of temporary support structures. The problem of printing the layers efficiently reduces to covering the interior of a polygon with a collection of thin rectangles. Other problems include slicing the model efficiently and generating a compact representation of the support structures.

GLOSSARY

STL format: The model is assumed to be given as a surface triangulation. The format specifies the triangles by listing the coordinates of their vertices and the direction cosines of their unit outer normals. This is the *de facto* industry standard for LM; the name is derived from STereoLithography, one of the first

LM processes to be developed.

Model orientation: The rotation of the model from its default orientation in the STL file, prior to being sliced into horizontal layers and built in the vertical direction.

Stairstep error: Stairstep-shaped artifacts introduced on the model's facets due to discretization into layers (similar to antialiasing in computer graphics), which affect surface finish and accuracy. The stairstep error on a facet is the height of the stairstep perpendicular to the facet. It is a function of the (smaller) angle between the vertical direction and the facet's outer normal, hence of the model's orientation.

Supports: Temporary structures that are built simultaneously with the model to prop up layers that overhang previously-built layers; these are removed in a postprocessing step. Formally, for a model P , a point $p \in \mathbb{R}^3 \setminus P$ is part of the supports if the upward-directed ray from p intersects P ; thus the membership of p in supports depends on the model's orientation. The supports form a collection of disjoint polyhedra. (Figure 55.1.1.)

Support requirements: Measured in two ways: The support volume is the total volume of the support polyhedra. The support contact-area is the area of that portion of the model's boundary that is in contact with supports. These should be minimized to reduce material costs, build time, and postprocessing time.

Hatching: The process of printing each layer (a polygon) by covering its interior with parallel rectangles of some small width; the width is a process parameter.

RESULTS

Figure 55.1.2 illustrates schematically a widely-used LM process called Stereolithography, where the printing of layers is achieved by having a laser trace out and hatch each layer on the surface of a liquid resin which hardens when exposed to light. After a layer is built, the platform is lowered by an amount equal to the layer thickness (on the order of a few thousandths of an inch) and the next layer is then built atop the previous one. The need for supports is ascertained beforehand, by analyzing the orientation and geometry of the model, and then generating and merging a description of the layers into the STL file for the model. Representative examples of other LM processes include Fused Deposition Modeling (where layers are printed by extruding and laying down molten plastic via a nozzle), Laminated Object Man-

ufacturing (where the layers are cut out from sheets of adhesive-backed paper), and 3D Printing (where the layers are realized by outlining their shape via a binder fluid and then depositing a special powder onto it).

FIGURE 55.1.2

The Stereolithography process. (Reprinted from [IJM+02], with permission from Elsevier.)

Geometric problems in LM can be grouped loosely into three categories:

Choice of model orientation. Here the goal is to choose an orientation for the model that optimizes some design criterion (or to simply decide if the criterion can be satisfied). In [AB⁺97], $O(n)$ -time algorithms are given for deciding whether an n -vertex polyhedron can be built without supports using two models of Stereolithography—one in which no layer can overhang the previous one, and another where some overhang, controlled by an angle parameter, is allowed. The classes of objects that can be built by these processes are also related to those buildable via NC-machining and casting. In [MJSG99], an algorithm is given to minimize the maximum stairstep error ([BB95]) over all facets of a polyhedron in $O(n \log n)$ time and to minimize the sum of the stairstep errors on all facets in $O(n^2)$ time; the first algorithm even allows facets to be weighted to indicate their relative importance with respect to surface finish. Also given are $O(n^2)$ -time algorithms to minimize the volume and (independently) the contact-area of supports for a convex polyhedron. In [MJSS01], the preceding results are combined to reconcile simultaneously multiple design criteria, including support volume, contact-area, stairstep error, and number of layers. (Minimizing the number of layers is equivalent to finding the width of a polyhedron, and efficient solutions are known for this [HT88, SSMJ99].) Three formulations for reconciling the criteria are considered: optimizing the criteria sequentially, optimizing a weighted combination of the criteria, and allowing the criteria to meet designer-specified thresholds. The methods in [MJSG99, MJSS01] use well-known techniques from computational geometry, such as spherical arrangements, convex hulls, and Voronoi diagrams, in conjunction with constrained optimization methods such as Lagrangian multipliers. In [AD00], an approximation algorithm is given for minimizing the contact-area for a convex polyhedron. This method, based on computing approximate levels in a weighted arrangement of lines, runs in $O((n/\epsilon^3) \log^3 n)$ expected time and has an approximation ratio of $1 + \epsilon$, for any $\epsilon > 0$.

Optimization of supports for a nonconvex polyhedron is much harder due to the complicated structure of the supports. As Figure 55.1.1 illustrates, supports need not extend all the way to the platform, but may instead terminate on the model itself. Furthermore, only a fraction of a facet need be in contact with supports, unlike the convex case where either a facet is entirely in contact with supports or not in contact at all. In [MJS⁺99], algorithms are given for the two-dimensional case, i.e., minimizing support area and contact-length. The approach is based on partitioning the unit-circle of directions into intervals and generating for each interval a formula for the support requirement of interest. The intervals are then scanned in order and the formula for each interval is updated incrementally from that of the previous interval and then optimized within the interval. The running time is $O(n \log n)$ plus the time to perform $O(n)$ minimizations of a certain polynomial of degree $\Theta(n)$. Heuristics for contact-area optimization are described in [AD95], where a subset of the facet normals of the convex hull of the model is used for choosing the orientation. For each orientation, the needed supports and their contact-area are computed approximately, and the best orientation is then output. No analysis of the quality of the approximation is provided. In earlier work, the problem of support optimization is addressed in [FF94], and heuristics are given in the context of an expert system.

Another design consideration in LM is to choose model orientations so that certain functionally-critical surfaces of the prototype (e.g., facets on gear teeth) are not in contact with supports, since the presence and subsequent removal of supports can affect surface finish and accuracy. In [SSJ⁺00, SSJJ], an $O(n^2)$ -time algorithm is given to compute a description of all model orientations for which a prescribed facet is not in contact with supports. The related optimization problem of computing a description of all orientations for which the total area of facets not in contact with supports is maximized is solved in $O(n^4)$ time. These results are based on convex hulls, arrangements, and overlays of subdivision—all on the unit-sphere.

Fixed-orientation problems. Once an orientation has been chosen, several tasks remain. These include computing a description of any needed supports, slicing the model and supports, and deciding on how best to hatch the layers. In commercial software packages for LM, slicing and support generation are usually done in tandem. Specifically, as the model is sliced, the volume subtended under each layer is subtracted from that subtended by the layer above it; the result is the support between the two layers. Thus the supports are generated as a sequence of thin layers. In [Joh99], an alternative approach is pursued, where the goal is to generate a combinatorial description of the supports, as a collection of disjoint polyhedra. The algorithm is based on cylindrical decomposition [Mul93] and runs in $O(n^2 \log n)$ time.

Slicing algorithms used in LM are inefficient in that they compute from scratch the intersection of each slicing plane with the polyhedron, instead of taking advantage of the coherence that exists from layer to layer. This is due, in part, to the lack of any topological information in the STL format. In [MS99], an efficient and robust slicing algorithm is proposed. The algorithm builds a data structure based on a generalization of the well-known winged-edge structure [Bau75] and then uses the plane sweep paradigm to compute and update the layers incrementally, by taking advantage of the topological similarity between closely-spaced layers. A different perspective on slicing is taken in [DM94, KD96], where the focus is on slicing a

model adaptively, with slices of variable thickness, so as to improve surface accuracy and to speed up the build time.

The hatching problem may be viewed as the two-dimensional analog of the model orientation problem. Here the goal is to find a common orientation of all the layer polygons (or, equivalently, a rotation of the model about the vertical axis) so that the total number of times the hatching tool (e.g., the laser in Stereolithography) meets the boundaries of all the polygons is minimized. This, in turn, minimizes the number of starts, stops, and direction changes of the tool and increases tool life. In [HJSS03], the problem is approximated as one of finding a direction in the plane that minimizes the sum of the lengths of the projections of all polygon edges in this direction. The latter problem is reduced to computing the width of a suitably defined convex polygon (see also [Sar99]). The overall running time is $O(n' \log n')$, where n' is the total number of number of polygon edges in all layers. On real-world STL models, the algorithm runs very fast and delivers solutions that are very close to the solution produced by an optimal, but much slower, algorithm [SSHJ02].

Decomposition problems. LM processes generally view the model as a single, monolithic unit. An alternative approach is to decompose the model into a small number of pieces, build the individual pieces, and then glue them back together. This allows large models to be built in parallel on multiple machines (or even simultaneously on the same machine) and also reduces the build time. Moreover, the support requirements of the decomposed parts is usually lower than that of the original. This decomposition-based approach is pursued in [IJM⁺02], where it is shown how to decompose, with a plane, a convex or nonconvex polyhedron in a given orientation into a user-specified number of pieces so that the support volume or contact-area is minimized. The algorithms run in $O(n \log n)$ and $O(n^2 \log n)$ time for convex and nonconvex models, respectively, and are based on cylindrical decomposition and space sweep. In related work [FM01], it has been shown that the problem of deciding whether a polyhedron of genus zero or a polygon with holes can be decomposed into k terrains (hence built with zero supports) is NP-complete; here k is part of the input. In [IJS02], it is shown how to decompose, with a line, a polygon into two smaller polygons such that each is a terrain in the direction normal to the line; the algorithm runs in $O(n \log n)$ or $O(n^2 \log n)$ time, depending on whether or not both terrains have their “base” edge on the dividing line (see also [AB⁺97, RR94] for related work).

Besides the problems described above, a (necessarily incomplete) list of other related work on LM includes: automatic repair of STL files [Bøh95, Bar97]; elimination of support structures for a class of models by selectively thickening the walls of the model [AD98]; the design of a complete software front-end for the LM pipeline, from digital model import, to model repair, to batch scheduling of multiple models [BK98]; new modeling techniques for LM based on voxels [CMP95] and on analytic surfaces such as quadrics [FK96]; and investigation of alternatives to the STL format in LM [KD97, DKPS98].

OPEN PROBLEMS

1. Support optimization for nonconvex polyhedra is a challenging problem and an optimal solution remains elusive. Specifically, given a nonconvex polyhedron, $\mathcal{P}$, the goal is to compute an orientation which minimizes the support volume or (independently) the contact-area when $\mathcal{P}$ is built in that orienta-

tion. Extending the method in [MJS⁺99] to three dimensions appears difficult and expensive, so a new approach may be needed. Also of interest would be simple and efficient approximation algorithms.

2. The decomposition algorithm in [IJM⁺02] assumes that an orientation is given for the model and then proceeds to find a decomposition which minimizes the support requirements. A natural extension of this is to find an optimal (or near-optimal) decomposition over all possible orientations. Similarly, for the hatching problem, it would be interesting to design an algorithm which computes an optimal or near-optimal hatching direction over all possible orientations of the model.
3. Although the STL format is the *de facto* industry standard for model representation in LM, it is plagued with many problems. It introduces an approximation error when used to represent smooth surfaces, it lacks useful topological information, it is highly redundant and error-prone, and it is very voluminous for surfaces of high curvature. As mentioned earlier, alternatives to STL have been investigated [KD97, DKPS98, CMP95, FK96] recently. In particular, in [FK96] a representation based on quadric surfaces has been considered. It has been shown empirically that for the tasks of slicing and filling in the layers using equidistant offset curves, this analytic representation is superior to STL both in accuracy and in computation time and memory requirements. A natural extension of this work would be to investigate the effect of such representations on other LM tasks such as support generation and minimization, reduction of stairstep error, layer minimization, and hatching.

55.2 MOLD DESIGN

Casting and injection molding processes are used extensively to mass-manufacture a wide variety of products. A key step here is the design of the mold from a digital model of the part, since this affects both the speed of the process and the quality of the finished part. For instance, how the model is decomposed into pieces to make the mold halves determines the number of undercuts in the mold: the greater the number of undercuts, the slower the de-molding process. As another example, the location of venting holes on the mold and the choice of pouring direction determine the extent of air pockets created during mold filling; this ultimately affects the strength and finish of the product.

GLOSSARY

Mold: A cavity in the shape of the part to be manufactured into which molten metal is poured. It consists of two mating parts called *mold halves*. Once the metal has hardened, the mold halves are pulled apart in opposite directions (i.e., *de-molded*) and the part is removed.

Undercut: Any point p on a part's surface such that the outward normal at p makes an angle greater than 90° with the de-molding direction for the mold half containing p . Generally, a group of such points forms a recess or projection in the part that prevents easy de-molding.

FIGURE 55.2.1

A parting line (e) for the exhaust manifold of an automobile.

Parting line: A continuous closed curve on the surface of the part that defines the two halves; thus it also defines the profile of the contact surface between the two mold halves (Figure 55.2.1).

CH(P): The convex hull of a polyhedron P .

Dent: For a polyhedron P , a connected component of $\text{CH}(P) \setminus P$.

Fillability: The ability to fill a mold from a given pouring direction without creating air pockets. This is a function of the mold geometry, the pouring direction, and the location of air-venting holes.

Part decomposition: The process of dividing a part into smaller pieces and making mold halves for these that satisfy certain optimization criteria.

RESULTS

Geometric problems in mold design generally fall into two categories.

Fillability problems. These are concerned with questions such as whether a mold can be filled from a given pouring direction without creating air pockets, and finding a pouring direction that eliminates air pockets using the smallest number of venting holes. In [BvKT98], several results are presented including: (a) deciding in $O(n)$ time whether an n -vertex polyhedron can be filled from a given pouring gate in a given direction without creating air pockets; (b) enumerating in $O(n^2)$ time all pouring directions that permit such a fill; (c) computing in $O(n^2)$ time a pouring direction which minimizes the number of air pockets; and (d) characterizing classes of polyhedra according to their fillability. The two-dimensional counterparts of these problems are solved in [BT95], with running time $O(n)$ for the decision problem and $O(n \log n)$ for the enumeration and optimization problems. Similar questions are also addressed in [FM93] for different mold-filling strategies and different types of filling material (ranging from gas to liquid to solid).

Part decomposition. This refers to the problem of “cutting” the digital model into smaller pieces and making mold halves for these that meet certain optimization criteria. For instance, how can a 3D part P be divided into two such that the parting line is as “flat” as possible? As noted in the mold-design literature, the flatter the parting line, the more cost-effective and accurate the mold. While the notion of flatness has not been quantified in the literature, it is generally taken to mean that the parting line should lie as nearly in a plane as possible. Although a parting line that lies completely in a plane can always be produced by intersecting P with a plane, this can create undercuts, even if P is a convex polyhedron (Figure 55.2.2).

The problem of computing a flattest undercut-free parting line for an n -vertex

FIGURE 55.2.2

An octahedron that cannot be divided by a plane into two halves without creating undercuts. For example, the plane containing vertices 1, 2, and 3 creates a projection under the chain 1–4–3. Undercuts can be avoided by choosing the parting line to be 1–2–3–4–1 (or 2–5–4–6–2), but this is no longer in a plane. (From [MGJ99], with permission.)

convex polyhedron P is considered in [MGJ99]. That such a line always exists is clear—simply take the boundary, $L(\vec{d})$, of P , as viewed along lines of sight parallel to any direction $\vec{d}$. The **flatness**, $\rho(\vec{d})$, of $L(\vec{d})$ is defined in [MGJ99] as the sum of the squares of the projected lengths of the segments of $L(\vec{d})$, where the projection is onto a plane normal to $\vec{d}$, divided by the sum of the squares of the lengths of the segments of $L(\vec{d})$. Thus, $\rho(\vec{d}) \leq 1$, with equality holding if and only if $L(\vec{d})$ lies in a plane. An $O(n^2)$ -time algorithm is given to compute a direction $\vec{d}$ that maximizes $\rho(\vec{d})$. The algorithm blends together geometric techniques such as visibility cones, arrangements, and shortest paths in a simple polygon, with methods from continuous optimization. Algorithms are also given for optimizing other measures of flatness. These include (a) finding a direction which maximizes the flatness criterion defined above, but uses segment lengths rather than squared lengths; and (b) finding a direction which minimizes the width of the parting line, where, for any direction $\vec{d}$, the width of the parting line $L(\vec{d})$ is defined to be the smallest separation between two parallel planes normal to $\vec{d}$ that enclose $L(\vec{d})$.

In [BBvK97] the problem of deciding if a given n -vertex polyhedron can be parted by a single plane without creating undercuts is addressed. For an n -vertex nonconvex (resp. convex) polyhedron, where the cast parts are to be removed by translation in mutually-opposing directions, the bounds are $O(n^{3/2+\epsilon})$ time and $O(n^{3/2+\epsilon})$ space (resp. $O(n \log^2 n)$ time and $O(n)$ space), where $\epsilon > 0$ is an arbitrarily small constant. A related result is presented in [AdB⁺02], where it is shown that, for an n -vertex polyhedron, all directions that admit an undercut-free parting line (for cast removal in mutually opposing directions) can be computed in $O(n^4)$ time. This is shown to be optimal in the worst case by demonstrating a polyhedron which admits $\Omega(n^4)$ such directions. Finally, in [CC⁺93a], an $O(nd \log d)$ -time algorithm is given to compute a pair of opposing directions maximizing the number of visible dents in an n -vertex polyhedron with d dents. This minimizes the number of undercuts; however, the method does not yield a parting line.

Other related work includes decomposition of two-dimensional molds [RR94], identification of criteria other than parting line shape and number of undercuts [RS90], and heuristics for computing a de-molding direction without too many undercuts [HT92].

OPEN PROBLEMS

1. It is unlikely that the $O(n^2)$ -time algorithm in [BvKT98] for minimizing the number of air-venting holes can be improved (in view of the 3SUM-HARD-based lower bound). However, can a significantly faster algorithm be devised that approximates the minimum number of air-venting holes to within a constant factor?
2. The goals of maximizing the flatness of the parting line and minimizing the number of undercuts are usually at odds. Often, however, meeting specified thresholds suffices: for instance, given parameters u_0 and ρ_0 , design an efficient algorithm to find a parting line with at most u_0 undercuts and flatness at least ρ_0 .
3. A polyhedron P is **1-castable** if it can be parted by a plane without creating undercuts. The results in [BBvK97] allow one to decide 1-castability efficiently. However, there exist polyhedra that are not 1-castable (Figure 55.2.3). To extend the class of polyhedra that can be cast with planes, call a polyhedron P **2-castable** if there is a plane h such that the polyhedra $P \cap h^+$ and $P \cap h^-$ are both 1-castable. (Here h^+ and h^- denote the two halfspaces of h .) Give efficient algorithms to decide 2-castability and characterize the class of 2-castable polyhedra.

FIGURE 55.2.3

Cross-sectional view of a polyhedron that is not 1-castable. The cross section tapers along the length of the polyhedron to a point and then expands again, so that the polyhedron consists of a “double pyramid.” Any casting plane will create an undercut at one (or more) of the spikes or at some of the slanted facets corresponding to the horizontal and vertical segments in the cross section.

55.3 NUMERICALLY CONTROLLED MACHINING

The dominant machining process today is *numerically controlled (NC) machining*, where parts are manufactured under computer control based on information extracted from a digital model. Examples of NC-machines include milling machines and lathes. Typical questions of interest concern accessibility of the tool to the part and generation of toolpaths that satisfy certain optimization criteria.

GLOSSARY

Degrees of freedom (dof): The types of motion permitted of an NC-machine. Specified as a combination of translation and (full or partial) rotation with respect to the coordinate axes.

Visibility map (or VMap): The set of points on the unit sphere representing the directions along which a tool can approach (or “see”; cf. Chapter 28) *all* points on the surface in question without being blocked by other portions of the part. The VMap is a function of the surface geometry and the geometry of the cutting tool, and is in practice usually representable as a (spherical) polygon formed by the intersection of a certain set of hemispheres [GWT94]. For instance, the VMap of a plane is the hemisphere whose pole is the normal to the plane, the VMap of a half-cylinder is a half-great circle, the VMap of a hemisphere is a point, and the VMap of a dent in a polyhedron is the intersection of the set of hemispheres determined by the normals to the dent’s faces.

Pocket: A region bounded by one or more closed curves, which delineates the area on the part from which material must be removed.

Spherical band of width b : The set of all points on the unit sphere that are at a distance of at most b on either side of a great circle, where the distance is measured along a great circle arc.

Part setup: The process of dismounting a part, and re-calibrating and re-mounting it in a new orientation on the worktable of an NC-machine.

Direction-parallel pocket machining: A machining discipline where the tool is constrained to stay within a pocket and, moreover, always moves from left to right with respect to a chosen reference line.

Zigzag pocket machining: Similar to direction-parallel machining, except that the tool moves from left to right, then right to left, and so on.

Contour-parallel pocket machining: The tool is constrained to move along a sequence of closed paths that are parallel to the pocket’s contour.

RESULTS

Two important parameters of an NC-machine are the dof of the machine and the type of cutting tool. The dof include translation along the principal coordinate directions (**3-axis machine**), plus rotation of the worktable about one axis (**4-axis machine**), plus partial swivel of the tool about a second axis (**5-axis machine**). The dof determines global motion of the tool. For example, in a 4-axis machine, the directions in which the tool can move can be represented on the unit sphere as a great circle whose normal is the rotational axis of the worktable. In a 5-axis machine, if the tool can swivel by $\pm b/2$ radians, then the tool motion directions are given by a spherical band of width b , where the great circle associated with the band is as in the 4-axis case. Cutters are classified, according to the maximum angle θ that they can tilt from the local surface normal, as: **flat-end** ($\theta = 0$ radians), **fillet-end** ($\theta < \pi/2$ radians), and **ball-end** ($\theta = \pi/2$ radians). Thus the cutter geometry determines local motion of the tool: a flat-end cutter can approach a point p on a surface only along the surface normal at p , while a ball-end cutter can approach p along any direction lying within the hemisphere with pole p .

Part orientation. In order to machine a surface on a part, the tool must be able to approach (or see) every point on the surface without being blocked by other portions of the part. For a given orientation of the part on the machine's worktable, only a subset of the surfaces that need to be machined might be so visible to the tool. Therefore, after each such set of visible surfaces has been machined, a part setup is performed to bring a new set of surfaces into view. However, part setup can be quite time-consuming in relation to the actual machining time (hours versus minutes, sometimes). This motivates the following problem. Given the part geometry and the machine parameters, compute a sequence of part orientations that minimizes the number of setups. Unfortunately, this problem is NP-hard, and so attention has focused on obtaining efficient algorithms that approximate closely the minimum number of setups.

A natural approach is a greedy heuristic which finds repeatedly a part orientation that allows access to the maximum number of as-yet-unnmachined surfaces [CC⁺93b, GJM⁺96]. Suppose, for example, that a 4-axis machine equipped with a ball-end cutter is used. Assume further that the VMaps for the part's surfaces are available; for a ball-end cutter, the VMaps are intersections of certain hemispheres and can be computed as described in [GWT94]. Recall that each VMap represents the directions along which every point on the corresponding surface can be seen by the tool. Therefore, to find an orientation in which the maximum number of surfaces can be seen is equivalent to finding a great circle, C , that intersects the maximum number of VMaps. (Here, C represents the directions in which the tool can move in a 4-axis machine.) Similarly, for a 5-axis (resp. 3-axis) machine, the problem is to find a spherical band B of width b (resp. a point P) that intersects the maximum number of VMaps (Figure 55.3.1).

Given m VMaps with a total of n vertices, this problem is solved in [CC⁺93b] in $O(nm \log m)$ time and $O(nm)$ space for a 3- and 4-axis machine equipped with a ball-end cutter. In [GJM⁺96], the time bound is improved to $O(n^2)$ in the worst case—when $m = \Theta(n)$ —and, moreover, an $O(nm \log m)$ -time and $O(nm)$ -space algorithm is given for 5-axis machines. These results are based on geometric duality, topological sweep (Section 24.4), and properties concerning intersections and covering of polygons on the unit sphere. In [GJM⁺96], an $O(n^2 + nm \log m)$ -time and $O(nm)$ -space algorithm is also given for fillet-end tools on 4- and 5-axis machines. All of these results imply an $O(\log m)$ -approximation to the minimum number of setups, via the well-known approximation result for the set-cover problem.

Tool paths. A related problem is that of generating tool paths that meet certain optimization criteria, given the pocket geometry, the tool size and geometry, and a machining discipline such as direction-parallel machining, zigzag machining, or contour-parallel machining. The optimization criteria include minimizing the total length traveled by the tool, minimizing the number of *tool retractions* (i.e., the number of times the tool is lifted off the workpiece), and minimizing the number of times any point is machined by the tool. (This problem bears similarities to the hatching problem discussed earlier.) In [AHS00], a zigzag pocket machining algorithm is given and it is proved that the number of retractions is at most $5r + 6h$ for a pocket with $h \geq 0$ holes, where r is the minimum number of retractions. Moreover, no point is machined more than once. (Experiments in [AHS00] indicate a better approximation factor of 1.5.) The approach is based on constructing and processing a so-called machining graph. The algorithm runs in $O(n)$ time, where n is the number of vertices in the machining graph. (Here n is a function of the

FIGURE 55.3.1

A great circle for a 4-axis machine (a) and a spherical band for a 5-axis machine (b) intersecting a set of VMaps. (From [GJM⁺96], with permission.)

pocket geometry and the tool size.)

In [AFM00], the following related optimization problem is shown to be NP-hard: Given a polygonal pocket of size n and a tool represented by a unit disk or a square, find a closed path of minimum length that visits every point of the pocket at least once. It is shown, however, that one can compute a path that is at most a constant times longer than a shortest path in time $O(n \log n)$.

Heuristics have also been investigated for other tool-path generation problems—see, for instance, the references cited in [AHS00]. However, no approximation bounds have been proved.

OPEN PROBLEMS

1. The type of visibility considered in the part setup problem is between two points (one being the tool and the other being a point on the part's surface) along a straight line. Characterizations of such VMaps and efficient algorithms are given in [GWT94]. Give characterizations and efficient algorithms for VMaps under point-point visibility along circular trajectories (e.g., as produced by the rotary joints of a robot arm) or along parabolic trajectories (e.g., as executed by droplets under gravity in vapor deposition processes). Also of interest are segment-segment and plane-plane visibility along straight line trajectories.
2. Consider an augmented 4-axis (resp. 5-axis) machine, where the worktable can rotate fully (resp. tilt by $\pi/2$ radians) about a second axis. In the greedy framework described earlier, this reduces to finding a pair of orthogonal great circles (resp. spherical bands) that intersect the maximum number of VMaps. No algorithms are known for this problem.

3. Prove that the zigzag pocket machining problem that calls for the minimum number of retractions and requires that no pocket point is machined more than once ([AHS00]) is NP-hard, or provide a polynomial-time algorithm.
4. Investigate tool-path generation problems for contour-parallel machining and provide provably good approximation algorithms.

55.4 OTHER TOPICS

Besides the three representative topics that we have addressed, there are other areas for fruitful interaction between computational geometry and manufacturing. These include: design of mechanisms and linkages (Section 48.1); geometric constraint systems (Section 56.3); tolerancing of machined parts; interpretation and reconstruction of engineering drawings, assembly and disassembly of components (Section 48.3); geometric software for manufacturing applications, process planning and simulation, mesh generation (Section 25.4); VLSI design and layout, and vision, robotics ([Chapter 48](#)); geometric modeling issues relevant to manufacturing ([Chapter 53](#) and [56](#)); and geometric problems arising in other manufacturing processes such as bending, forming, welding, forging, etc.

55.5 SOURCES AND RELATED MATERIAL

FURTHER READING

The following contain additional discussion and references related to the topics in this chapter.

[Bos95, Maj98]: Provide good expositions of the application of computational geometry techniques to problems in molding, casting, and layered manufacturing.

[Woo94]: Discusses various kinds of visibility in the context of different manufacturing processes.

[Hel91]: Contains a detailed discussion of the application of geometric techniques to problems in pocket machining.

[Bra86]: A good general reference on a variety of design and manufacturing processes, including casting, molding, forging, stamping, machining, etc.

56 SOLID MODELING

Christoph M. Hoffmann

INTRODUCTION

The objective of solid modeling is to represent, manipulate, and reason about the 3D shape of solid physical objects, by computer.

Solid modeling is an application-oriented field that has a tradition of implementing systems and algorithms. Major applications include manufacturing, computer vision, graphics, and virtual reality. Technically, the field draws on diverse sources including numerical analysis, symbolic algebraic computation, approximation theory, point set topology, algebraic geometry, and computational geometry.

First, the major representations of solids are reviewed in Section 56.1. They include constructive solid geometry, boundary representation, spatial subdivision, medial surface representations, and procedural representations. Then, major layers of abstraction in a typical solid modeling system are characterized in Section 56.2. The lowest level of abstraction comprises a substratum of basic service algorithms. At an intermediate level of abstraction there are algorithms for larger, more conceptual operations. Finally, a yet higher level of abstraction presents to the user a functional view that is typically targeted toward solid design.

Solid design paradigms work with form features and constraints. Often, they define classes of shape instances, and venture into territory that has yet to be plumbed mathematically and computationally. Concurrently, there is also a shift in the system architecture toward modularized confederations of plug-compatible functional components. We explore these trends lightly in Section 56.3.

Open problems are gathered in Section 56.4.

56.1 MAJOR REPRESENTATION SCHEMATA

GLOSSARY

Solid representation: Any representation allowing a deterministic, algorithmic point membership test.

Constructive solid geometry (CSG): The solid is represented as union, intersection, and difference of primitive solids.

Boundary representation (Brep): The solid surface is represented as a quilt of vertices, edges, and faces.

Spatial subdivision: The solid is decomposed into a set of nonintersecting primitive volumes.

Medial surface transformation: Closure of the locus of centers of maximal inscribed spheres, and a function giving the minimum distance to the solid boundary. Usually called the ***MAT*** for “medial axis transformation.”

Procedural representation: The solid is described by a scripting language or a notational schema that must be evaluated.

A solid representation must allow the unambiguous, algorithmic determination of point membership: given any point $p = (x, y, z)$, there must be an algorithm that determines whether the point is inside, outside, or on the surface of the solid. Moreover, restrictions are placed on the topology of the solid and its embedding, excluding, for example, fractal solids.

These restrictions are eminently reasonable. Increasingly, however, solid modeling systems depart from this strict notion of solid and permit representing a mixture of solids, surfaces, curves, and points, for example, in surface modeling in graphics via “particle systems.” The additional geometric structures are useful for certain design processes, for interfacing with applications such as meshing solid volumes, and for abstracting solid features, to name a few.

56.1.1 CONSTRUCTIVE SOLID GEOMETRY

GLOSSARY

Primitive solids: Traditionally: block, sphere, cylinder, cone, and torus. More general primitives are possible.

Sweep: Volume covered by sweeping a solid or a closed contour in space.

Extrusion: Sweep along a straight line segment.

Revolution: Circular sweep.

Regularized Boolean operation: The closure of the interior of a set-theoretic union, intersection, or difference.

Algebraic halfspace: Points such that $f(x, y, z) \leq 0$ where f is an irreducible polynomial.

Irreducible polynomial: Polynomial that cannot be factored over the complex numbers.

Classical Constructive Solid Geometry (CSG) represents a solid as a set-theoretic Boolean expression of *primitive* solid objects, of a simpler structure. Both the surface and the interior of the final solid are thereby defined, albeit implicitly. The CSG representation is valid if the primitives are valid. A solid’s surface is closed and orientable and encloses a volume. The traditional CSG primitives are block, sphere, cylinder, cone, and torus.

A solid is represented as an algebraic expression that uses rigid motions and regularized set operations. The traditional operations are regularized union, intersection, and difference. A regularized set operation is obtained by taking the closure of the interior of the set-theoretic result. The effect is to obtain solids that do not contain lower-dimensional parts, such as interior (or dangling exterior) faces, edges, and vertices.

Each solid has a default coordinate system that can be changed with a rigid body transformation. A Boolean operation identifies the two coordinate systems of the solids to be combined and makes it the default coordinate system of the resulting solid.

FIGURE 56.1.1

Left and middle: CSG primitives **block**(w, d, h) and **cylinder**(r, h) with default coordinate systems. Right: T-bracket as union of two blocks minus a cylinder.

As an example, consider Figure 56.1.1. Using the coordinate system conventions shown, the CSG representation of the bracket is the expression

$$\text{block}(8, 3, 1) \cup^* \text{move}(\text{block}(2, 2.5, 3), (0, 4.5, 1)) \\ -^* \text{move}(\text{cylinder}(0.75, 1), (1.5, 1.5, -0.5))$$

where the $*$ indicates a regularized operation. (See also [Figure 38.4.1](#).)

The basic operations one wishes to perform on CSG representations are classifying points, curves, and surfaces with respect to a solid; detecting redundancies in the representation; and approximating CSG objects systematically.

More general primitives are obtained by considering the volume covered by sweeping a solid along a space curve, or sweeping a planar contour bounding an area. Defining a sweep is delicate, requiring many parameters to be exactly defined, but simple cases are widely used. They are extrusion, i.e., sweep along a straight line; and revolution, i.e., a sweep about an axis. The evaluation of general sweeps can be accomplished by a number of methods. An even more general set of primitives is algebraic halfspaces, point sets defined by

$$P = \{(x, y, z) \in \mathbb{R}^3 \mid f(x, y, z) \leq 0\},$$

where $f(x, y, z)$ is an irreducible polynomial in x , y , and z .

More general operations are obtained by using nonregularizing Boolean operations or by defining a nonstandard semantics for Boolean operations on surfaces and curves.

56.1.2 BOUNDARY REPRESENTATION

In boundary representation (Brep), the solid surface is represented as a quilt of faces, edges, and vertices. A distinction is drawn between the topological entities, vertex, edge, and face, related to each other by incidence and adjacency, and the geometric location and shape of these entities. See also [Figure 56.1.2](#). For example, when polyhedra are represented, the faces are polygons described geometrically by a face equation plus a description of the polygon boundary. Geometrically, the entities in a Brep are not permitted to intersect anywhere except in edges and vertices that are explicitly represented in the topology data structure. In addition to the classification operations mentioned for CSG, Boolean union, intersection, and difference operations are usually implemented for Brep systems. Both regularized and nonregularizing Boolean operations may occur.

Different Brep schemata appear in the literature, divided into two major families. One family restricts the solid surfaces to oriented manifolds. Here, every edge

FIGURE 56.1.2

Topological entities of a box. Adjacency and incidence are recorded in Brep. Dotted arrows indicate face orientation.

is incident to two faces, and every vertex is the apex of a single cone of incident edges and faces. The second family of Brep schemata allows oriented nonmanifolds in which edges are adjacent to an even number of faces. When these faces are ordered radially around the common edge, consecutive face pairs alternately bound solid interior and exterior. See Figure 56.1.3 for examples.

FIGURE 56.1.3

A nonmanifold solid without dangling or interior faces, edges, and vertices; the nonmanifold edges and vertices are drawn with a thicker pen.

More general nonmanifold Breps are used in systems that combine surface modeling with solid modeling. In such representation schemata, a solid may have interior (two-sided) faces, dangling edges, and so on. The current trend is to incorporate surface modeling capabilities into solid modelers.

The topology may be restricted in other ways. For instance, the interior of a face may be required to be homeomorphic to a disk, and edges required to have two distinct vertices. In that case, the Brep of a cylinder would have four faces, two planar and two curved. This may be desirable because of the geometric surface representation, or may be intended to simplify the algorithms operating on solids.

56.1.3 SPATIAL SUBDIVISION REPRESENTATIONS

GLOSSARY

Boundary conforming subdivision: Spatial subdivision of a solid that represents the boundary of the solid exactly.

Boundary approximating subdivision: Spatial subdivision that represents the boundary of the solid only approximately.

Regular subdivision: A subdivision whose cells are congruent. Grids are regular subdivisions.

Irregular subdivision: A subdivision with noncongruent cells.

Octree: Recursive selective subdivision of a cuboid volume into eight subcuboids.

Binary space partition (BSP) tree: Recursive irregular subdivision of space, traditionally by halfplanes. See also [Sections 28.8.2](#) and [38.5](#).

Spatial subdivision decomposes a solid into cells, each with a simple topological structure and often also with a simple geometric structure. Subdivision representations are divided into *boundary conforming* and *boundary approximating*.

Important boundary conforming subdivision schemata are *meshes* and the *BSP tree*. Mesh representations are used in finite element analysis, a method for solving continuous physical problems. The mesh elements can be geometric tetrahedra, hexahedra, or other simple polyhedra, or they can be deformations of topological polyhedra so that curved boundaries can be approximated exactly. See [Sections 25.4–5](#).

Binary space partition trees are recursive subdivisions of 3-space. Each interior node of the tree separates space into two disjoint point sets. In the simplest case, the root denotes a separator plane. All points of $\mathbb{R}^3$ below or on the plane are represented by one subtree, all points above the plane are represented by the other subtree. The two point sets are recursively subdivided by halfplanes at the subtree nodes. The leaves of the tree represent cells that are labeled IN or OUT. The (half) planes are usually face planes of a polyhedron, and the union of all cells labeled IN is the polyhedron. For an example in $\mathbb{R}^2$ see Figure 56.1.4. Note that algebraic halfspaces can be used as separators, so that curved solids can be represented exactly.

FIGURE 56.1.4

A polygon and a representing BSP tree.

Boundary approximating representations are *grids* and *octrees*. In grids, space is subdivided in conformity with a coordinate system. For Cartesian coordinates, the division is into hexahedra whose sides are parallel to the coordinate planes. In cylindrical coordinate systems, the division is into concentric sectors, and so on. The grids may be regular or adaptive, and may be used to solve continuous physical problems by differencing schemes. Rectilinear grids that are geometrically deformed can be boundary-conforming. Otherwise, they approximate curved boundaries.

An octree divides a cube into eight subcubes. Each subcube may be further subdivided recursively. Cubes and their subdivision cubes are labeled white, black, or grey. A grey cube is one that has been subdivided and contains both white and black subcubes. A subcube is black if it is inside the solid to be represented, white if it is outside. Quadtrees, the two-dimensional analogue of octrees, are used in many geographical information systems. See [Figure 38.5.1](#).

56.1.4 MEDIAL SURFACE REPRESENTATIONS

GLOSSARY

MAT: Medial axis transform, the two-dimensional version of the medial surface representation. Some authors use “medial axis transform” regardless of the dimension of the domain.

Maximal inscribed disk: Disk inscribed in a domain and not properly contained in another inscribed disk.

Medial axis and medial surface can unambiguously represent two-dimensional domains and 3D solids, respectively. The representations are not widely used for this purpose at this time; more frequently they are used for shape recognition (see [Section 51.4](#)). However, as explained below, some sophisticated meshing algorithms are based on the medial axis and the medial surface.

The medial axis of a two-dimensional domain is defined as the closure of the locus of centers of disks inscribed within the domain. A disk is maximal if no other disk properly contains it. An example is shown in Figure 56.1.5 along with some maximal disks.

FIGURE 56.1.5

L-shaped domain and associated medial axis. Some maximal inscribed circles contributing to the medial axis are shown.

The medial surface of a solid is the closure of the locus of centers of maximal inscribed spheres. When we know the radius (the limit radius in case of closure points) of the corresponding sphere for each point on the medial surface, then an unambiguous solid representation is obtained that is sometimes called the medial axis transform (MAT). The MAT has a number of intriguing mathematical properties. For example, by enlarging the radius values by a constant, the MAT of a dilatation of the solid is obtained.

Originally, solid modeling has investigated the MAT for the purpose of constructing shell solids (obtained by subtracting a small inset), for organizing finite element meshing algorithms, and for recognizing form features. More recently, the role of the MAT in surface reconstruction has begun to impact solid modeling; see [Chapter 30](#). Surface reconstruction arises in solid modeling for its application in reverse engineering where a model is to be constructed from a physical object by an automated measuring strategy.

56.1.5 PROCEDURAL REPRESENTATIONS

Procedural solid representations fall into two families: script language representations that have a strong programming language character, and descriptive representations evaluated by a program or system.

The PADL system used FORTRAN as script language to specify solids. CSG expressions and directives were embedded into the Fortran program. The solid was evaluated into an internal format. Alpha_1 originally used Lisp as script language and evaluated the solid so described into a boundary representation. Subsequently, a direct manipulation interface was added to the system. The recent SGDL system uses Scheme as script language, evaluating it into an internal proprietary data format. Since such script languages are based on a general programming language, the solid evaluation can be highly complex and may include any computation. Unless the evaluated solid is represented in one of the other representation schemata, it is in general not possible to reason about solids using the procedural representation directly.

Descriptive representations, including the Erep notation are data representations by nature. Their procedural nature derives from the need to evaluate and instantiate parameters, based on (computed) geometric relationship and, in many cases, geometric constraints. Once the parameters are determined, the shape is evaluated in steps, where the major steps typically correspond to form features. Usually, an entire family of solids can be so described and instance solids are obtained by valuating parameters and dimensional constraints. A semantic characterization of the family remains largely an open problem, as discussed later.

56.1.6 CONVERSION BETWEEN REPRESENTATIONS

Most solid modeling systems use Brep. Conversion from CSG to Brep is well understood and is implemented as regularized Boolean operations on Brep solids. An extensive literature addresses these complex algorithms.

The conversion from Brep to CSG is not completely understood. In the polyhedral case, the conversion is essentially the same as the conversion from Brep to BSP tree. Pure CSG solids, using the PADL primitives, can also be converted. Conversion involving higher degree surfaces is largely open.

Some progress has been made by Naylor and Rogers in the case of Bézier curves and B-splines (for definitions, see [Section 53.1](#)). Roughly speaking, a coarse BSP tree is constructed that encloses sections of the curve in convex polygonal regions. On demand, the tree can be extended dynamically, thereby refining the enclosing regions. In this way, points may be classified efficiently with respect to the curve to a required resolution.

There are several algorithms for converting from CSG or Brep to the MAT. Some are based on geometric principles, some on a Delaunay triangulation of an approximated boundary, and some on a grid subdivision of ambient space. Because simple boundary geometry elements can produce very complicated curves and surface elements in the MAT, approximation approaches are favored in practice. The conversion from MAT to Brep has been addressed by Vermeer [Ver94] and later by Amenta [ACK01]. Note that a polyhedral MAT produces a solid boundary that can contain spherical, conical, and cylindrical elements.

The conversion from CSG or Brep to mesh representations is a partially solved problem when the conversion is done for finite element analysis or other numerical treatment of continuum problems. In that context, the problem is not a geometric problem alone: the quality of the subdivision must also be judged by nongeometric criteria that derive from the nature of the physical problem and the numerical algorithm used to solve it. Many approaches are based on octree subdivision, on Delaunay triangulation, and on MAT computations.

The conversion relationships are summarized in Table 56.1.1.

TABLE 56.1.1 Representation conversion.

CONVERSION	REMARKS
CSG → Brep	Many methods, e.g., [Chi88, Hof89, Män88]. Active research seeks better tradeoff between speed, accuracy, and geometric coverage.
Brep → CSG	
Brep, CSG → MAT	Largely open. Polyhedral case similar to BSP tree construction [Hof93b]; quadric cases treated in [Sha91, SV93]. See also [NR95] for parametric case.
MAT → Brep	[CHL91] uses grid approximation, [SAR95] uses Delaunay approximation of domain.
Brep, CSG → spatial subdivision	[Ver94] converts polyhedral MAT. Many approaches; see, e.g., [Hof95, TWM85, SERB99]. Active research seeks improved techniques.

GEOMETRIC COVERAGE

The range and geometric representation of solid surfaces is referred to as *geometric coverage*. Polyhedral modeling restricts to planes. Classical CSG allows only planes, cones, cylinders, spheres, and tori. Experimental modelers have been built allowing arbitrary algebraic halfspaces. SGDL uses implicit algebraic surfaces of degree up to 4.

Most commercial and many research modelers use B-splines (uniform or nonuniform, nonrational or rational) or Bézier surfaces. The properties and algorithmic treatment of these surfaces is studied by computer-aided geometric design. See [Chapter 53](#), as well as the monographs and surveys [Far88, Hos92, HL93].

Subdivision surfaces have also been proposed but, despite their success in graphics, have thus far not gained wide acceptance in solid modeling. There are many connections between certain kinds of subdivision curves and surfaces and certain classes of spline curves and surfaces. See also [Chapter 53](#).

SPATIAL RELATIONSHIPS

In many applications one would like to understand spatial relationships. Some of the solid representations reviewed have been considered for this purpose. For instance, the MAT has been used to guide meshing algorithms globally and some attempts have been made to devise simplifications for isolating specific features of a shape. Attempts have been made to define suitable simplifications and variations of the MAT; e.g., [FLM03].

Shape simplification (Chapter 54) is fundamental for many tasks, including in collision detection (Chapter 35). When a shape is offset by a large distance, smaller features tend to disappear; hence offsetting, a close relative of the MAT, can be used to explore shape simplification [BDG97]. Other approaches have constructed hierarchical representations in which shape is approximated by a hierarchy of simple bounding volumes that at the tree root enclose the entire shape, and in the interior refine the shape estimate by alternately subtracting and adding smaller bounding volumes; e.g., [GLM96, KGL⁺98]. Such trees of bounding volumes have similarity with CSG trees.

56.2 LEVELS OF ABSTRACTION

GLOSSARY

Substratum: Basic computational primitives of a solid modeler, such as incidence tests, vector arithmetic, etc.

Algorithmic infrastructure: Major algorithms implementing conceptual operations, such as surface intersection, edge blending, etc.

Graphical user interface (GUI): Visual presentation of the functionality of the system.

Application procedural interface (API): Presentation of system functionality in terms of methods and routines that can be included in user programs.

Substratum problem: Unreliability of logical decisions based on floating-point computations.

Large software systems should be structured into layers of abstraction. Doing so simplifies the implementation effort because the higher levels of abstraction can be compactly programmed in terms of the functionality of the lower levels. Thereby, the complexity of the system is reduced. A solid modeling system spans several levels of abstraction:

1. On the lowest level, there is the substratum of arithmetic and symbolic computations that are used as primitives by the algorithmic infrastructure. This level contains point and vector manipulation routines, incidence tests, and so on.
2. Next, there is an intermediate level comprising the algorithmic infrastructure. This level implements the conceptual operations available in the user interface, as well as a wide range of auxiliary tools needed by these operations. There is often an application programming interface available with which programs can be written that use the algorithmic infrastructure of the modeling system.
3. A graphical user interface (GUI) presents to the user a view of the functional capabilities of the system. Interaction with the GUI exercises these functions, for instance, for solid design. Tools for editing and archiving solids are included.

Ideally, the levels of abstraction should be kept separate, with the higher levels leveraging the functionality of the lower levels. However, this separation is fundamentally limited by the interaction of numeric and symbolic computation.

56.2.1 THE SUBSTRATUM

The substratum consists of many low-level computations and tests; for example, vector computations, simple incidence tests, and computations for ordering points along a simple curve in space. Ideally, these operations create an abstract machine whose functionality simplifies the algorithms at the intermediate level of abstraction. But it turns out that this abstract machine is unreliable in a subtle way when implemented using floating-point arithmetic. Exact arithmetic would remedy this unreliability, but is held by many to be unacceptably inefficient when dealing with solids that have curved boundaries. See [Section 41.4](#). Problems include input accuracy.

To illustrate how inexact arithmetic at the substratum level can impact the geometric computation, consider modeling polyhedral solids, the simplest possible situation for solid modeling. All computational decisions that arise in the course of a regularized Boolean operation on polyhedra can be reduced to determining the sign of 4×4 determinants. Geometrically, this is a test of whether a point is above, on, or below a plane. When the determinant's value is nearly zero, floating-point evaluation will decide based on a tolerance. But the decision is unreliable because logically equivalent tests may arise as different determinants in the course of the algorithm: some of the determinants could have small, others large values, thus necessitating different tolerances to arrive at consistent decisions. This gives an opportunity for the algorithm to build inconsistent data structures and fail. The problems are magnified when dealing with curved solids.

Recent academic solid modeling systems adopt exact arithmetic either outright, or use exact arithmetic on demand. In the latter approach, an error bound is evaluated along with the predicate on whose value a logical decision depends. If the decision is unambiguous based on floating-point arithmetic, no further action is taken. Otherwise, an exact evaluation is done. If an exact evaluation is to be made, the input is understood to be exact as given, and the predicate must be evaluated from the input data without using intermediate, possibly inaccurate, data. The assumption of exact input data is problematic for Brep solids. Unless the input solid is very simple, or it was computed using exact arithmetic, it is an open problem how to interpret the data such that a valid solid is obtained. For a deeper evaluation of the problem, and for some approaches to solving it, see [Chapter 41](#).

56.2.2 ALGORITHMIC INFRASTRUCTURE

Algorithmic infrastructure is a prominent research subject in solid modeling. Among the many questions addressed is the development of efficient and robust algorithms for carrying out the geometric computations that arise in solid modeling. The problems include point/solid classification, computing the intersection of two solids, determining the intersection of two surfaces, interpolating smooth surfaces to eliminate sharp edges on solids, and many more. See the reference section for a sampling of the literature.

Recent academic work considers structuring *application procedural interfaces*

(API's) that encapsulate the functional capabilities of solid modelers so they can be used in other programs; [ABC⁺00]. Such API's play a prominent role in applications because they allow building on existing software functionality and constructing different abstraction hierarchies than the one implemented by a full-service solid modeling system. The work attempts to give a system-independent specification of basic API functionality for solid modeling.

An important consideration when devising infrastructure is that the algorithms are often used by other programs, whether or not there is an API. Therefore, they must be ultra-reliable and in most cases must not require user intervention for exceptional situations.

The major geometric computations implemented at the infrastructure level have to balance the conflicting goals of efficiency, accuracy, and robustness. For this reason, many operations continue to be researched in efforts to seek new perceived optima. Moreover, new variants of surface representations continue to be devised that necessitate different approaches. Some of the major operations on which research continues are the following.

Surface intersection. Given two bounded areas of two surfaces, determine all intersection curve components. A major difficulty of the problem is to identify correctly all components of the intersection, including isolated points and singularities. Since this computation is done in $\mathbb{R}^3$, classical algebraic geometry is of limited help. The other difficulty is to address properly the substratum unreliabilities.

Surface intersection remains a key problem with continuing attempts at balancing efficiency, accuracy, and stability of the algorithms.

Offsetting. Given a surface, its *offset* is the set of all points that have fixed minimum distance from the surface. Offsets can have self-intersections that must be culled, and there is a technical relationship between offsetting and forming the MAT. Namely, when offsetting a curve or surface by a fixed distance, the self-intersections must lie on the medial axis. Offsetting is used to determine certain blending surfaces, and is also used in the solid operation of *shelling* that creates thin-walled solids.

Blending. Given two intersecting surfaces, a third surface is interpolated between them to smooth the intersection edge. A simple example is shown in [Figure 56.2.1](#). A locally convex blend surface is often called a *round*, and a locally concave one a *fillet*. The blend surface in [Figure 56.2.1](#) is a fillet.

Blending has been considered almost since the beginning of solid modeling, and some intuitive and interesting techniques have been developed over the years. For example, consider blending two primary surfaces f and g . Roll a ball of fixed radius r along the intersection such that it maintains contact with both f and g . Then the surface of the volume swept by the ball can be used as a blending surface, suitably trimmed. Note that the center of the ball lies on the intersection of the offsets, by r , of both f and g . In more complicated schemes the radius of the ball is varied along the intersection.

A less well-understood issue for blending solids arises from the global problem of how to devise the contact curves and blending surfaces, so that the surfaces connect properly at adjacent faces, behave correctly at vertices, and so on. [Figure 56.2.2](#) shows the problem of overlapping blends. The fillet and round

constructed separately do not meet in the region of overlap. The problem is that then there is no closed surface defining the blended solid. A resolution could modify the round, or the fillet, or could insert a separate surface in the overlap region after suitably cutting back both primary blends.

When the primary surfaces meet at a vertex tangentially, blending surfaces must “dissipate.” Figure 56.2.3 shows several methods to dissipate round and

FIGURE 56.2.1

Left: two cylinders intersecting in a closed edge. Right: edge blended with a constant-radius, rolling-ball blend; the bounding curves of the blend are shown.

FIGURE 56.2.2

Global blend interference [Bra97]: The round of the front edge overlaps with the fillet of the cylinder edge on top (left). Without further action, the two blends do not connect, leaving a gap in the surface. The solution shown in the middle modifies the front round. Other possibilities include modifying the fillet or inserting a separate blend in the overlap region (right).

FIGURE 56.2.3

Global blend interference [Bra97]: At ending vertex, the round and the fillet must be merged into a compatible structure. Several solutions are illustrated.

fillet at the end vertices. The examples are from [Bra97] and point out the dimensions of the global problem.

Deformations. Given a solid body, deform it locally or globally. The deformation could be required to obey constraints such as preserving volume or optimizing physical constraints. For example, we could deform the basic shape of a ship hull to minimize drag in fluids of various viscosities.

Shelling. Given a solid, hollow out the volume so that a thin-wall solid shape remains whose outer surface is part of the boundary of the input solid. The wall thickness is a parameter of the operation. Variations include designating parts of the solid surface as “open.” For instance, taking a solid cylinder and designating both flat end faces as open the operation creates a hollow tube of the same outside diameter. Conceptually, the operation subtracts an inset of the solid, obtained by shrinking the original solid, an offset operation.

56.2.3 USER INTERFACES

Ultimately, the functional capabilities of a solid modeling system have to be presented to a user, typically through a *graphical user interface* (GUI). It would be a mistake to dismiss GUI design as a simple exercise. If the GUI merely presents the functionality of the infrastructure literally, an opportunity for operational leveraging has been lost. Instead, the GUI should conceptualize the functionalities an application needs. As in programming language design, this conceptual view can be convenient or inconvenient for a particular application. Research on GUI's therefore is largely done with a particular application area in mind.

For example, in mechanical engineering product design, an important aspect of the GUI might be to allow the user to specify the shape conveniently and precisely. This might be accomplished using geometric constraints and constraints of length, radius, and angle. In GUI's for virtual environment definition and navigation, on the other hand, approximate constraints and direct manipulation interfaces would be better.

56.3 FEATURES AND CONSTRAINTS

GLOSSARY

Form feature: Any stereotypical shape detail that has application significance.

Geometric constraint: Prescribed distance, angle, collinearity, concentricity, etc.

Generic design: Solid design with constraints and parameters without regard to specific values.

Design instance: Resulting solid after substituting specific values for parameters and constraints.

Parametric constraint solving: Solving a system of nonlinear equations that has a fixed triangular structure.

Variational constraint solving: Solving a system of nonlinear simultaneous equations.

In solid modeling, two design paradigms have become standard for manufacturing applications, *feature-based design* and *constraint-based design*. The new paradigms expose a need to reconsider solid representations at a different level of abstraction. The representations reviewed before are for individual, specific solids. However, we need to represent entire *classes* of solids, comprising a generic design. Roughly speaking, solids in a class are built structurally in the same way, from complex shape primitives, and are instantiated subject to constraints that interrelate specific shape elements and parameters. How these families should be defined precisely, how each generic design should be represented, and how designs should be edited are all important research issues of considerable depth.

56.3.1 FEATURE-BASED DESIGN

Feature-based design is usually understood to mean designing with shape elements such as slots, holes, pockets, etc., that have significance to manufacturing applications relating to function, manufacturing process, performance, cost, and so on. Focusing on shape primarily, we can conceptualize solid design in terms of three classes of features: generative, modifying, and referencing features. A feature is added to an existing design using attachment attributes and placement conditions. Subsequent editing may change both types of attachment information.

As an example, consider the solid shown to the right in Figure 56.3.1. A hole was added to the design on the left, and this could be specified by giving the diameter of the hole, placing its cross section, a circle, on the side face, and requiring that the hole extend to the next face. Should the slot at which the hole ends be moved or altered by subsequent editing, then the hole would automatically be adjusted to the required extent.

FIGURE 56.3.1

Left: solid block with a profiled slot. Right: After adding a hole with the attribute “through next face,” an edited solid is obtained. If the slot is moved later, the hole will adjust automatically.

56.3.2 CONSTRAINT-BASED DESIGN

Constraint-based design refers to specifying shape with the help of constraints, when placing features or when defining shape parameters. For instance, assume that we are to design a cross section for use in defining a solid of revolution. A rough topological sketch is prepared (Figure 56.3.2, left), annotated with constraints, and instantiated to a sketch that satisfies the constraints exactly (Figure 56.3.2, right).

Auxiliary geometric structures can be added, such as an axis of rotation. There is an extensive literature on constraint solving, from a variety of perspectives.

FIGURE 56.3.2

Geometric constraint solving. Input to the constraint solver shown on the left. Here, the arc should be tangent to the adjacent segments, and the two other segments should be perpendicular. Output of the constraint solver shown on the right.

Most solid modeling systems use both features and constraints in the design interface. Often, the constraints on cross sections and other two-dimensional structures are unordered, but the constraints on 3D geometry are usually considered in a fixed sequence. Solving systems of unordered constraints is sometimes referred to as *variational constraint solving*. Mathematically, it is equivalent to solving a system of nonlinear simultaneous equations. Solving constraints in a fixed sequence is also known as *parametric constraint solving*. The latter is equivalent to solving a system of nonlinear equations that has a fixed, triangular structure where each equation introduces a new variable.

A well-constrained geometric constraint problem corresponds naturally to a system of nonlinear algebraic equations with a finite set of solutions. In general, there will be several solutions of a single, well-constrained geometric problem. An example is shown in Figure 56.3.3. This raises the interesting question of exactly how a constraint solver should select one of those solutions efficiently, and why.

FIGURE 56.3.3

The well-constrained geometric problem of placing 4 points by 5 distances has two distinct solutions.

From symbolic computation we know that there are algorithms to convert a nontriangular system of nonlinear equations into a triangular system. The distinction between parametric and variational constraint solving is therefore artificial in theory. However, full-scale triangularization of systems of nonlinear equations is not tractable in many cases, so the distinction is relevant in practice. Moreover, a predetermined sequential evaluation of constraints is simple to implement and can be interfaced easily with conditional constraint evaluation, thereby increasing the expressive power of the constraint system without raising new semantic issues. For these reasons, many developers of solid modeling systems leverage core modeling

capabilities by such (simple) extensions.

Spatial constraint solving is very much more demanding than planar constraint solving. In the planar case, simple (simultaneous) subsystems can be identified and isolated using straightforward graph algorithms, and result in practically important solvers. Furthermore, in the planar case, there are not many such subsystems needed. In contrast, no simple simultaneous spatial subsystems exist. When lines are allowed as geometric primitives, then the systems become very much harder and there are many such subsystems even when restricting to only five or six geometric elements. The number of basic cases number in the hundreds; [GHY02]. This structural barrier seems to preclude the emergence of truly spatial constraint solvers, and with it, of spatial design paradigms. In practice, CAD systems skirt the issue by building interrelated planar constraint problems which are variational in each plane but follow a clear, parametric sequence for elaborating the spatial relationship between the various planar problems.

56.3.3 SEMANTIC PROBLEMS

When constraints and parameters are used in solid design, a *generic design* is obtained. Generic designs are instantiated by constraint values, and may be edited by changing the constraint values, the constraint schema, and the feature attributes. A design so edited can then be automatically re-instantiated by the solid modeler. A central difficulty in implementing this scenario, however, is that the generic design is usually defined visually on the basis of a particular instance, and when the design changes, the instance geometry is no longer present. Thus, visually identified instance structures must be suitably described, so that re-instantiation can be carried out correctly.

As an example, consider the solid shown in Figure 56.3.4, left. It was constructed as follows. First, a rectangle was drawn and extruded into a block. On the front face of the block, a circle was drawn as a profile of a slot across the top of the block. Then, an edge was visually identified for rounding. This design is edited by altering the position of the circular slot profile. The edge to be rounded is not an explicit design entity, however. Hence, the edge has to be described implicitly, perhaps by the intersection of the circle and the top edge of the face on which the circle has been drawn. This description does not distinguish between the two straight edges of the slot, however, so additional information has to be used. Such information would have to allow a consistent identification under all possible constraint values, and is called the *persistent naming* problem.

FIGURE 56.3.4

A block with a slot and round on the left edge is shown left. After editing, in this case decreasing the depth of the slot, re-instantiation should produce the solid shown in the middle. However, some systems may re-instantiate as shown to the right, an error.

There has been a small stream of academic work on this topic, although it is of intense interest in applications. In particular, the formalization of the design information has profound implications on system architectures because it formalizes, in effect, the information flow between functional components. Whenever such formalization seeks independence from the specific implementation of the system components, system modularization is facilitated. Ultimately, this will accelerate the current trend of decomposing solid modeling systems into standardized components that can function interchangeably and can be combined in a variety of ways.

56.4 OPEN PROBLEMS

Most major problems in solid modeling contain a conceptualization aspect. That is, a precise, technical formulation of the problem commits to a specific conceptualization of the larger context that may be contentious. For example, consider the following technical problem. *Given an implicit algebraic surface S and a distance d , find the “offset” of S by d .* Assuming a precise definition of offset, and a restriction to irreducible algebraic surfaces S , the problem statement ignores the fact that a solid model is not bounded by a single, implicit surface, and that implicit surfaces of high algebraic degree may cause severe computational problems when used in a solid modeler.

CONSTRAINT SOLVING

Geometric constraint solvers trade efficiency for generality. Some very interesting techniques have been developed for planar problem that are fast but not very general. They could be extended in various ways without substantially impacting on efficiency. Such extensions, for constraint solving in the plane, include the incorporation of parametric curve segments as geometric elements, more general constraint configurations, relations among distances, and angles.

Spatial geometric constraint solving poses a number of open problems, including determining whether a constraint problem is generically well-constrained. The problem of how many lines can be found at prescribed distance from four fixed points has been solved, one of the sequential construction problems for lines. Other construction problems for lines are not completely solved. The smaller simultaneous problems involving points and planes have been solved. Most simultaneous problems involving lines require numerical treatment, however, and are not well understood.

FEATURES

Manufacturing applications need cogent definitions of features to accelerate design. Such definitions ought to be in terms of generic mechanisms of form and of function. Also needed are mapping algorithms interrelating different feature schemata.

A set of features, say those conceptualizing machining a shape from stock, is called a *design view*. In manufacturing applications there are many views, including machining, tolerancing, design view, etc. Work has begun to address the problem of altering a design in one view with an automatic update of the other views. To

do so requires reasoning about shape and is a hard problem. Some approaches have been based on subdividing the shape by superimposing all feature boundaries, and then tracking how the subdivision is affected by changes to one of the features.

SEMANTICS OF CONSTRAINT-BASED DESIGN

A solid shape design in terms of constraints can be changed simply by changing constraint values. To date, all such changes have been specified in terms of the procedures and algorithms that effect the change. What is needed is an abstract definition of shape change under such constraint changes to obtain a semantic definition of generic design and constraint-based editing. Such a definition must be visually intuitive.

MODEL RECTIFICATION

Because of the substratum problem, Brep data structures can be invalid in the sense that the geometric description does not agree fully with the topological description. For instance, there may be small cracks between adjacent faces, the edge between two adjacent faces may not be where the curve description would place it, and so on. This has motivated work to “heal” the defective surface by closing cracks, eliminating overlaps, and so on. Some approaches sew up cracks with smaller faces, and in the case of polyhedra with triangles. Optimal healing is known to be NP-hard.

An intuitive idea is to assign a thickness to faces, edges and vertices, and enlarge the thickness so that the surface closes up. The difficulty is to work out what happens when nonadjacent faces merge into adjacent ones. The natural geometric enlargement creates mathematically difficult surfaces; for instance, the offset surface of an ellipsoid increases the algebraic degree by a factor of 4. So, an interval based approach has also been proposed in which there is no closed-form description of the enlarged geometric elements.

56.5 SOURCES AND RELATED MATERIAL

FURTHER READING

Monographs on solid modeling. Monographs and surveys provide an excellent entry into solid modeling. Major monographs on solid modeling are [Chi88, Hof89, Män88]. Books on the related field of CAGD (computer-aided geometric design) may also contain material on solid modeling but concentrate primarily on curve and surface design and manipulation. Surface interrogation from a solid modeling point of view is explored in [Hos92, PM02].

Solid representations and conversion. There is a large and diverse literature on representations and representation conversion. Classical work focused primarily on the semantic foundations of CSG and Brep and includes [Req77, Wei86]. Maintaining Brep and CSG simultaneously has been explored in [RS00]. The mesh and octree representations are treated in [BN90, Hof95, Sam89a, Sam89b, TWM85], including the associated conversion problems. The medial axis representation of solids, and how to compute with it, are considered in [Hof92, SAR95, Ver94]. Implicit algebraic

halfspaces as solid primitives are discussed in [BDL⁺91]. The conversion between boundary representation and CSG can be considered a generalization of the binary space partition tree and is explored in [Hof93b, Nay90, NR95, Sha91, SV93]. Curve and surface representations, and their manipulation, are the subject of [Far88, Hos92, HL93, PM02]. More specialized treatment of offsets and sweeps is found in [BL90, CHL91]. Procedural script language representations are discussed in [Bro82, UU94, SS01] for PADL, Alpha_1, and SGDL. Data representations that neutrally describe form features and constraints are developed in [HJ92].

Substratum, infrastructure, and user interfaces. The substratum robustness issue is presented in greater depth in [Chapter 41](#); [SI89, For97] explores the use of exact arithmetic in polyhedral modeling. Manocha and Keyser work with exact arithmetic for curved solids; [KKM99a, KKM99b]. A recent survey is found in [Hof01].

Infrastructure work is traditionally quite extensive. Surface intersection is treated in [Hoh92]; this thesis contains an excellent summary of previous work. A recent monograph on the subject is [PM02]. Global solid operations are considered in [BW89, For95, PS95, RSB96]; local solid operations are discussed in [HH87, Pet92]. Much work has been done in blending. The local problem is often addressed in the context of CAGD, and the monographs on that subject contain much material. The global blending problem is treated extensively in [Bra97]. Work in symbolic algebraic computation ([Chapter 33](#)) has foundational importance, for instance in regard to converting between surface representations. Some of the applications of symbolic computation are explored in [BCK88, Cho87, Hof90].

Features and constraints. Neither topic is new, so there is a sizable literature on both. The confluence of the two issues in recent solid modeling systems, however, is new. It raises a number of questions that have only recently been articulated and addressed. [SHL92, KRU94] discuss feature work. Constraints are the subject of [BFH⁺95, HV94, Kra92]. The confluence of the two strands and some of the implications are discussed in [HJ92]. Some of the technical issues that must be addressed are explained in [Hof93a, CH95], and there is more work emerging on this subject. In particular, Shapiro and Raghothama propose several criteria for defining a family of solids; [RS02, RS98].

57 COMPUTATION OF ROBUST STATISTICS: DEPTH, MEDIAN, AND RELATED MEASURES

Peter J. Rousseeuw and Anja Struyf

INTRODUCTION

As statistical data sets grow larger and larger, the availability of fast and efficient algorithms becomes ever more important in practice. Classical methods are often easy to compute, even in high dimensions, but they are sensitive to outlying data points. Robust statistics develops methods that are less influenced by abnormal observations, often at the cost of higher computational complexity. Many robust methods, especially those based on ranks, are closely related to geometric or combinatorial problems. An early overview of relations between statistics and geometry was given in [Sha76].

Recently many other (mostly multivariate) statistical methods have been developed that have a combinatorial or geometric character and are computationally intensive. Techniques of computational geometry appear to be very well suited for the development of fast algorithms. Over the last decade, the notion of statistical depth especially received considerable attention from the computational geometry community. We mainly concentrate on depth and multivariate medians in this chapter, and in Section 57.3 we list other areas of statistics where computational geometry has recently been of use in constructing efficient algorithms.

57.1 MULTIVARIATE RANKING

A data set consisting of n univariate points is usually ranked in ascending or descending order. Univariate order statistics (i.e., the ' k th smallest value out of n ') and derived quantities have been studied extensively. The median is defined as the order statistic of rank $(n + 1)/2$ when n is odd, and as the average of the order statistics of ranks $n/2$ and $(n + 2)/2$ when n is even. The median and any other order statistic of a univariate data set can be computed in $O(n)$ time. Generalization to higher dimensions is, however, not straightforward.

Alternatively, univariate points may be ranked from the outside inward by assigning the most extreme data points depth 1, the second smallest and second largest data points depth 2, etc. The deepest point then equals the usual median of the sample. The advantage of this type of ranking is that it can be extended to higher dimensions more easily. This section gives an overview of several possible generalizations of depth and the median to multivariate settings. A comprehensive survey of statistical applications of multivariate data depth may be found in [LPS99].

GLOSSARY

Bagplot: Bivariate generalization of the boxplot based on depth regions.

Breakdown value: The smallest fraction of contaminated data points that can move the estimator arbitrarily far away.

Centerpoint: Any point with halfspace depth $\geq \lceil n/(d+1) \rceil$.

Deepest fit: Median hyperplane based on regression depth.

Depth: The outside-inward “rank” of a point (not necessarily a data point).

Depth region: The set of all points with depth $\geq k$ is called the k th depth region D_k .

Median: The point with maximal depth. When this point is not uniquely defined, the median is taken to be the centroid of the depth region with highest depth.

Tukey median: Median based on halfspace depth.

HALFSPACE LOCATION DEPTH

Let $X_n = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ be a finite set of data points in $\mathbb{R}^d$. The *Tukey depth* or *halfspace depth* (introduced by [Tuk75] and further developed by [DG92]) of any point $\boldsymbol{\theta}$ in $\mathbb{R}^d$ (not necessarily a data point) determines how central the point is inside the data cloud. The halfspace depth of $\boldsymbol{\theta}$ is defined as the minimal number of data points in any closed halfspace determined by a hyperplane through $\boldsymbol{\theta}$:

$$ldepth(\boldsymbol{\theta}; X_n) = \min_{\|\mathbf{u}\|=1} \#\{i; \mathbf{u}^\tau \mathbf{x}_i \geq \mathbf{u}^\tau \boldsymbol{\theta}\}.$$

Thus, a point lying outside the convex hull of X_n has depth 0, and any data point has depth at least 1. Figure 57.1.1 illustrates this definition for $d = 2$.

FIGURE 57.1.1

Illustration of the bivariate halfspace depth. Here $\boldsymbol{\theta}$ (which is not a data point itself) has depth 1 because the halfspace determined by $\mathbf{u}$ contains only one data point.

The halfspace depth regions form a sequence of nested polyhedra. Each D_k is the intersection of all halfspaces containing at least $n - k + 1$ data points. Moreover,

every data point must be a vertex of one or more depth regions. The median for halfspace depth is called the *Tukey median*. When the innermost depth region is larger than a singleton, the Tukey median is defined as its centroid. This makes the Tukey median unique by construction.

Note that the depth regions give an indication of the shape of the data cloud. Based on this idea one can construct the *bagplot* [RRT99], a bivariate version of the univariate boxplot. Figure 57.1.2 shows such a bagplot. The cross in the white disk is the Tukey median. The dark area is an interpolation between two subsequent depth contours, and contains 50% of the data. This area (the “bag”) gives an idea of the shape of the majority of the data cloud. Inflating the bag by a factor of 3 relative to the Tukey median yields the “fence” (not shown), and data points outside the fence are called outliers and marked by stars. Finally, the light gray area is the convex hull of the non-outlying data points.

FIGURE 57.1.2

Bagplot of the heart and spleen size of 73 hamsters.

An often used criterion to judge the robustness of an estimator is its *breakdown value*. The breakdown value is the smallest fraction of data points that we need to replace in order to move the estimator of the contaminated data set arbitrarily far away. The classical mean of a data set has breakdown value zero since it will already explode when we move one observation far out. Note that for any estimator which is equivariant for translation (which is required to call it a location estimator) the breakdown value can be at most $1/2$. (If we replace half of the points by a far-away

translation image of the remaining half, the estimator cannot distinguish which were the original data.)

The Tukey depth and the corresponding median have good statistical properties. The Tukey median T^* is a location estimator with breakdown value $\epsilon_n(T^*; X_n) \geq 1/(d+1)$ for any data set in general position. This means that it remains in a predetermined bounded region unless $n/(d+1)$ or more data points are moved. At an elliptically symmetric distribution the breakdown value becomes $1/3$ for large n , irrespective of d . Moreover, the halfspace depth is invariant under all nonsingular affine transformations of the data, making the Tukey median affine equivariant. Since data transformations such as rotation and rescaling, are very common in statistics, this is an important property. The statistical asymptotics of the Tukey median have been studied in [BH99].

CENTERPOINTS

There is a close relationship between the Tukey depth and centerpoints, which have been long studied in computational geometry. In fact, Tukey depth extends the notion of centerpoint. A *centerpoint* is any point with halfspace depth $\geq \lceil n/(d+1) \rceil$. A consequence of Helly's theorem is that there always exists at least one centerpoint, so the depth of the Tukey median cannot be less than $\lceil n/(d+1) \rceil$.

OTHER LOCATION DEPTH NOTIONS

1. **Simplicial depth** ([Liu90]). The depth of θ equals the number of simplices formed by $d+1$ data points that contain θ . Formally,

$$sdepth(\theta; X_n) = \#\{(i_1, \dots, i_{d+1}); \theta \in S[x_{i_1}, \dots, x_{i_{d+1}}]\}.$$

The simplicial median is affine equivariant with a breakdown value bounded above by $1/(d+2)$.

2. **Oja depth** ([Oja83]). This is also called simplicial volume depth:

$$odepth(\theta; X_n) = \left(1 + \sum_{(i_1, \dots, i_d)} \{volume S[\theta, x_{i_1}, \dots, x_{i_d}]\}\right)^{-1}.$$

The corresponding median is also affine equivariant, but has zero breakdown value.

3. **Projection depth**. We first define the *outlyingness* ([DG92]) of any point θ relative to the data set X_n as

$$O(\theta; X_n) = \max_{\|u\|=1} \frac{|u^\tau \theta - \text{med}_i \{u^\tau x_i\}|}{\text{MAD}_i \{u^\tau x_i\}},$$

where the median absolute deviation (MAD) of a univariate data set $\{y_1, \dots, y_n\}$ is the statistic $\text{MAD}_i \{y_i\} = \text{med}_i |y_i - \text{med}_j \{y_j\}|$. The outlyingness is small for centrally located points and increases if we move toward the boundary of the data cloud. Instead of the median and the MAD, also another pair (T, S) of a location and scatter estimate may be chosen. This leads to different notions of projection depth, all defined as

$$pdepth(\theta; X_n) = (1 + O(\theta; X_n))^{-1}.$$

General projection depth is studied in [Zuo03]. As with the median and the MAD, the projection depth has breakdown value $1/2$ and is affine equivariant.

4. **Spatial median** ([Gow74]). This median maximizes the function

$$L^1 \text{depth}(\boldsymbol{\theta}; X_n) = (1 + \sum_{i=1}^n \|\mathbf{x}_i - \boldsymbol{\theta}\|)^{-1}.$$

It has breakdown value $1/2$, but is not affine equivariant (it is only equivariant with respect to translations, multiplication by a scalar factor, and orthogonal transformations).

5. **Convex hull peeling**. Here the depth of a point $\boldsymbol{\theta}$ is defined as the level of the convex layer of X_n to which $\boldsymbol{\theta}$ belongs. The convex hull of the data set has level 1. By removing these points and repeating the procedure on the remaining points we obtain a sequence of nested convex layers which define the higher levels. The resulting depth has no population analog, unlike the other definitions given above. Moreover, its robustness properties are not good, hence it will not be considered further in this chapter.

A comparison of the main properties of the different location depth medians is given in Table 57.1.1.

TABLE 57.1.1 Comparison of several location depth medians.

MEDIAN	BREAKDOWN VALUE	AFFINE EQUIVARIANCE
Tukey	worst-case $1/(d+1)$ typically $1/3$	yes
Oja	$2/n \approx 0$	yes
Simplicial	$\leq 1/(d+2)$	yes
Projection	$1/2$	yes
Spatial	$1/2$	no

REGRESSION DEPTH

Following [RH99b] we now define the depth of a point relative to an arrangement of hyperplanes (see [Chapter 24](#)). A point $\boldsymbol{\theta}$ is said to have depth 0 if there exists a ray $\{\boldsymbol{\theta} + \lambda \mathbf{u}; \lambda \geq 0\}$ that does not cross any of the hyperplanes h_i in the arrangement. (A hyperplane parallel to the ray is counted as intersecting at infinity.) The depth of any point $\boldsymbol{\theta}$ is then the minimum number of hyperplanes intersected by any ray from $\boldsymbol{\theta}$. [Figure 57.1.3](#) shows an arrangement of lines. In this plot, the points $\boldsymbol{\theta}$ and η have depth 0 and the point ξ has depth 2. The depth is always constant on open cells and on cell edges. It was shown ([RH99b]) that any arrangement of lines in the plane encloses a point with depth at least $\lceil n/3 \rceil$, giving rise to a new type of “centerpoints.”

This notion of depth was originally defined ([RH99]) in the dual, as the depth of a regression hyperplane H_{θ} relative to a point configuration of the form $Z_n = \{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)\}$ in $\mathbb{R}^{d+1}$. Regression depth ranks hyperplanes according to how well they fit the data in a regression model, with $\mathbf{x}$ containing the predictor variables and y the response. A vertical hyperplane ($\mathbf{x} = \text{constant}$), which cannot be used to predict future response values, is called a “nonfit” and has depth 0. The regression depth of a hyperplane H_{θ} is found by rotating H_{θ} in a continuous movement until it becomes vertical. The minimum number of data points that is passed in such a rotation is called the **regression depth** of H_{θ} . Figure 57.1.4 is the dual representation of Figure 57.1.3. (For instance, the line θ has slope θ_1 and intercept θ_2 and corresponds to the point (θ_1, θ_2) in Figure 57.1.3.) The lines θ and η have depth equal to 0, whereas the line ξ has depth 2.

FIGURE 57.1.3

Example of the regression depth of a point in an arrangement of lines (see Figure 57.1.4 for the dual plot).

In statistics one is interested in the *deepest fit* or regression depth median, because this is a line (hyperplane) about which the data are well-balanced. The statistical properties of regression depth and the deepest fit are very similar to those of the Tukey depth and median. The bounds on the maximal depth are almost the same. Moreover, for both depth notions the value of the maximal depth can be used to characterize the symmetry of the distribution ([RS04]). The breakdown value of the deepest fit is at least $1/(d+1)$ and under linearity of the conditional median of y given $\mathbf{x}$ it converges to $1/3$. In the next section, we will see that the optimal complexities for computing the depth and the median are also comparable. For a detailed comparison of the properties of halfspace and regression depth, see [HRV01].

The regression depth region D_k is defined in the primal, as the set of points

FIGURE 57.1.4

Example of the regression depth of a line in a bivariate configuration of points (this is the dual of Figure 57.1.3).

with arrangement depth at least k . Contrary to the Tukey depth, these depth regions need not be convex. But nevertheless it was proved that there always exists a point with arrangement depth at least $\lceil n/(d+1) \rceil$ ([ABE⁺00]).

ARRANGEMENT LEVELS

Regression depth is undirected (isotropic) in the sense that it is defined as a minimum over all possible directions. If we restrict ourselves to vertical directions $\mathbf{u}$ (i.e., up or down), we obtain the usual levels of the arrangement (cf. Section 24.2). The absence of preferential directions makes regression depth invariant under affine transformations.

57.2 COMPUTING DEPTH

Although the definitions of depth are intuitive, the computational aspects can be quite challenging. The calculation of depth regions and medians is computationally intensive, especially for large data sets in higher dimensions. In statistical practice, such data are quite common and therefore reliable and efficient algorithms are needed. For the bivariate case several algorithms have been developed. Unfortunately, some are complex and have yet to be implemented. The computational aspects of depth in higher dimensions are still mostly unexplored.

Algorithms for depth-related measures are often more complex for data sets which are not in general position than for data sets in general position. For example, the boundaries of subsequent halfspace depth regions are always disjoint when

the data are in general position, but this does not hold for nongeneral position. Preferably, algorithms should be able to handle both the general position case and the nongeneral position case directly. As a quick fix, algorithms which were made for general position can also be applied in the other case if one first adds small random errors to the data points. For large data sets, this dithering will have a limited influence on the results.

BIVARIATE ALGORITHMS

Table 57.2.1 gives an overview of algorithms, each of which has been implemented, to compute the depth in a given point θ in $\mathbb{R}^2$. These algorithms are time-optimal, since the problem of computing these bivariate depths has an $\Omega(n \log n)$ lower bound ([ACG⁺02], [LS00b]).

The algorithms for halfspace and simplicial depth are both based on the same technique. First, data points are radially sorted around θ . Then a line is rotated through θ . The depth is calculated by counting the number of points that are passed by the rotating line in a specific manner. The planar regression depth algorithm is easiest to visualize in the regression setting. To compute the depth of a hyperplane H_θ with coefficients θ , the data are first sorted along the x -axis. A vertical line L is then moved from left to right and each time a data point is passed, the number of points above and below H_θ on both sides of L is updated.

TABLE 57.2.1 Computing the depth of a bivariate point.

DEPTH	TIME COMPLEXITY	SOURCE
Tukey depth	$O(n \log n)$	[RR96]
Regression depth	$O(n \log n)$	[RH99]
Simplicial depth	$O(n \log n)$	[RR96]

In general, computing a median is harder than computing the depth in a point, because typically there are many candidate points. For instance, for the simplicial median the currently best algorithm requires $O(n^4)$ time, whereas its corresponding depth needs only $O(n \log n)$. The simplicial median seems difficult to compute because there are $O(n^4)$ candidate points (namely, all intersections of lines passing through two data points) and the simplicial depth regions have irregular shapes, but of course a faster algorithm may yet be found.

Fortunately, in several important cases the median can be computed without computing the depth of individual points. Table 57.2.2 gives an overview of algorithms to compute bivariate depth-based medians. For the regression depth median, an $\Omega(n \log n)$ lower bound was established by [LS00b], and the same lower bound holds for computing the Tukey median ([LS00]). The currently best algorithm for the Tukey median is based on Matoušek's algorithm to find the median in $O(n \log^5 n)$ time ([Mat91]). This algorithm first finds a region D_k with $k \geq \lceil n/3 \rceil$.

Then, a binary search is used to find the largest k for which $D_k \neq \emptyset$. Unfortunately this procedure seems too complex to implement. (An actual implementation is available for a slower algorithm in [RR98].)

A linear-time algorithm to compute a bivariate centerpoint is described in [JM94].

TABLE 57.2.2 Computing the bivariate median.

MEDIAN	TIME COMPLEXITY	SOURCE
Tukey median	$O(n \log^4 n)$	[LS00]
Regression depth median	$O(n \log n)$	[LS00b]
Simplicial median	$O(n^4)$	[ALS ⁺ 03]
Oja median	$O(n \log^3 n)$	[ALS ⁺ 03]

The computation of bivariate halfspace depth regions has also been studied. The first algorithm [RR96b] required $O(n^2 \log n)$ time per depth region. An algorithm to compute all regions in $O(n^2)$ time is constructed and implemented in [MRR⁺01]. This algorithm thus also yields the Tukey median in $O(n^2)$ time. It is based on the dual arrangement of lines where topological sweep is applied. A completely different approach is implemented in [KMV02]. They make direct use of the graphics hardware to approximate the depth contours of a set of points in $O(nW + W^3) + nCW^2/512$ time, where the pixel grid is of dimension $(2W + 1) \times (2W + 1)$.

ALGORITHMS IN HIGHER DIMENSIONS

Algorithms to compute the halfspace and regression depth of a given point in $\mathbb{R}^d$ in $O(n^{d-1} \log n)$ time are constructed in [RS98], where also faster approximate algorithms are given.

The simplicial depth of a point in $\mathbb{R}^3$ can be computed in $O(n^2)$ time, and in $\mathbb{R}^4$ the fastest algorithm needs $O(n^4)$ time [CO01]. For higher dimensions, no better algorithm is known than the straightforward $O(n^{d+1})$ method to compute all simplices.

The currently best available algorithms for computing the halfspace, regression, and simplicial depth in higher dimensions all use projections onto a lower-dimensional space. This reduces the problem to computing bivariate depths, for which optimal algorithms exist.

Very little is known about the computation of high-dimensional depth medians and regions. A steepest descent algorithm to approximate the Tukey median in any dimension was developed in [SR00]. In [VRH⁺02] an algorithm is described to approximate the deepest fit in any dimension. No efficient implementable algorithm for the depth regions in 3 dimensions is yet available. The algorithm of [MRR⁺01] can theoretically be generalized to higher dimensions, but the sweeping method they use has not yet been implemented for more than two dimensions.

OPEN PROBLEMS

Aside from the fact that many of the above described algorithms are clearly not optimal, and that the optimal possible complexity for most remains unknown, three important open problems stand out:

1. The projection depth has better statistical properties than most other location depth notions. However, its practical use is severely limited by the absence of an efficient algorithm to compute the projection depth and the associated median.
2. An efficient and implementable algorithm for 3D depth contours is needed. This would allow for a natural extension of the bagplot to three dimensions.
3. Most data sets have more than two variables. Algorithms to compute the medians for location as well as regression depth in any dimension are therefore needed in practice. For large data sets, good approximate algorithms can be a valuable alternative to optimal exact algorithms, which may be quite slow.

57.3 OTHER STATISTICAL TECHNIQUES

Computational geometry has provided fast and reliable algorithms for many other statistical techniques, especially for bivariate problems.

Linear regression is a frequently used statistical technique. The ordinary least squares regression, minimizing the sum of squares of the residuals, is easy to calculate, but produces unreliable results whenever one or more outliers are present in the data. Robust alternatives are often computationally intensive. We here give some examples of regression methods for which geometric or combinatorial algorithms have been constructed.

1. **L^1 regression.** This well-known alternative to least squares regression minimizes the sum of the absolute values of the residuals, and is robust to vertical outliers. Algorithms for L^1 regression may be found in, e.g., [YKI⁺88].
2. **Least median of squares (LMS) regression** ([Rou84]). This method minimizes the median of the squared residuals and has a breakdown value of $1/2$. To compute the bivariate LMS line, an $O(n^2)$ algorithm using topological sweep has been developed [ES90]. An approximation algorithm for the LMS line is constructed in [MN⁺97].
3. **Median slope regression** ([The50], [Sen68]). This bivariate regression technique selects the line with median slope of all lines through two data points. An optimal $O(n \log n)$ algorithm is given in [BC98], and a more practical randomized algorithm in [DMN92].
4. **Repeated median regression** ([Sie82]). Median slope regression takes the median over all couples (d -tuples in general) of data points. Here, this median is replaced by d nested medians. For the bivariate repeated median regression line, [MMN98] provide an efficient randomized algorithm.

Algorithms for higher-dimensional generalizations of the median slope and repeated median regression estimators are discussed in [MN94].

The aim of cluster analysis (Section 51.1) is to divide a data set into clusters of similar objects. Partitioning methods divide the data into k groups. Hierarchical methods construct a complete clustering tree, such that each cut of the tree gives a partition of the data set. A selection of clustering methods with accompanying algorithms is presented in [SHR97]. The general problem of partitioning a data set into groups such that the partition minimizes a given error function f is NP-hard. However, for some special cases efficient algorithms exist. For a small number of clusters in low dimensions, exact algorithms for partitioning methods can be constructed. Constructing clustering trees is also closely related to geometric problems (see e.g., [Epp97], [Epp98]).

58 GEOGRAPHIC INFORMATION SYSTEMS

Marc van Kreveld

INTRODUCTION

Geographic information systems (GIS) facilitate the input, storage, manipulation, analysis, and visualization of geographic data. Geographic data generally has a location, size, shape, and various attributes, and may have a temporal component as well. Geographical analysis is important for a GIS. It includes combining different spatial themes, relating the dependency of phenomena to distance, interpolating, studying trends and patterns, and more. Without analysis, a GIS could be called a spatial database.

Not all aspects of GIS are relevant for computational geometers. Human-computer interaction, and legal aspects of GIS, are also considered part of GIS research. This chapter focuses primarily on those aspects that are susceptible to algorithms research. Even here, the approach taken within GIS research is different from the approach a computational geometer would take, with much less initial abstraction of the problem, and less emphasis on theoretical efficiency. The GIS research field is multi-disciplinary: it includes researchers from geography, geodesy, cartography, and computer science. The research areas geodesy, surveying, photogrammetry, and remote sensing primarily deal with the data input, storage, and correction aspects of GIS. Cartography mainly concentrates on the visualization aspects.

Section 58.1 deals with spatial data structures important to GIS. Section 58.2 discusses the most common spatial analysis methods. Section 58.3 discusses the visualization of spatial data, also called automated cartography. Section 58.4 deals with Digital Elevation Models (DEMs) and their algorithms. Section 58.5 discusses the most important contributions that can be made from the computational geometry perspective to research problems in GIS. Section 58.6 lists several open problems.

58.1 SPATIAL DATA STRUCTURES

GIS store different types of data separately, such as land cover, elevation, and municipality boundaries. Therefore, each such data set is stored in a separate data structure that is tailored to the data, both in terms of representation and searching efficiency.

Geometric data structures for intersection, point location, and windowing are a mainstream topic in computational geometry, and are treated at length in [Chapters 34, 36, and 38](#). This section concentrates on concepts and results that are specific and important to GIS. We overview raster and vector representation of data, problems that appear in data input and correction in a GIS, and a well-known spatial indexing structure.

GLOSSARY

Thematic map layer: Separately stored and manipulatable component of a map that contains the data of only one specific theme or geographic variable.

(Geographic) feature: Any geographically meaningful object.

Raster structure: Representation of geometric data based on a subdivision of the underlying space into a regular grid of square pixels.

Vector structure: Representation of geometric data based on the representation of points with coordinates, and line segments between those points.

Digitizing: Process of transforming cartographic data such as paper maps into digital form by tracing boundaries with a mouse-like device.

Conflation: Process of rectifying a digital data set by comparison with another digital data set that covers the same region (cf. rubber sheeting).

Topological vector structure: Vector structure in which incidence and adjacency of points and line segments is explicitly represented.

Quadtree: Tree where every internal node has four children, and which corresponds to a recursive subdivision of a square into four subsquares. The standard quadtree is for raster data. Leaves correspond to pixels or larger squares that appear in the recursive subdivision and are uniform in the thematic value.

R-tree: Tree based on a recursive partitioning of a set of objects into subsets, where every node stores the axis-parallel bounding box of all objects that appear in its subtree. All leaves have the same depth. R-trees usually have high (but constant) degree and are well-suited for secondary memory.

58.1.1 RASTER AND VECTOR STRUCTURES

Geographic data is composed of geometry, topology, and attributes. The attributes contain the semantics of a geographic feature. There are two essentially different ways to represent the geometric part of geographic data: raster and vector. This distinction is the same as representation in image space and object space in computer graphics ([Chapter 49](#)).

Data acquisition and input into a GIS often cause error and imprecision in the data, which must be corrected either manually or in an automated way. Also, the digitizing of paper maps yields unstructured collections of polygonal lines in vector format, to which topological structure is usually added using the GIS.

The topological vector structure obtained could be represented as, for example, a doubly-connected edge list or a quad-edge structure. But for maps with administrative boundaries, where long polygonal boundary lines occur where all vertices have degree 2, such a representation is space-inefficient. It is undesirable to have a separate object for every vertex and edge, with pointers to the incident features. The following variation gives better efficiency. Group maximal chains of degree-2 vertices into single objects, and treat them like an edge in the doubly-connected edge list. More explicitly, a chain stores pointers to the origin vertex (junction or endpoint), the destination vertex (junction or endpoint), the left face, the right face, and the next and previous chains in the two cycles of the faces incident to this

FIGURE 58.1.1

A set of polygons and an example of an R-tree for it.

chain. Such a representation allows retrieval of k adjacent faces of a face with m vertices to be reported in $O(k)$ time rather than in $O(m)$ time.

Relatively recent trends in geographic data modeling and representation include multi-scale models, temporal and spatio-temporal models, fuzzy models, and qualitative representations of location.

58.1.2 R-TREES

The most widely used spatial data structure in GIS is the R-tree of Guttman [Gut84]. It is a type of box-tree (see [BCG⁺96]) that has high (but constant) degree internal nodes, with all leaves at the same depth. It permits any type of object to be stored, and supports several types of queries, such as windowing, point location, and intersection. Insertions and deletions are both supported. The definition of R-trees does not specify which objects go in which subtree, and different heuristics for grouping give rise to different versions [BKSS90, KF94, LLE97].

R-trees generally do not have nontrivial worst-case query time bounds, so different versions must be compared experimentally. Only the version of Agarwal et al. [AdB⁺02] has a query time bound better than linear (close to $O(\sqrt{n})$) when the stored objects are rectangles, but this structure cannot be maintained dynamically while retaining the query time.

58.2 SPATIAL ANALYSIS

Spatial analysis is the process of discovering information implicitly present in one or more spatial data sets. This includes common GIS operations such as map overlay, buffer computation, and shortest paths on road networks, but also geostatistical and spatial data analysis functions such as cluster detection, spatial interpolation, and spatial modeling. We discuss the most common forms and results in this section. For cluster analysis and classification, see [Chapter 51](#).

GLOSSARY

Map overlay: The operation of combining two thematic map layers of the same region in order to obtain one new map layer, often with a refinement of the subdivisions used for the input map layers.

Buffer: The region of the plane within a certain specified distance to a geographic feature.

Neighborhood analysis: The study of how relations between geographic features depend on the distance.

Network analysis: The study of distance, reachability, travel time, and similar geographic functions that can be defined for network data (graphs with a geographic meaning).

Cluster analysis: The study of the grouping in sets of geographic features by proximity.

Trend analysis: The study of time-dependent patterns in geographic data.

Spatial interpolation: The derivation of values at locations based on values at other (nearby) locations.

Geostatistics: Statistics for data associated with locations in the plane.

58.2.1 MAP OVERLAY

With map overlay, two or more thematic map layers are combined into one. For example, if one map layer contains elevation contours and another map layer (of the same region) forest types, then their overlay reveals which types of forest occur at which elevations. One layer can also serve as a mask for the other layer. Overlay is essential to locating a region that has various properties that appear in different thematic map layers. In the spatial database literature, map overlay is also called *spatial join*.

Map overlay is commonly solved using a plane sweep like the Bentley-Ottmann algorithm [BO79] for line segment intersection. This leads to an $O((n + k) \log n)$ time algorithm for two planar subdivisions of complexity $O(n)$, and output complexity $O(k)$. However, map overlay of two thematic map layers is essentially an extension of a red-blue line segment intersection problem, and can therefore be solved in optimal $O(n \log n + k)$ time [CEGS94, Cha94, PS94]. In case each subdivision is simply connected, the given result can be improved to $O(n + k)$ [FH95].

Map overlay in GIS must handle imprecise data as well, and therefore overlay methods that include sliver removal have been suggested. Essentially, boundaries that are closer than some pre-specified value are identified in the overlay. This is also called *epsilon filter* or *fuzzy tolerance* [Chr97]. The idea of using an epsilon band around a cartographic line is due to Perkal [Per66].

Since R-trees can also be used as access structures for subdivisions, map overlay can also be performed efficiently using R-trees [BKS93, KBS91, vO94].

FIGURE 58.2.1

Natural neighbor interpolation at p_0 ; five measurements determine the interpolated value with weights proportional to the areas of the five grey regions.

58.2.2 BUFFER COMPUTATION

The buffer of a geographic feature of width ϵ is the same as the Minkowski sum of that feature with a disk of radius ϵ , centered at the origin; see [Chapter 47](#). Computation can be done with the algorithms mentioned in that chapter.

Buffer computation and map overlay are two main ingredients for urban planning. As an example, tree requirements for a new factory may be the proximity of a river, at least some distance to houses, and not in nature areas. A map with suitable locations is obtained after computing buffers for two of the thematic map layers, and then combining these with each other and the third layer.

58.2.3 SPATIAL INTERPOLATION

Spatial interpolation is one of the main operations in geostatistics. It is the operation of defining values at locations when only values at other locations are known. For example, when ground measurements are taken at various locations, we only know values at a finite set of points, but we would like to know the values everywhere. Several methods exist for this version of the spatial interpolation problem, including triangulation, moving windows, natural neighbors, and Kriging. Triangulation is discussed in the next section. Moving windows is simply weighted averaging of known (or observed) values within a window around the point with unknown value.

Natural neighbor interpolation is a method based on Voronoi diagrams [Sib81, SBM95]. Suppose the Voronoi diagram of the points with known values is given, and we want to obtain an interpolated value at another location p_0 . We determine what Voronoi cell p_0 would “own” if it were inserted in the point set defining the Voronoi diagram. Let A be the area of the Voronoi cell of p_0 , and let $A_1, \dots, A_k$ be the areas removed from the Voronoi cells of the points $p_1, \dots, p_k$, due to the insertion of p_0 . Then, by natural neighbor interpolation, the interpolated value at p_0 is $\sum_{i=1}^k (A_i/A) \cdot V(p_i)$, where $V(p_i)$ denotes the known or observed value at p_i . The bivariate function obtained is continuous everywhere, and differentiable except at the points with known values.

Kriging is an interesting method that also applies weighted linear combinations of the known (or observed) values, that is, $V(p_0) = \sum_{i=1}^n \lambda_i \cdot V(p_i)$. The λ_i are the weights, which sum to 1. Furthermore, the weights are chosen so that

the estimation variance is less than for any other linear combination of known values. One additional advantage of Kriging is that it provides an estimation error as well [BM98].

Splines, discussed extensively in [Chapter 53](#), can also be used for interpolation. A version used in GIS are the thin-plate splines. They do not necessarily pass through the known values of the points, and can therefore reduce artifacts. The spline function minimizes the sum of two components, one representing the smoothness and the other representing the proximity to the known values of the points [BM98].

58.3 VISUALIZATION OF SPATIAL DATA

Various tasks traditionally performed manually by cartographers can be automated. GIS allow users to select their own combination of themes and data sets, and their own way of visualizing this information. It is therefore necessary that certain cartographic tasks be done in an automated manner, such as non-overlapping label placement. Since it is not known beforehand which information is shown on a map, it is impossible to pre-compute a good label placement for the geographic features of each thematic map layer separately: it must be done after it is known which layers are selected for visualization.

GLOSSARY

Choropleth map: Type of map in which the regions of an administrative subdivision are shown using a particular color scheme to represent some specified geographic variable.

Isoline map: Type of map for a continuous spatial phenomenon where lines of equal value for that phenomenon are displayed.

Cartogram: Type of map in which the area of the regions of an administrative subdivision represent some specified geographic variable (also called *value-by-area map*).

Schematic map: Type of map where important locations and connections between them (direct transportation) are shown highly stylized, and where location is preserved only approximately.

Label placement problem: The problem of placing text to annotate features on a map, according to various constraints and optimization criteria.

Line simplification problem: The problem of computing a polygonal line with fewer vertices from another polygonal line, while satisfying given constraints of distance.

Cartographic generalization problem: The problem of computing a map at a coarser (smaller) scale from a data set whose detail would be appropriate for a map at a finer (larger) scale.

58.3.1 LABEL PLACEMENT

Automated label placement has been the topic of considerable research, both within cartography and within the field of algorithms. One can distinguish three types of labels: labels for point objects, labels for line objects, and labels for polygonal objects. Imhof [Imh75] provides many examples of well-placed and poorly-placed labels, demonstrating the several different requirements for practical, high-quality label placement.

The point-label placement problem is the following optimization problem. Given a set of points, each with a specified label (name or other text), place as many labels as possible adjacent to their point, but without overlap between any two labels. One can extend the problem by restricting, or not allowing, overlap with other map features, avoiding ambiguity, and so on. Another version of point labeling is to maximize label size under the condition that all points be labeled. Label placement for point objects is usually approached as follows. A label is modeled by an axis-parallel rectangle, the bounding box of the text. For each point, define a restricted set of positions considered for its label, the candidates. Typically, the four positions where a corner of the label coincides with the point are chosen. In the label number maximization problem, the problem is abstracted to maximum independent set in a graph where edges represent intersections of two candidate label positions. Tables 58.3.1 and 58.3.2 contain some results.

TABLE 58.3.1 Point-label placement: size maximization; selected results.

TYPE OF LABEL	POSITIONS	APPROX. FACTOR	TIME	SOURCE
Equal-size square	4	2	$O(n \log n)$	[FW91, WW97]
Equal-size square	2	1	$O(n \log n)$	[FW91]
Arbitrary rectangle	2	1	$O(n \log^2 n)$	[FW91]
Equal-size circle	constant	$3.6 + \epsilon$	$O(n \log n + n \log(OPT^*/\epsilon))$	[DMM02].

TABLE 58.3.2 Point-label placement: number maximization; selected results.

TYPE OF LABEL	POSITIONS	APPROX. FACTOR	TIME	SOURCE
Rectangle	constant	$O(\log n)$	$O(n \log n)$	[AvKS98]
Fixed-height rectangle	constant	2 (or PTAS)	$O(n \log n)$	[AvKS98]
Fixed-height rectangle	touching	2 (or PTAS)	$O(n \log n)$	[vKSW99]

Combinatorial optimization approaches have also been applied frequently to the point-label placement problem [CMS95, vDTdB02]. However, experiments show that simple heuristics work well in practice [CMS95, WWKS01].

We next discuss the labeling of linear features. Here we distinguish streets and rivers. The labeling of street patterns yields a combinatorial optimization problem

FIGURE 58.3.1

River labeling due to Wolff et al. [WK⁺00].

similar to point labeling [NW00, Str01]. River labeling is quite different, because there are several different criteria that constitute a good river label placement. The label should be close to the river, it should follow the shape of the river, it should not have too high curvature, it should be as horizontal as possible, and it should have few inflection points. The algorithm of Wolff et al. [WK⁺00] includes all of these criteria; Figure 58.3.1.

The labeling of polygonal features appears for instance when placing the name of a country or lake inside that feature. It is common to either choose horizontal and straight placement, or let the shape follow the main shape of the polygonal feature. In the first case, one can place the label in the middle of the largest scaled copy of the label that fits inside the region. In the second case, one can use the medial axis to retrieve the main shape and place the label along it.

58.3.2 CARTOGRAPHIC GENERALIZATION

Cartographic generalization is the process of transforming and displaying cartographic data with less detail and information (i.e., on a coarser, smaller scale) than the input data contains. Examples include omitting small towns and minor roads, using only one color for nature regions rather than a distinction in forest, heath, moor, etc., aggregating several buildings into one block, and exaggerating the width of a road on a small-scale map. Generalization is a very important research topic in automated cartography [BM91, MLW95, WJ98].

The changes to the map data for generalization are done by *generalization operators*. They include selection, aggregation, typification, reclassification, smoothing, displacement, exaggeration, symbolization, collapse, and many others. See [Figure 58.3.2](#) for some examples. Detecting a need for generalization is accomplished by computing certain geometric measures on distance, density, and detail. This will trigger the generalization operators to perform transformations. It may happen that one operator causes the need of a change somewhere else on the map, possibly leading to a domino effect. For example, one of the common generalization operators is displacement, to assure a certain distance between two map features that should not appear adjacent. Moving one feature may cause the need to move another, leading to iterative displacement algorithms [Høj98, LJ01, MP01]. The same effect can occur when smoothing a single polygonal line that represents a curved road [BM97, BB00]. Also the operators aggregation (of two or more polygons into one) and exaggeration can cause displacement of other features [BW97, Har99].

A complicating issue is the preservation of consistency in generalization. For example, generally one wants to avoid omitting a large town that is close to several cities while retaining a small town that has no cities or towns in its immediate neighborhood. This motivates the need for a global selection mechanism that models how important features are based on attributes, geometry, and neighborhood. For point features this problem is called *settlement selection* [LP86, vKvOS97].

FIGURE 58.3.2

Examples of cartographic generalization.

Several studies have also been done for selection in road networks [MM97, TR95] and in polygonal subdivisions [vO95, Jaa98].

The problem of (polygonal) line simplification (cf. Section 51.3) is often considered a cartographic generalization problem, too. However, if the motivation for line simplification is only data reduction, then line simplification cannot be considered generalization. But since line simplification methods automatically reduce detail in polygonal lines, we will discuss some methods here.

The best-known cartographic line simplification method is due to Douglas and Peucker [DP73]. Starting with a line segment between the endpoints of the polygonal line, it selects the most distant vertex to be added to the simplification, and then continues recursively on the two parts that appear. This process continues until the most distant vertex is closer than some chosen threshold value to the approximating line segment. Theoretically, the method is highly unsatisfactory because it can create self-intersections in the output, requires quadratic time in the worst case, and may need many more segments in the approximation than the optimal approximation. However, it is very simple and usually works well in practice. Hershberger and Snoeyink devised a different algorithm to compute the same approximation which runs in $O(n \log^* n)$ time [HS98].

Weibel [Wei97b] and van der Poorten and Jones [vdPJ99] demonstrate that many aspects are involved in practical line simplification for GIS, and that many different criteria may be used. The GIS literature contains several more practical approaches.

Guibas et al. [GHMS93] and Estkowski and Michell [EM01] show that minimum vertex simplification is NP-hard when self-intersections are not allowed. Selected algorithmic results are listed in [Table 58.3.3](#).

58.3.3 SPECIAL-PURPOSE MAPS

Topographic maps are general-purpose maps that display a variety of themes of general interest together, like roads, towns, forests, and elevation contours. Special-purpose maps, on the other hand, concentrate on a particular theme, and may use

TABLE 58.3.3 Line simplification: selected results.

OUTPUT VERTICES	COMPLEXITY	ERROR CRITERION	NOTES AND PROBLEMS	SOURCE
From input	$O(n^2)$	distance	min. link, self-inter.	[CC96]
From input	$O(n^{4/3+\delta})$	vertical distance	min. link, self-inter.	[AV00]
From input	$O(n^2 \log n)$	distance	no self-inter.	[dBvKS98]
From input	$O(n^3)$	distance	no self-inter.	[EM01]
Arbitrary	$O(n^2 \log n)$	distance	min. link, self-inter.	[GHMS93]

alternative methods of visualizing the information. A choropleth map could, e.g., show the population densities of the states of the U.S. by coloring each with a color from a well-chosen set of colors, for instance, five saturation values of red. The geographic theme of population density can be seen as a function from the plane (the Earth’s surface) to the nonnegative reals. Here the points of the plane are aggregated by state.

There are other ways of visualizing functions from the plane to the reals cartographically, including isoline maps, dot maps, and cartograms. The latter again applies to aggregated regions of the plane. Flow maps visualize a presence and quantity of flow from one (aggregated) region to another. Schematic maps visualize connections between locations, such as subway maps. Dent provides a useful overview of several special-purpose map types [Den99].

Cartograms show values for regions by shrinking and expanding those regions, so that the area of each region corresponds to the value represented. The most important usage is the population cartogram, where a region A with a population twice that of region B will be shown twice as large as B . Necessarily, cartograms show a distortion of the geographic space. To keep the regions more or less recognizable, they should keep their shape, location, and adjacency as much as possible.

Several algorithms have been proposed to construct cartograms, given an administrative subdivision and a value for each region. Tobler [Tob86] simply uses scaling on the x - and y -coordinates, which may prevent regions from being shown at the correct size. Dougenick et al. [DCN85] compute a centroid for each region, which is assigned a repelling force if the region should grow, and an attracting force if the region should shrink. The forces of all centroids on all boundaries of the map then result in new positions of these boundaries. This is used in an iterative algorithm. Kocmoud and House’s approach [KH98] is constraint programming. They also attempt to preserve the main orientations of the boundaries. Edelsbrunner and Waupotitsch [EW97] give a cartogram construction algorithm based on simplicial complexes in the plane, where paths of triangles are used to define deformations that let one region grow at the cost of the size of another. See [Figure 58.3.3](#).

Dot maps show values by dots, where one dot represents, e.g., ten thousand people. This allows the distribution of the population to be shown better than in cartograms, but the relative populations for two regions are more difficult to compare. De Berg et al. [dBB⁺02] show the connection between dot maps and discrepancy, and compare various heuristics to construct dot maps.

Schematic maps are commonly used for public transportation systems. Direct lines, or connections between major stations, are shown with a polygonal line that is highly abstracted: it has only a few segments, and these segments are horizontal,

FIGURE 58.3.3

Cartogram showing electoral votes in the 1992 presidential elections, where shaded States indicate a majority for Bill Clinton (from Edelsbrunner and Waupotitsch [EW97]).

vertical, or have slope 1 or -1 . Avelar and Müller [AM00] give an iterative algorithm that moves vertices so that the segments become more and more oriented in one of the desired orientations. Cabello et al. [CdBv⁺01] place the connections incrementally in a pre-computed order, leading to an $O(n \log n)$ time algorithm that does not require iteration. Neyer [Ney99] views the problem as a line simplification problem and approximates each connection with the minimum number of segments in the specified orientations. The three approaches to computing schematic maps are quite different and each has its own advantages and drawbacks.

Brandes and Wagner [BW98] show connections between stations by circular arcs and address the visualization problem as a graph layout problem ([Chapter 52](#)).

58.3.4 DYNAMIC AND ANIMATED MAPS

Besides computations for traditional paper maps, a more recent trend is to study dynamic maps, animated maps, interactive maps, Web maps, and multimedia maps [KB01, CPG99]. This area leads to a number of new computational issues, where efficiency is very important and quality is less critical. For example, a label placement on the screen must be updated when the user starts panning or zooming. Only as few changes as possible should be made; see, e.g., [PPH99]. Related labeling problems arise in user interface design [BFH01].

Zooming out on a map also makes real-time cartographic generalization necessary. The problem is that not only the size of features must be changed, but also the way of visualization. On large-scale maps, cities are shown by polygonal outlines, but on small-scale maps, they are shown by point symbols. The process is called *dynamic* or *on-the-fly generalization* [vO95, MG99]. Ideally, the changes made

during zooming should be made in a continuous manner, with no major, sudden changes on the map [vK01]. In static generalization, the objective is to compute a new representation. But in dynamic generalization, the problem is the computation of the transition. The relation to morphing should be clear.

58.4 DIGITAL ELEVATION MODELS

We have concentrated on types of data based on subdivisions with well-marked boundaries. Another important type of data is the scalar function in two variables. The most common example from geography is elevation above sea level, also called terrain. Three other examples are annual precipitation, nitrate concentration per cubic meter, and average noise level.

There are two common representations for elevation: the regular square grid, or *elevation matrix*, which is a raster representation, and the triangular irregular network (TIN), which is a vector representation. For the latter representation, the Delaunay triangulation is often used.

GLOSSARY

Digital elevation model (DEM): Representation of a scalar function in two variables. Sometimes specifically used for the raster-based representation.

Triangular irregular network (TIN): Vector-based representation of a digital elevation model defined by a triangulation of a point set. Also called polyhedral terrain.

Drainage network: Collection of linear features that represent the locations where water on a terrain has formed rivers.

Viewshed analysis: The study of visibility on a terrain.

58.4.1 CONSTRUCTION AND SIMPLIFICATION OF DEMS

The problem of simplifying a digital elevation model, or performing raster to vector conversion for a digital elevation model, is a higher-dimensional version of line simplification. The best algorithm known is similar in approach to the Douglas-Peucker algorithm for line simplification given in Section 58.3.2. Assume that the outer boundary of the DEM is rectangular, a set of points with their elevation is given (e.g., based on a regular square grid), and assume that a maximum allowed vertical error $\epsilon > 0$ is specified. An initial coarse simplification of the DEM is a triangulation of the four corners of the rectangle. If that simplification is no vertically further than ϵ at all points, then it is accepted. Otherwise, the point with largest vertical distance is selected and added to the triangulation, which is restored by flipping to the Delaunay triangulation. The process is then repeated.

The method requires quadratic time in the worst case, but an implementation can be given which, under natural assumptions, takes $O(n \log n)$ time in practice [Hel90, Fj91, HG95].

Agarwal and Suri [AS98] show that a corresponding optimization problem is

NP-hard, and give an approximation algorithm that requires $O(n^8)$ time. If m is the size of the optimal piecewise linear ϵ -approximation of the n given points, then the computed approximation has size $O(m \log m)$. Agarwal and Desikan [AD97] give a cubic time ϵ -approximation algorithm with a worse size bound on the approximation, but with some assumptions the approximation has the same size asymptotically and runs in near-quadratic time.

When a TIN is constructed for modeling terrains, various geometric computation problems arise. When the input is a set of (digitized) contour lines, a triangulation between the contour lines such as the constrained Delaunay triangulation can be used [DP89, Sch98]. Care must be taken that no triangle with all three vertices on the same contour line is created, as this gives undesirable artifacts. Thibault and Gold [TG00] provide a solution that avoids flat triangles by adding vertices on the medial axis or skeleton, which are given intermediate elevations (see also [GD02]). If information on rivers is present too, then these can be included as edges of the TIN using a constrained Delaunay triangulation [MS99]. Two other approaches of interest are by Silva et al. [SMK95] and by Little and Shi [LS01]. Both methods construct a TIN from gridded data and can preserve important features like valleys and ridges of the terrain. Gudmundsson et al. [GHvK02] define a class of triangulations, called higher-order Delaunay triangulations, and use them to create TINs with fewer local minima in the terrain, because minima generally do not occur.

Multi-resolution terrain modeling has attracted considerable research, largely covered by Puppo and Scopigno [PS97]. See [Chapter 54](#) for more information on surface simplification and multi-resolution representations.

58.4.2 VISUALIZATION OF DEMS

Digital elevation models may be visualized in several ways. A traditional way is by contour maps, and the process of deriving a contour map is called *contouring* [Wat92].

A perspective view of a digital elevation model can be obtained by back-to-front rendering of the grid elements or triangles. If a vector representation of a perspective view is needed, an algorithm of Katz et al. [KOS92] achieves this for a TIN in $O((n + k) \log n \log \log n)$ time, where n is the number of triangles and k is the complexity of the visibility map.

58.4.3 DERIVED MAPS AND PRODUCTS

In the analysis of terrain—e.g., for land suitability studies—slope and aspect maps are important derived products of a digital elevation model. They are straightforward to compute. Similarly, the plan and profile curvature can be of importance, for example for waterflow and erosion modeling.

The computation of the drainage network, based on the shape of the terrain, has been frequently studied, most often for grid data. Besides the drainage network, watersheds also provide important terrain information. A surprising combinatorial result of de Berg et al. [dBB⁺96] is that if water always follows the direction of steepest descent, and the drainage network consists of all points that receive flow from some region with positive area, then triangulations exist with n triangles for which the drainage network has complexity $\Theta(n^3)$.

Viewshed analysis is the study of visibility in the terrain. For gridded DEMs, the visibility index of a grid cell c is used as a measure of visibility for c . It is defined as the number of other grid cells visible from grid cell c . Viewshed analysis has applications in urban and touristical planning, and for telecommunication. The shortest watchtower problem is to compute a point with smallest vertical distance above a terrain which has visibility to all points of the terrain. It can be computed in $O(n \log n)$ time [Zhu97]. Another interesting problem is to place a small number of antennas so that any point on the terrain has direct visibility to at least one antenna [BMM⁺02, Fra02]. Other visibility results for terrains may be found in Section 28.8.3.

The computation of shortest paths between two points on a terrain is a problem of both theoretical and practical interest. The approach of Lanthier et al. [LMS01, ALMS98] is significant both theoretically and practically, also because it deals with the weighted version. The main idea is to place Steiner points on edges to convert the problem into a graph problem, and then apply Dijkstra's algorithm. This gives a simple approximation algorithm for least-cost paths.

58.5 ALGORITHMIC CHALLENGES IN GIS

The application area GIS is the source of a number of interesting research problems. Many of these are simply-stated algorithmic problems, such as finding the most efficient algorithm for a well-defined problem, or finding the best approximation factor for some computationally hard problem. But from the application perspective, more important is the study of relatively simple solutions for problems in which a number of different requirements must be satisfied or optimized simultaneously. For example, label placement with high cartographic quality has to be achieved with no overlap between different labels, no or little overlap of a label with other map features, clear association between a feature and its label, and avoidance of areas that are too dense with text. As a second example, in realistic terrain reconstruction, seven constraints have been listed [Sch98]. Such constraints cannot be formulated straightforwardly as algorithmic optimization. It is usually more important which requirements can be handled simultaneously than how efficient a solution is.

Challenges for algorithms research on GIS problems are methods that deal with multiple criteria simultaneously, either as a whole solution or as part of an optimization approach such as genetic or evolutionary algorithms. The appropriate formulation of the GIS problem itself, and comparison of results based on different formulations, are also issues of major importance.

58.6 OPEN PROBLEMS

The references in the open problems below refer to papers related to the open problem. Those papers do not always state the problem explicitly.

1. Improve on the known 3.6-approximation factor for circular label placement (3.6 times the optimal size that permits all labels to be placed) [DMM02].
2. Provide an approximation algorithm for the maximum independent set in

rectangle intersection graphs with an approximation factor better than $\Theta(\log n)$ [AvKS98].

3. Give an approximation algorithm for maximum independent set in square intersection graphs with an approximation factor less than 4.
4. Given a simple polygon P , compute the minimum perimeter shape with the same area but whose boundary remains within a given distance $\epsilon > 0$ of the original boundary of P . A solution is useful for cartographic generalization, in particular for the simplification and aggregation operators.
5. Given two simple polygons P and Q , compute two subpolygons $P' \subseteq P$ and $Q' \subseteq Q$ of maximum summed area such that, for any $p \in P'$ and $q \in Q'$, the distance between p and q is at least $\epsilon > 0$.
6. Given a simple polygonal line with n vertices, what is the complexity of computing the minimum-vertex polygonal line simplification that keeps the two endpoints, uses a subset of the intermediate vertices, has error below a given $\epsilon > 0$, and guarantees no self-intersection [AV00, dBvKS98]? (See also [Section 51.3](#).)
7. Can the output of the Douglas-Peucker line-simplification method be generated using a different algorithm that runs in linear time [HS98]?
8. Does an efficient data structure exist for natural neighbor interpolation queries in a point set S of n points with values? It is easy to develop a linear-size data structure with $O(\log n + k)$ query time, where k is the number of Voronoi neighbors of the query point amidst the points of the set S . However, k can be linear in n in the worst case.
9. Can the polyhedral terrain simplification algorithm of Section 58.4.1 be implemented to run in $o(n^2)$ time? Implementations exist where $O(n \log n)$ time is typical for realistic inputs, but no implementation guarantees a running time less than quadratic [Hel90, Fjä91, HG95].
10. Develop elevation grid-to-TIN conversion algorithms that approximately preserve the slope of the terrain, rather than the elevation. Correct slope values are more important in practice than correct elevation values [GD02].
11. Let T_1 and T_2 be two polyhedral terrains covering the same region. Develop an algorithm that constructs a new polyhedral terrain T_3 which represents the multiplication of the corresponding elevation values of T_1 and T_2 within a given error ϵ . For certain variables that are scalar functions of location, models exist that express the value as the product of other variables that are scalar functions of location [Mit91].
12. How efficiently can the visibility index of all grid cells of an $n \times n$ grid of elevation values be computed?
13. Develop approximation algorithms for antenna placement on terrains, where the objective is placing as few antennas as possible for a given antenna height, while each point on the terrain has visibility to the top of some antenna. Furthermore, develop approximation algorithms when the antenna height is not fixed but should be kept small [Fra02, BMM⁺02].

14. Given a simple polygon and a positive real ϵ , what is the smallest (or largest) area of the polygon if each vertex can be moved over a distance at most ϵ ? A similar problem can be stated to give upper and lower bounds on the volume of a subsurface reservoir of oil, based on imprecise measurements of depth at various points. Several other problems arise due to measurement imprecision.

There are many open problems on improved algorithms for specific generalization operators, cartograms, flow maps, and other special-purpose maps, where “improved” refers to the visual output of the algorithm.

Following up on the previous point, it is important to study which geometric measures are most relevant to quantify visual aspects like sinuosity, density, similarity, and so on and so forth.

There are also many open problems concerning an appropriate (geometric) definition of physical geographic objects like mountains, valleys, and meanders. Such definitions lead to new algorithmic problems whose solutions will allow the automated characterization of the objects from data sets.

59 GEOMETRIC APPLICATIONS OF THE GRASSMANN-CAYLEY ALGEBRA

Neil L. White

INTRODUCTION

Grassmann-Cayley algebra is first and foremost a means of translating synthetic projective geometric statements into invariant algebraic statements in the bracket ring, which is the ring of projective invariants. A general philosophical principle of invariant theory, sometimes referred to as *Gram's theorem*, says that any projectively invariant geometric statement has an equivalent expression in the bracket ring; thus we are providing here the practical means to carry this out. We give an introduction to the basic concepts, and illustrate the method with several examples from projective geometry, rigidity theory, and robotics.

59.1 BASIC CONCEPTS

Let P be a $(d-1)$ -dimensional projective space over the field F , and V the canonically associated d -dimensional vector space over F . Let S be a finite set of n points in P and, for each point, fix a homogeneous coordinate vector in V . We assume that S spans V , hence also that $n \geq d$. Initially, we choose all of the coordinates to be distinct, algebraically independent indeterminates in F , although we can always specialize to the actual coordinates we want in applications. For $p_i \in S$, let the coordinate vector be $(x_{1,i}, \dots, x_{d,i})$.

GLOSSARY

Bracket: A $d \times d$ determinant of the homogeneous coordinate vectors of d points in S . Brackets are relative projective invariants, meaning that under projective transformations their value changes only in a very predictable way (in fact, under a basis change of determinant 1, they are literally invariant). Hence brackets may also be thought of as coordinate-free symbolic expressions. The bracket of $u_1, \dots, u_d$ is denoted by $[u_1, \dots, u_d]$.

Bracket ring: The ring B generated by the set of all brackets of d -tuples of points in S , where $n = |S| \geq d$. It is a subring of the ring $F[x_{1,1}, x_{1,2}, \dots, x_{d,n}]$ of polynomials in the coordinates of points in S .

Straightening algorithm: A normal form algorithm in the bracket ring.

Join of points: An exterior product of k points, $k \leq d$, computed in the exterior algebra of V . We denote such a product by $a_1 \vee a_2 \vee \dots \vee a_k$, or simply $a_1 a_2 \dots a_k$, rather than $a_1 \wedge a_2 \wedge \dots \wedge a_k$, which is commonly used in exterior algebra. A

concrete version of this operation is to compute the Plücker coordinate vector of (the subspace spanned by) the k points, that is, the vector whose components are all $k \times k$ minors (in some prespecified order) of the $d \times k$ matrix whose columns are the homogeneous coordinates of the k points.

Extensor of step k , or decomposable k -tensor: A join of k points. Extensors of step k span a vector space $V^{(k)}$ of dimension $\binom{d}{k}$. (Note that not every element of $V^{(k)}$ is an extensor.)

Antisymmetric tensor: Any element of the direct sum $\Lambda V = \bigoplus_k V^{(k)}$.

Copoint: Any antisymmetric tensor of step $d-1$. A copoint is always an extensor.

Join: The exterior product operation on ΛV . The join of two tensors can always be reduced by distributivity to a linear combination of joins of points.

Integral: $E = u_1 u_2 \cdots u_d$, for any vectors $u_1, u_2, \dots, u_d$ such that $[u_1, u_2, \dots, u_d] = 1$. Every extensor of step d is a scalar multiple of the integral E .

Meet: If $A = a_1 a_2 \cdots a_j$ and $B = b_1 b_2 \cdots b_k$, with $j + k \geq d$, then

$$\begin{aligned} A \wedge B &= \sum_{\sigma} \operatorname{sgn}(\sigma) [a_{\sigma(1)}, \dots, a_{\sigma(d-k)}, b_1, \dots, b_k] a_{\sigma(d-k+1)} \cdots a_{\sigma(j)} \\ &\equiv [\dot{a}_1, \dots, \dot{a}_{d-k}, b_1, \dots, b_k] \dot{a}_{d-k+1} \cdots \dot{a}_j. \end{aligned}$$

The sum is taken over all permutations σ of $\{1, 2, \dots, j\}$ such that $\sigma(1) < \sigma(2) < \cdots < \sigma(d-k)$ and $\sigma(d-k+1) < \sigma(d-k+2) < \cdots < \sigma(j)$. Each such permutation is called a *shuffle* of the $(d-k, j-(d-k))$ split of A , and the dots represent such a signed sum over all the shuffles of the dotted symbols.

Grassmann-Cayley algebra: The vector space $\Lambda(V)$ together with the operations $\vee$ and $\wedge$.

PROPERTIES OF GRASSMANN-CAYLEY ALGEBRA

- (i) $A \vee B = (-1)^{jk} B \vee A$ and $A \wedge B = (-1)^{(d-k)(d-j)} B \wedge A$, if A and B are extensors of steps j and k .
- (ii) $\vee$ and $\wedge$ are associative and distributive over addition and scalar multiplication.
- (iii) $A \vee B = (A \wedge B) \vee E$ if $\operatorname{step}(A) + \operatorname{step}(B) = d$.
- (iv) A meet of two extensors is again an extensor.
- (v) The meet is dual to the join, where duality exchanges points and copoints.
- (vi) **Alternative Law:** Let $a_1, a_2, \dots, a_k$ be points and $\gamma_1, \gamma_2, \dots, \gamma_s$ copoints. Then if $k \geq s$,

$$(a_1 a_2 \cdots a_k) \wedge (\gamma_1 \wedge \gamma_2 \wedge \cdots \wedge \gamma_s) = [\dot{a}_1, \gamma_1] [\dot{a}_2, \gamma_2] \cdots [\dot{a}_s, \gamma_s] \dot{a}_{s+1} \vee \cdots \vee \dot{a}_k.$$

Here the dots refer to all shuffles over the $(1, 1, \dots, 1, k-s)$ split of $a_1 \cdots a_k$, that is, a signed sum over all permutations of the a 's such that the last $k-s$ of them are in increasing order.

59.2 GEOMETRY $\leftrightarrow$ G.-C. ALGEBRA $\rightarrow$ BRACKET ALGEBRA

If X is a projective subspace of dimension $k - 1$, pick a basis $a_1, a_2, \dots, a_k$ and let $A = a_1 a_2 \cdots a_k$ be an extensor. We call $X = \overline{A}$ the **support** of A .

- (i) If $A \neq 0$ is an extensor, then A determines $\overline{A}$ uniquely.
- (ii) If $\overline{A} \cap \overline{B} \neq \emptyset$, then $\overline{A \vee B} = \overline{A} + \overline{B}$.
- (iii) If $\overline{A} \cup \overline{B}$ spans V , then $\overline{A \wedge B} = \overline{A} \cap \overline{B}$.

TABLE 59.2.1 Examples of geometric conditions and corresponding Grassmann-Cayley algebra statements.

GEOMETRIC CONDITION	DIM	G.-C. ALGEBRA STATEMENT	BRACKET STATEMENT
Point $\overline{a}$ is on the line $\overline{bc}$ (or $\overline{b}$ is on $\overline{ac}$, etc.)	2	$a \wedge bc = 0$	$[abc] = 0$
Lines $\overline{ab}$ and $\overline{cd}$ intersect	3	$ab \wedge cd = 0$	$[abcd] = 0$
Lines $\overline{ab}$, $\overline{cd}$, $\overline{ef}$ concur	2	$ab \wedge cd \wedge ef = 0$	$\overset{\bullet}{[acd]}\overset{\bullet}{[bef]} = 0$
Planes $\overline{abc}$, $\overline{def}$, and $\overline{ghi}$ have a line in common	3	$abc \wedge def \wedge ghi = 0$	$\overset{\bullet}{[adef]}\overset{\bullet}{[bghi]}\overset{\bullet}{[cxyz]} = 0 \ \forall x, y, z$
The intersections of $\overline{ab}$ with $\overline{cd}$ and of $\overline{ef}$ with $\overline{gh}$ are collinear with $\overline{i}$	2	$(ab \wedge cd) \vee (ef \wedge gh) \vee i = 0$	$\overset{\bullet}{[acd]}\overset{\circ}{[egh]}\overset{\bullet}{[bfi]} = 0$

The geometric conditions in Table 59.2.1 should be interpreted projectively. For example, the concurrency of three lines includes as a special case that the three lines are mutually parallel, if one prefers to interpret the conditions in affine space. Degenerate cases are always included, so that the concurrency of three lines includes as a special case the equality of two or even all three of the lines, for example.

Most of the interesting geometric conditions translate into Grassmann-Cayley conditions of step 0 (or, equivalently, step d), and therefore expand into bracket conditions directly. When the Grassmann-Cayley condition is not of step 0, as in the example in Table 59.2.1 of three planes in three-space containing a common line, then the Grassmann-Cayley condition may be joined with an appropriate number of universally quantified points to get a conjunction of bracket conditions. The joined points may also be required to come from a specified basis to make this a conjunction of a finite number of bracket conditions.

In this fashion, any incidence relation in projective geometry may be translated into a conjunction of Grassmann-Cayley statements, and, conversely, Grassmann-Cayley statements may be translated back to projective geometry just as easily, provided they involve only join and meet, not addition.

Many identities in the Grassmann-Cayley algebra yield algebraic, coordinate-free proofs of important geometric theorems. These proofs typically take the form “the left-hand side of the identity is 0 if and only if the right-hand side of the identity is 0,” and the resulting equivalent Grassmann-Cayley conditions translate to interesting geometric conditions as above.

TABLE 59.2.2 Examples of Grassmann-Cayley identities and corresponding geometric theorems, in dimension 2.

GEOMETRIC THEOREM	G.-C. ALGEBRA IDENTITY
Desargues's theorem: Derived points $ab \wedge a'b'$, $ac \wedge a'c'$, and $bc \wedge b'c'$ are collinear if and only if abc or $a'b'c'$ are collinear or aa' , bb' , and cc' concur.	$(ab \wedge a'b') \vee (ac \wedge a'c') \vee (bc \wedge b'c') = [abc][a'b'c'](aa' \wedge bb' \wedge cc')$
Pappus's theorem and Pascal's theorem: If abc and $a'b'c'$ are both collinear sets, then $(bc' \wedge b'c)$, $(ca' \wedge c'a)$, and $(ab' \wedge a'b)$ are collinear.	$[ab'c'][a'bc'][a'b'c][abc] - [abc'][ab'c][a'bc][a'b'c'] = (bc' \wedge b'c) \vee (ca' \wedge c'a) \vee (ab' \wedge a'b)$
Pappus's theorem (alternate version): If $aa'x$, $bb'x$, $cc'x$, $ab'y$, $bc'y$, and $ca'y$ are collinear, then ac' , ba' , cb' concur.	$aa' \wedge bb' \wedge cc' + ab' \wedge bc' \wedge ca' + ac' \wedge ba' \wedge cb' = 0$
Fano's theorem: If no three of a, b, c, d are collinear, then $(ab \wedge cd)$, $(bc \wedge ad)$, and $(ca \wedge bd)$ are collinear if and only if $\text{char } F = 2$.	$(ab \wedge cd) \vee (bc \wedge ad) \vee (ca \wedge bd) = 2[abc][abd][acd][bcd]$

The identities in Table 59.2.2 are proved by expanding both sides, using the rules for join and meet, and then verifying the equality of the resulting expressions by using the straightening algorithm of bracket algebra (see [Stu93]).

The right-hand side of the identity for the first version of Pappus's theorem is also the Grassmann-Cayley form of the geometric construction used in Pascal's theorem, and hence is 0 if and only if the six points lie on a common conic (Pappus's theorem being the degenerate case of Pascal's theorem in which the conic consists of two lines). Hence the left-hand side of the same identity is the bracket expression that is 0 if and only if the six points lie on a common conic. In particular, if abc and $a'b'c'$ are both collinear, we see immediately from the underlined brackets that the left-hand side is 0.

Numerous other projective geometry incidence theorems may be proved using the Grassmann-Cayley algebra. We illustrate this with an example modified from [RS76]. Other examples may be found in the same reference.

THEOREM 59.2.1

In 3-space, if triangles abc and $a'b'c'$ are in perspective from the point d , then the lines $a'bc \wedge ab'c'$, $b'ca \wedge bc'a'$, $c'ab \wedge ca'b'$, and $a'b'c' \wedge abc$ are all coplanar.

Proof. We prove the general case, where a, b, c, d, a', b', c' are all distinct, triangles abc and $a'b'c'$ are nondegenerate, and d is in neither the plane abc nor the plane $a'b'c'$. Then, since a, a', d are collinear, we may write $\alpha a' = \beta a + d$ for nonzero scalars α and β . Since we are using homogeneous coordinates for points, a , and similarly a' , may be replaced by nonzero scalar multiples of themselves without changing the geometry. Thus, without loss of generality, we may write $a' = a + d$. Similarly, $b' = b + d$ and $c' = c + d$. Now

$$\begin{aligned} L_1 &:= a'bc \wedge ab'c' = [a'ab'c']bc - [bab'c']a'c + [cab'c']a'b \\ &= [dabc]bc + [bade]ca + [cabd]ab + [badc]cd + [cabd]db \\ &= [abcd](-bc - ac + ab + cd - bd). \end{aligned}$$

Similarly,

$$\begin{aligned} L_2 &:= b'ca \wedge bc'a' = [abcd](ac + ab + bc + ad - cd), \\ L_3 &:= c'ab \wedge ca'b' = [abcd](-ab + bc - ac + bd - ad), \\ L_4 &:= a'b'c' \wedge abc = [abcd](bc - ac + ab). \end{aligned}$$

Now we check that any two of these lines intersect. For example,

$$L_1 \wedge L_2 = [abcd]^2(-bc - ac + ab + cd - bd) \wedge (ac + ab + bc + ad - cd) = 0.$$

However, this shows only that either all four lines are coplanar or all four lines concur. To prove the former, it suffices to check that the intersection of $\overline{L_1}$ and $\overline{L_4}$ is distinct from that of $\overline{L_2}$ and $\overline{L_4}$. Notice that $L_1 \wedge L_4$ does not tell us the point of intersection, because $\overline{L_1}$ and $\overline{L_4}$ do not jointly span V , by our previous computation. But if we choose a generic vector x representing a point in general position, it follows from $\overline{L_1} \neq \overline{L_4}$, which must hold in our general case, that $(L_1 \vee x) \wedge L_4$ is nonzero and does represent the desired point of intersection. Then we compute

$$\begin{aligned} (L_1 \vee x) \wedge L_4 &= [abcd]^2(-bcx - acx + abx + cdx - bdx) \wedge (bc - ac + ab) \\ &= [abcd]^2(2[abcx] - [bcdx] - [acdx])(c - b) \\ &= \alpha(c - b) \end{aligned}$$

for some nonzero scalar α . Similarly, $(L_2 \vee x) \wedge L_4 = \beta(c - a)$ for some nonzero scalar β . By the nondegeneracy of the triangle abc , these two points of intersection are distinct. $\square$

59.3 CAYLEY FACTORIZATION: BRACKET ALGEBRA $\rightarrow$ GEOMETRY

$(1) \leftrightarrow (2) \rightarrow (3)$ in the chart above is explained in Section 59.2 above, with $(2) \rightarrow (1)$ being straightforward only in the case of a Grassmann-Cayley expression involving only joins and meets. $(3) \rightarrow (4)$ is the trivial expansion of a determinant into a polynomial in its d^2 entries. $(4) \rightarrow (3)$ is possible only for invariant polynomials (under the special linear group); see [Stu93] for an algorithm.

PHILOSOPHY OF INVARIANT THEORY: It is best for many purposes to avoid level (4), and to work instead with the symbolic coordinate-free expressions on levels (2) and (3).

Cayley factorization, (3)→(2), refers to the translation of a bracket polynomial into an equivalent Grassmann-Cayley expression involving only joins and meets. The input polynomial must be homogeneous (i.e., each point must occur the same number of times in the brackets of each bracket monomial of the polynomial), and Cayley factorization is not always possible. No practical algorithm is known in general, but an algorithm [Whi91] is known that finds such a factorization—or else announces its impossibility—in the multilinear case (each point occurs exactly once in each monomial). This algorithm is practical up to about 20 points.

MULTILINEAR CAYLEY FACTORIZATION

The multilinear Cayley factorization (MCF) algorithm is too complex to present here in detail; instead, we give an example and indicate roughly how the algorithm proceeds on the example.

Let

$$\begin{aligned} P = & -[acj][deh][bfg] - [cdj][aeh][bfg] - [cdj][abe][fgh] \\ & + [acj][bdf][egh] - [acj][bdg][efh] + [acj][bdh][efg]. \end{aligned}$$

Note that P is multilinear in the 9 points. The MCF algorithm now looks for sets of points $x, y, \dots, z$ such that the extensor $xy \cdots z$ could be part of a Cayley factorization of P . For this choice of P , it turns out that no such set larger than a pair of elements occurs. An example of such a pair is a, d ; in fact, if d is replaced by a in P , leaving two a 's in each term of P , although in different brackets, the resulting bracket polynomial is equal to 0, as can be verified using the straightening algorithm. The MCF algorithm, using the straightening algorithm as a subroutine, finds that $(a, d), (b, h), (c, j), (f, g)$ are all the pairs with this property.

The algorithm now looks for combinations of these extensors that could appear as a meet in a Cayley factorization of P . (For details, see [Whi91].) It finds in our example that $ad \wedge cj$ is such a combination. As soon as a single such combination is found, an algebraic substitution involving a new variable, $z = ad \wedge cj$, is performed, and a new bracket polynomial of smaller degree involving this new variable is derived; the algorithm then begins anew on this polynomial. If no such combination is found, the input bracket polynomial is then known to have no Cayley factorization. In our example, this derived polynomial turns out to be $P = [zef][gbh] - [zeg][fbh]$, which of necessity is still multilinear. The MCF algorithm proceeds to find (and we can directly see by consulting [Table 59.2.1](#)) that $P = ze \wedge fg \wedge bh$. Thus, our final Cayley factorization is output as

$$P = ((ad \wedge cj) \vee e) \wedge fg \wedge bh.$$

It is significant that this algorithm requires no backtracking. For example, once $ad \wedge cj$ is found as a possible meet in a Cayley factorization of P , it is known that if P has a Cayley factorization at all, then it must also have one using the factor $ad \wedge cj$; hence we are justified in factoring it out, i.e., substituting a new variable for it. Other Cayley factorizations may be possible, for example,

$$P = ((fg \wedge bh) \vee (ad \wedge cj)) \wedge e.$$

Note that these two factorizations have the same geometric meaning.

59.4 APPLICATIONS

59.4.1 ROBOTICS

GLOSSARY

Robot arm: A set of rigid bodies, or links, connected in series by joints that allow relative movement of the successive links, as described below. The first link is regarded as fixed in position, or tied to the ground, while the last link, called the *end-effector*, is the one that grasps objects or performs tasks.

Revolute joint: A joint between two successive links of a robot arm that allows only a rotation between them. In simpler terms, a revolute joint is a hinge connecting two links.

Prismatic joint: A joint between two successive links of a robot arm that allows only a translational movement between the two links.

Screw joint: A joint between two successive links of a robot arm that allows only a screw movement between the two links.

TABLE 59.4.1 Modeling instantaneous robotics.

ROBOTICS CONCEPT	GRASSMANN-CAYLEY EQUIVALENT
Revolute joint on axis $\overline{ab}$	$\alpha(a \vee b)$, a 2-extensor
Rotation about line $\overline{ab}$	$\beta(a \vee b)$
Motion of point p in rotation about line $\overline{ab}$	$\beta(a \vee b) \vee p$
Screw joint	indecomposable 2-tensor
Prismatic joint	2-extensor at infinity
Motion space of the end-effector, where $j_1, j_2, \dots, j_k$ are joints in series	span of the extensors $\langle j_1, j_2, \dots, j_k \rangle$

We are considering here only the instantaneous kinematics or statics of robot arms, that is, positions and motions at a given instant in time. A robot arm has a *critical configuration* if the joint extensors become linearly dependent. If the arm has six joints in three-space, a critical configuration means a loss of full mobility. If the arm has a larger number of joints, criticality is defined as any six of the joint extensors becoming linearly dependent. This can mean severe problems with the driving program in real-life robots, even when the motion space retains full dimensionality.

In one sense, criticality is trivial to determine, since we need only compute a determinant function, called the *superbracket*, on the six-dimensional space $\Lambda^2(V)$. However, if we want to know all the critical configurations of a given robot arm, this becomes a nontrivial question, that of determining all of the zeroes of the superbracket. To answer it, we need to express the superbracket in terms of ordinary brackets. This has been done in [MW91], where the superbracket of the six 2-extensors $a_1 a_2, b_1 b_2, \dots, f_1 f_2$ is given by

$$\begin{aligned}
& [[a_1 a_2, b_1 b_2, c_1 c_2, d_1 d_2, e_1 e_2, f_1 f_2]] = \\
& - [a_1 a_2 b_1 b_2] [c_1 c_2 \overset{\bullet}{d_1} \overset{\circ}{e_1}] [\overset{\bullet}{d_2} \overset{\circ}{e_2} f_1 f_2] \\
& + [a_1 a_2 \overset{\bullet}{b_1} \overset{\circ}{c_1}] [\overset{\bullet}{b_2} \overset{\circ}{c_2} d_1 d_2] [e_1 e_2 f_1 f_2] \\
& - [a_1 a_2 \overset{\bullet}{b_1} \overset{\circ}{c_1}] [\overset{\bullet}{b_2} d_1 d_2 \overset{\triangleleft}{e_1}] [\overset{\circ}{c_2} \overset{\triangleleft}{e_2} f_1 f_2] \\
& + [a_1 a_2 \overset{\bullet}{b_1} \overset{\circ}{d_1}] [\overset{\bullet}{b_2} c_1 c_2 \overset{\triangleleft}{e_1}] [\overset{\circ}{d_2} \overset{\triangleleft}{e_2} f_1 f_2].
\end{aligned}$$

(Here the dots, diamonds, and triangles have the same meaning as the dots in Section 59.1.)

Consider the particular example of the six-revolute-joint robot arm illustrated in Figure 59.4.1, whose first two joints lie on intersecting lines, whose third and fourth joints are parallel, and whose last two joints also lie on intersecting lines. The larger cylinders in the figure represent the revolute joints. To express the superbracket, we must choose two points on each joint axis. We may choose $b_1 = a_2$, $d_1 = c_2$ (where this point is at infinity), and $f_1 = e_2$, as shown by the black dots. The thin cylinders represent the links; for example, the first link, between a_2 and b_2 , is connected to the ground (not shown) by joint $a_1 a_2$, and can therefore only rotate around the axis $\overline{a_1 a_2}$.

FIGURE 59.4.1

Six-revolute-joint robot arm.

Plugging in and deleting terms with a repeated point inside a bracket, we get

$$- [a_1 a_2 b_2 \overset{\bullet}{c_1}] [a_2 c_2 d_2 e_2] [\overset{\bullet}{c_2} e_1 e_2 f_2] \quad (59.4.1)$$

$$+ [a_1 a_2 b_2 \overset{\bullet}{c_2}] [a_2 c_1 c_2 e_2] [\overset{\bullet}{d_2} e_1 e_2 f_2] \quad (59.4.2)$$

$$= [\overset{\bullet}{c_1} a_1 a_2 b_2] [\overset{\bullet}{d_2} a_2 c_2 e_2] [\overset{\bullet}{c_2} e_1 e_2 f_2], \quad (59.4.3)$$

where each of (59.4.1) and (59.4.2) has two terms because of the dotting, and the same four terms constitute (59.4.3), since two of the six terms generated by the dotting are zero because of the repetition of c_2 in the second bracket.

Finally, we recognize (59.4.3) as the bracket expansion of

$$(c_1 d_2 c_2) \wedge (a_1 a_2 b_2) \wedge (a_2 c_2 e_2) \wedge (e_1 e_2 f_2).$$

We then recognize that the geometric conditions for criticality are any positions that make this Grassmann-Cayley expression 0, namely

- (i) one or more of the planes $\overline{c_1c_2d_2}, \overline{a_1a_2b_2}, \overline{a_2c_2e_2}, \overline{e_1e_2f_2}$ is degenerate, or
- (ii) the four planes have nonempty intersection.

Notice that in an actual robot arm of the type we are considering, none of the degeneracies in (i) can actually occur.

See [Section 48.1](#) for more information.

59.4.2 BAR FRAMEWORKS

Consider a generically $(d-1)$ -isostatic graph G (see [Section 60.1](#) of this Handbook), that is, a graph for which almost all realizations in $(d-1)$ -space as a bar framework are minimally first-order rigid. Since first-order rigidity is a projective invariant (see [Theorem 60.1.23](#)), we would like to know the projective geometric conditions that characterize all of its nonrigid (first-order flexible) realizations. By Gram's theorem, these conditions must be expressible in terms of bracket conditions, and [WW83] shows that the first-order flexible realizations are characterized by the zeroes of a single bracket polynomial C_G , called the *pure condition* (see [Theorem 60.1.25](#)). Furthermore, [WW83] gives an algorithm to construct the pure condition C_G directly from the graph G . Then we require Cayley factorization to recover the geometric incidence condition, if it is not already known. Consider the following examples, illustrated in Figure 59.4.2.

FIGURE 59.4.2

Three examples of bar frameworks.

- (i) The graph G is the edge skeleton of a triangular prism, realized in the plane. We have $C_G = [abc][def]([abe][dfc] - [dbe][afc])$, and we may recognize the factor in parentheses as the third example in [Table 59.2.1](#). Thus $C_G = 0$, and the framework is first-order flexible, if and only if one of the triangles $\overline{abc}$ or $\overline{def}$ is degenerate, or the three lines $\overline{ad}, \overline{be}, \overline{cf}$ are concurrent, or one or more of these lines is degenerate.
- (ii) The graph G is $K_{3,3}$, a complete bipartite graph, realized in the plane. Then $C_G = [a_1a_2a_3][a_1b_2b_3][b_1a_2b_3][b_1b_2a_3] - [b_1b_2b_3][b_1a_2a_3][a_1b_2a_3][a_1a_2b_3]$, and this is the second example in [Table 59.2.2](#). Thus $C_G = 0$, and the framework is first-order flexible, if and only if the six points lie on a common conic or, equivalently by Pascal's theorem, the three points $\overline{a_1b_2 \wedge a_2b_1}, \overline{a_1b_3 \wedge a_3b_1}, \overline{a_2b_3 \wedge a_3b_2}$ are collinear.
- (iii) The graph G is the edge skeleton of an octahedron, realized in Euclidean 3-space. Then $C_G = [abc'a'] [bca'b'] [cab'c'] + [abc'b'] [bca'c'] [cab'a']$, and this can

be recognized directly as the expansion of the Grassmann-Cayley expression $abc \wedge a'bc' \wedge a'b'c \wedge ab'c'$. Thus $C_G = 0$, and the framework is first-order flexible, if and only if the four alternating octahedral face planes $\overline{abc}$, $\overline{a'bc'}$, $\overline{a'b'c}$, and $\overline{ab'c'}$ concur, or any one or more of these planes is degenerate. This, in turn, is equivalent to the same condition on the other four face planes, $\overline{abc'}$, $\overline{ab'c}$, $\overline{a'bc}$, $\overline{a'b'c'}$.

59.4.3 BAR-AND-BODY FRAMEWORKS

A *bar-and-body framework* consists of a finite number of $(d-1)$ -dimensional rigid bodies, free to move in Euclidean $(d-1)$ -space, and connected by rigid bars, with the connections at the ends of each bar allowing free rotation of the bar relative to the rigid body; i.e., the connections are “universal joints.” Each rigid body may be replaced by a first-order rigid bar framework in such a way that the result is one large bar framework, thus in one sense reducing the study of bar-and-body frameworks to that of bar frameworks. Nevertheless, the combinatorics of bar-and-body frameworks is quite different from that of bar frameworks, since the original rigid bodies are not allowed to become first-order flexible in any realization, contrary to the case with bar frameworks.

A generically isostatic bar-and-body framework has a pure condition, just as a bar framework has, whose zeroes are precisely the special positions in which the framework has a first-order flex. However, this pure condition is a bracket polynomial in the *bars* of the framework, as opposed to a bracket polynomial in the vertices, as was the case with bar frameworks. An algorithm to directly compute the pure condition for a bar-and-body framework, somewhat similar to that for bar frameworks, is given in [WW87]. We illustrate with the example in Figure 59.4.3, consisting of three rigid bodies and six bars in the plane. We may interpret the word “plane” here as “real projective plane.”

FIGURE 59.4.3

A *bar-and-body framework*.

Hence $V = \mathbb{R}^3$, and we let $W = \Lambda^2(V) \cong V^* \cong \mathbb{R}^3$. We think of the endpoints of the bars as elements of V , and hence the lines determined by the bars are two-extensors of these points, or elements of W . The algorithm produces the pure condition $[abc][def] - [abd][cef]$. This bracket polynomial may be Cayley factored

as $ab \wedge cd \wedge ef$, as seen in Table 59.2.1. Now we switch to thinking of $a, b, \dots, f$ as 2-extensors in V rather than elements of W , and recall that there is a duality between V and W , hence between $\Lambda(V)$ and $\Lambda(W)$. Thus, the framework has a first-order flex if and only if $(a \wedge b) \vee (c \wedge d) \vee (e \wedge f) = 0$ in $\Lambda(V)$. Hence the desired geometric condition for the existence of a first-order flex is that the three points $\overline{a \wedge b}$, $\overline{c \wedge d}$, and $\overline{e \wedge f}$ are collinear. Now $\overline{a \wedge b}$ is just the center of relative (instantaneous) motion for the two bodies connected by those two bars: think of fixing one of the bodies and then rotating the other body about this center; the lengths of the two bars are instantaneously preserved. The geometric result we have obtained is just a restatement of the classical theorem of Arnhold-Kempe that in any flex of three rigid bodies, the centers of relative motion of the three pairs of bodies must be collinear.

59.4.4 AUTOMATED GEOMETRIC THEOREM-PROVING

J. Richter-Gebert [RG95] uses Grassmann-Cayley algebra to derive bracket conditions for projective geometric incidences in order to produce coordinate-free automatic proofs of theorems in projective geometry. By introducing two circular points at infinity, the same can be done for theorems in Euclidean geometry [CRG95].

Richter-Gebert's technique is to reduce each hypothesis to a *binomial* equation, that is, an equation with a single product of brackets on each side. For example, as we have seen, the concurrence of three lines $\overline{ab}$, $\overline{cd}$, $\overline{ef}$ may be rewritten as $[acd][bef] = [bcd][aef]$. Similarly, the collinearity of three points $\overline{a}$, $\overline{b}$, $\overline{c}$ may be expressed as $[abd][bce] = [abe][bcd]$, avoiding the much more obvious expression $[abc] = 0$ since it is not of the required form. If all binomial equations are now multiplied together, and provided they were appropriately chosen in the first place, common factors may be canceled (which involves nondegeneracy assumptions, so that the common factors are nonzero), resulting in the desired conclusion. A surprising array of theorems may be cast in this format, and this approach has been successfully implemented.

More recent work along similar lines, extending it especially to conic geometry, is by H. Li and Y. Wu [LW03a, LW03b].

59.4.5 COMPUTER VISION

Much of computer vision study involves projective geometry, and hence is very amenable to the techniques of the Grassmann-Cayley algebra. One reference that explicitly applies these techniques to a system of up to three pinhole cameras is Faugeras and Papadopoulos [FP98].

59.5 SOURCES AND RELATED MATERIAL

SURVEYS

[DRS74] and [BBR85]: These two papers survey the properties of the Grassmann-Cayley algebra (called the “double algebra” in [BBR85]).

[Whi95]: A more elementary survey than the two above.

[Whi94]: Emphasizes the concrete approach via Plücker coordinates, and gives more detail on the connections to robotics.

60 RIGIDITY AND SCENE ANALYSIS

Walter Whiteley

INTRODUCTION

Rigidity and flexibility of frameworks (motions preserving lengths of bars) and scene analysis (liftings from plane polyhedral pictures to spatial polyhedra) are two core examples of a general class of geometric problems:

- (a) Given a discrete configuration of points, lines, planes, . . . in Euclidean space, and a set of geometric constraints (fixed lengths for rigidity, fixed incidences, and fixed projections of points for scene analysis), what is the set of solutions and what is its local form: discrete? k -dimensional?
- (b) Given a structure satisfying the constraints, is it unique, or at least locally unique, up to trivial changes, such as congruences for rigidity, or vertical scale for liftings?
- (c) How does this answer depend on the combinatorics of the structure and how does it depend on the specific geometry of the initial data or object?

The rigidity of frameworks examines points constrained by fixed distances between pairs, using vocabulary and linear techniques drawn from structural engineering: bars and joints, first-order rigidity and first-order flexes, and static rigidity and static self-stresses (Section 60.1). Scene analysis and the dual concept of parallel drawings are described in Section 60.2. Finally, reciprocal diagrams form a fundamental geometric connection between liftings of polyhedral pictures and self-stresses in frameworks (Section 60.3).

These core problems have a wide range of applications across many areas of applied geometry. The methods used and the results obtained for these problems serve as a model for what might be hoped for other sets of constraints (plane first-order results) and as a warning of the complexity that does arise (higher dimensions and broader forms of rigidity). The subject has a rich history, stretching back into at least the middle of the 19th century, in structural and mechanical engineering. Other independent rediscoveries and connections have arisen in crystallography and scene analysis. Some other geometric problems with related mathematical and algorithmic patterns are mentioned in Sections 60.1.5, 60.2.3, and 60.3. For more general geometric reconstruction problems, see [Chapter 29](#).

60.1 RIGIDITY OF BAR FRAMEWORKS

Given a set of points in space, with certain distances to be preserved, what other configurations have the same distances? If we make small changes in the distances, will there be a small (linear scale) change in the position? What is the structure, locally and globally, of the algebraic variety of these “realizations”?

We begin with the simplest linear theory: first-order rigidity, and the equivalent dual static rigidity, which are the linearized (and therefore linear algebra) version of rigidity. Generic rigidity refers to first-order rigidity of “almost all” geometric positions of the underlying combinatorial structure. After the initial results presenting first-order rigidity (Section 60.1.1), the study divides into the combinatorics of generic rigidity, using graphs (Section 60.1.2); the geometry of special positions in first-order rigidity, using projective geometry (Section 60.1.3); more general concepts of rigidity (Section 60.1.4); and extensions to tensegrity frameworks, using geometry and minima of energy functions for rigidity (Section 60.1.5).

60.1.1 FIRST-ORDER RIGIDITY

GLOSSARY

Configuration of points in d -space: An assignment $p = (p_1, \dots, p_v)$ of points $p_i \in \mathbb{R}^d$ to an index set V , where $v = |V|$.

Congruent configurations: Two configurations p and q in d -space, on the same set V , related by an isometry T of $\mathbb{R}^d$ (with $T(p_i) = q_i$ for all $i \in V$).

Bar framework in d -space $G(p)$ (or **framework**): A graph $G = (V; E)$ (no loops or multiple edges) and a configuration p in d -space for the vertices V (Figure 60.1.1A).

Bar: An edge $\{i, j\} \in E$ for a framework $G(p)$.

First-order flex or **infinitesimal motion:** For a bar framework $G(p)$, an assignment of velocities $p' : V \rightarrow \mathbb{R}^d$, such that for each edge $\{i, j\} \in E$: $(p_i - p_j) \cdot (p'_i - p'_j) = 0$ (Figure 60.1.1.C,D, where the arrows represent nonzero velocities).

Trivial first-order flex: A first-order flex p' that is the derivative of a flex of congruent frameworks (Figure 60.1.1C). (There is a fixed skew-symmetric matrix S (a rotation) and a fixed vector t (a translation) such that, for all vertices $i \in V$, $p'_i = p_i S + t$.)

First-order flexible framework: A framework $G(p)$ with a nontrivial first-order flex (Figure 60.1.1D).

First-order rigid framework: A bar framework $G(p)$ for which every first-order flex is trivial (Figures 60.1.1A, 60.1.2A).

Rigidity matrix: For a framework $G(p)$ in d -space, $R_G(p)$ is the $|E| \times d|V|$ matrix for the system of equations: $(p_i - p_j) \cdot (p'_i - p'_j) = 0$ in the unknown velocities p'_i . The first-order flex equations are expressed as

$$R_G(p)p'^T = \begin{bmatrix} \vdots & \ddots & \vdots & \cdots & \vdots & \ddots & \vdots \\ 0 & \cdots & (p_i - p_j) & \cdots & (p_j - p_i) & \cdots & 0 \\ \vdots & \ddots & \vdots & \cdots & \vdots & \ddots & \vdots \end{bmatrix} \times p'^T = 0^T.$$

Self-stress: For a framework $G(p)$, a row dependence ω for the rigidity matrix: $\omega R_G(p) = 0$. Equivalently, an assignment of scalars ω_{ij} to the edges such that

at each vertex i , $\sum_{\{j \mid \{i,j\} \in E\}} \omega_{ij}(p_i - p_j) = 0$ (placing these “internal forces” $\omega_{ij}(p_i - p_j)$ in equilibrium at vertex i). $\omega_{ij} < 0$ is tension, $\omega_{ij} > 0$ is compression.

Independent framework: A bar framework $G(p)$ for which the rigidity matrix has independent rows. Equivalently, there is only the zero self-stress.

Isostatic framework: A framework $G(p)$ that is first-order rigid and independent.

Generically rigid graph in d -space: A graph G for which the frameworks $G(p)$ are first-order rigid on an open dense subset of configurations p in d -space (Figures 60.1.1A, 60.1.2A).

FIGURE 60.1.1

Generic d -circuit: A graph G such that with the deletion of any edge e , $G - e$ is generically rigid in d -space.

BASIC CONNECTIONS

Because the constraints $|p_i - p_j| = |q_i - q_j|$ are algebraic in the coordinates of the points (after squaring), we can work with the Jacobian matrix formed by the partial derivatives of these equations—the rigidity matrix of the framework.

The dimension of the space of trivial first-order motions of a framework in d -space is $\binom{d+1}{2}$ provided $|V| \geq d$ (the velocities generated by d translations and by $\binom{d}{2}$ rotations form a basis).

THEOREM 60.1.1 First-order Rank

A framework $G(p)$ with $|V| \geq d$ is first-order rigid if and only if the rigidity matrix $R_G(p)$ has rank $d|V| - \binom{d+1}{2}$.

A framework $G(p)$ with few vertices, $|V| \leq d$, is isostatic if and only if the rigidity matrix $R_G(p)$ has rank $\binom{v}{2}$ (if and only if G is the complete graph on V and the points p_i do not lie in an affine space of dimension $|V| - 2$).

First-order rigidity is linear algebra, with first-order rigid frameworks, self-stresses, and isostatic frameworks playing the roles of spanning sets, linear dependence, and bases of the row space for the rigidity matrix of the complete graph on the configuration p .

There is a dual theory of static rigidity for bar frameworks. Where first-order rigidity focuses on the kernel of the rigidity matrix (first-order flexes) and on the column space and column rank, static rigidity focuses on the cokernel of the rigidity matrix (the self-stresses) and on the row space of the rigidity matrix (the resolvable static loads). Methods from both approaches are widely used [CW82, Whi84, Whi96], although in this chapter we present the results primarily in the vocabulary of first-order rigidity.

THEOREM 60.1.2 *Isostatic Frameworks*

For a framework $G(p)$ in d -space, with $|V| \geq d$, the following are equivalent:

- (a) $G(p)$ is isostatic (first-order rigid and independent);
- (b) $G(p)$ is first-order rigid with $|E| = d|V| - \binom{d+1}{2}$;
- (c) $G(p)$ is independent with $|E| = d|V| - \binom{d+1}{2}$;
- (d) $G(p)$ is first-order rigid, and removing any one bar (but no vertices) leaves a first-order flexible framework.

First-order rigidity of a framework $G(p)$ is a robust property: a small change in the configuration p preserves this rigidity. Independence implies that the distances are robust: any small change in these distances can be realized by a nearby configuration. On the other hand, self-stresses mean that one of the distances is algebraically dependent on the others: many small changes in the distances will have no realizations, or no nearby realizations.

Figure 60.1.2 illustrates a single graph with plane configurations that produce: (A) a first-order rigid framework; (B) a first-order flexible, but rigid, framework, and (C) a flexible framework (see Section 60.1.4). The graph itself is generically 2-rigid.

FIGURE 60.1.2

THEOREM 60.1.3 *Generic Rigidity Theorem*

For a graph G and a fixed dimension d the following are equivalent:

- (a) G is generically rigid in d -space;
- (b) for each configuration $p \in \mathbb{R}^{dv}$ using algebraically independent numbers over the rationals as coordinates, the framework $G(p)$ is first-order rigid;
- (c) $G(p)$ is first-order rigid for some configuration $p \in \mathbb{R}^{dv}$.

60.1.2 COMBINATORICS FOR GENERIC RIGIDITY

The major goal in generic rigidity is a combinatorial characterization of graphs that are generically rigid in d -space. The companion problem is to find efficient combinatorial algorithms to test graphs for generic rigidity. For the plane (and the line), this is solved. Beyond the plane the results are essentially incomplete, but some significant partial results are available.

GLOSSARY

Generically d -independent: A graph G for which some (equivalently, almost all) configurations p produce independent frameworks in d -space.

Generically d -isostatic graph: A graph G for which some (equivalently, almost all) configurations p produce isostatic frameworks in d -space.

Generic d -circuit: A graph G that is dependent for all configurations p in d -space but for all edges $\{i, j\} \in E$, $G - \{i, j\}$ is generically independent in d -space.

Complete bipartite graph: A graph $K_{m,n} = (A \cup B, A \times B)$, where A and B are disjoint sets of cardinality $|A| = m$ and $|B| = n$.

Triangulated d -pseudomanifold: A finite set of d -simplices (complete graphs on $d + 1$ points) with the property that each d subset (facet) occurs in exactly two simplices, any two simplices are connected by a path of simplices and shared facets, and any two simplices sharing a vertex are connected through other simplices at this vertex. (For example, the triangles, edges, and vertices of a closed triangulated 2-surface without boundary, such as a sphere or torus, form a 2-pseudomanifold.) Cf. Section 18.3.

Henneberg d -construction for a graph G : A sequence $(V_d, E_d), \dots, (V_n, E_n)$ of graphs, such that:

- (i) For each index $d < j \leq n$, (V_j, E_j) is obtained from (V_{j-1}, E_{j-1}) by
 - vertex addition:** attaching a new vertex by d edges (Figure 60.1.4A for $d = 2$), or
 - edge splitting:** replacing an edge from (V_{j-1}, E_{j-1}) with a new vertex joined to its ends and to $d - 1$ other vertices (Figure 60.1.4B for $d = 2$); and
- (ii) (V_d, E_d) is the complete graph on d vertices, and $(V_n, E_n) = G$ (Figure 60.1.6A).

Proper 3Tree2 partition: A partition of the edges of a graph into three trees, such that each vertex is attached to exactly two of these trees and no nontrivial subtrees of distinct trees T_i have the same support (i.e., the same vertices) (Figure 60.1.6B).

Proper 2Tree partition: A partition of the edges of a graph into two spanning trees, such that no nontrivial subtrees of distinct trees T_i have the same support (i.e., the same vertices) (Figure 60.1.6C).

d -connected graph: A graph G such that removing any $d - 1$ vertices (and all incident edges) leaves a connected graph. (Equivalently, a graph such that any two vertices can be connected by at least d paths that are vertex-disjoint except for their endpoints.)

BASIC PROPERTIES IN ALL DIMENSIONS

THEOREM 60.1.4 *Necessary Counts and Connectivity Theorem*

If a graph G is generically d -isostatic, then, if $V \geq d$, $|E| \leq d|V| - \binom{d+1}{2}$ and for every subgraph on $|V'| \geq d$ vertices with edges E' in $V' \times V'$, $|E'| \leq d|V'| - \binom{d+1}{2}$.

If $G = (V, E)$ is a generically d -isostatic graph with $|V| > d$, then (V, E) is a d -connected graph.

FIGURE 60.1.3

For dimensions 1 and 2, the first count alone is sufficient for generic rigidity (see below). For dimensions $d > 2$, these two conditions are not enough to characterize the generically d -isostatic graphs. Figure 60.1.3A shows a generically flexible counterexample for the sufficiency of the counts in dimension 3. This example is generated by a “circuit exchange” on two over-counted graphs (Figure 60.1.3B). Figure 60.1.3C adds 3-connectivity, but preserves the flexibility and the counts.

THEOREM 60.1.5 *Bipartite Graphs*

A complete bipartite graph $K_{m,n}$, with $m > 1$, is generically rigid in dimension d if and only if $m + n \geq \binom{d+2}{2}$ and $m, n > d$.

INDUCTIVE CONSTRUCTIONS FOR ISOSTATIC GRAPHS

Inductive constructions for graphs that preserve generic rigidity are used both to prove theorems for general classes of frameworks and to analyze particular graphs.

THEOREM 60.1.6 *Vertex Addition Theorem*

Let $G = (V, E)$ be a graph with a vertex i of valence d ; let $H = (U, F)$ denote the subgraph obtained by deleting i and the edges incident with it. Then G is generically d -isostatic if and only if H is generically d -isostatic (Figure 60.1.4A for $d = 2$).

THEOREM 60.1.7 *Edge Split Theorem*

Let $G = (V, E)$ be a graph with a vertex i of valence $d+1$, let S be the set of vertices adjacent to i , and let $H = (U, F)$ be the subgraph obtained by deleting i and its $d+1$ incident edges. Then G is generically d -isostatic if and only if there is a pair j, k of vertices of V such that the edge $\{j, k\}$ is not in F and the graph $H' = (U, F \cup \{j, k\})$ is generically d -isostatic (Figure 60.1.4B for $d = 2$).

FIGURE 60.1.4

THEOREM 60.1.8 *Construction Theorem*

If a graph G is obtained by a Henneberg d -construction, then G is generically d -isostatic (Figure 60.1.6A for $d = 2$).

THEOREM 60.1.9 *Gluing Theorem*

If $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ are generically d -rigid graphs sharing at least d vertices, then $G = (V_1 \cup V_2, E_1 \cup E_2)$ is generically d -rigid.

THEOREM 60.1.10 *Vertex Splitting Theorem*

If the graph G' is a vertex split of a generically d -isostatic graph G on d edges (Figure 60.1.5A for $d = 3$) or a vertex split on $d - 1$ edges (Figure 60.1.5B for $d = 3$), then G' is generically d -isostatic.

**PLANE ISOSTATIC GRAPHS**

Many plane results are expressed in terms of trees in the graph, building on a simpler correspondence between rigidity on the line and the connectivity of the graph.

THEOREM 60.1.11 *Line Rigidity*

For graph G and configuration p on the line with $p_i \neq p_j$ for all $\{i, j\} \in E$, the following are equivalent:

- (a) $G(p)$ is minimal among rigid frameworks on the line with these vertices;
- (b) $G(p)$ is isostatic on the line;
- (c) G is a spanning tree on the vertices;
- (d) $|E| = |V| - 1$ and for every nonempty subset E' with vertices V' , $|E'| \leq |V'| - 1$.

THEOREM 60.1.12 *Plane Isostatic Graphs Theorem*

For a graph G with $|V| \geq 2$, the following are equivalent:

- (a) G is generically isostatic in the plane;
- (b) $|E| = 2|V| - 3$, and for every subgraph (V', E') with $|V'| \geq 2$ vertices, $|E'| \leq 2|V'| - 3$ (Laman's theorem);
- (c) there is a Henneberg 2-construction for G (Henneberg's theorem);
- (d) E has a proper 3Tree2 partition (Crapo's theorem);
- (e) for each $\{i, j\} \in E$, the multigraph obtained by doubling the edge $\{i, j\}$ is the union of two spanning trees (Recski's theorem).

FIGURE 60.1.6

Figure 60.1.6A shows the Henneberg plane construction for the isostatic graph of Figure 60.1.2. Figure 60.1.6B shows a proper 3Tree2 partition of the isostatic complete bipartite graph $K_{3,3}$. With an added edge, joining T_2 to T_3 , this partition creates several of the pairs of spanning trees predicted by Recski's theorem.

THEOREM 60.1.13 *Plane 2-Circuits Theorem*

For a graph G with $|V| \geq 2$, the following are equivalent:

- (a) G is a generic 2-circuit;
- (b) $|E| = 2|V| - 2$, and for every proper subset E' on vertices V' , $|E'| \leq 2|V'| - 3$;
- (c) there is a construction for G from K_4 , using only edge splitting and gluing; (Berg and Jordan's theorem);
- (d) E has a proper 2Tree partition.

Figure 60.1.6C shows the construction for a 2-circuit, and an associated 2Tree partition. For 2-circuits with planar graphs, the planar dual is also a 2-circuit. The inductive techniques given above, and others, form dual pairs of constructions for these planar 2-circuits [BCW02].

THEOREM 60.1.14 *Sufficient Connectivity*

If a graph G is 6-connected, then G is generically rigid in the plane.

There are 5-connected graphs that are not generically rigid in the plane.

ALGORITHMS FOR GENERIC 2-RIGIDITY

Each of the combinatorial characterizations has an associated algorithm for verifying whether a graph is generically 2-isostatic:

- (i) Counts: This can be checked by an $O(|V|^2)$ algorithm based on bipartite matchings or network flows on an associated graph [Sug86].
- (ii) 2-construction: Existence of a 2-construction can be checked by an $O(2^{|V|})$ algorithm, but a proposed 2-construction can be verified in $O(|V|)$ time.
- (iii) 3Tree2 covering: Existence can be checked by an $O(|V|^2)$ matroid partition algorithm [Cra].
- (iv) Double tree partition: All required double-tree partitions can be found by a matroidal algorithm of order $O(|V|^3)$.

GENERICALLY RIGID GRAPHS IN HIGHER DIMENSIONS

Most of the results are covered by the initial summary for all dimensions d . Special results apply to the graphs of triangulated polytopes, as well as more general surfaces.

THEOREM 60.1.15 *Triangulated Pseudomanifolds Theorem*

For $d \geq 2$, the graph of a triangulated d -pseudomanifold is generically $(d+1)$ -rigid.

In particular, the graph of any closed triangulated 2-surface without boundary is generically rigid in 3-space (Fogelsanger's theorem), and the graph of any triangulated sphere is generically 3-isostatic (Gluck's theorem). Beyond the triangulated spheres in 3-space, most of these graphs are not isostatic, but are dependent.

OPEN PROBLEMS

There is no combinatorial characterization of generically 3-isostatic graphs. There are several related conjectures, due to Dress, Graver, and Tay and Whiteley, that may be correct but are unproven. We offer one of these.

CONJECTURE 60.1.16 *3-D Replacement Conjecture*

The X -replacement in Figure 60.1.7A takes a graph G_1 that is generically rigid in 3-space to a graph G that is generically rigid in 3-space.

The double V -replacement in Figure 60.1.7B takes two graphs G_1, G_2 that are generically rigid in 3-space to a graph G that is generically rigid in 3-space.

Every 3-isostatic graph is generated by an “extended Henneberg 3-construction,” which adds these two moves to the simpler edge splitting and vertex addition. What is unproven is that *only* 3-isostatic graphs are generated in this way.

The plane analogue of X-replacement is true for plane generic rigidity (without adding the fifth bar) [BCW02], and the 4-space analogue is false for some graphs (with two extra bars added in this analogue). If these conjectured steps prove correct in 3-space, then we would have inductive techniques to generate the graphs of all isostatic frameworks in 3-space, but the algorithm would be exponential.

For 4-space, there is no conjecture that has held up against the known counterexamples based on generically 4-flexible complete bipartite graphs such as $K_{7,7}$.

CONJECTURE 60.1.17 *Sufficient Connectivity Conjecture*

If a graph G is 12-connected, then G is generically rigid in 3-space.

A graph can be checked for generic 3-rigidity by a “brute force” $O(2^{2^{|V|}})$ algorithm. Assign the points independent variables as coordinates, form the rigidity matrix, then check the rank by symbolic computation. On the other hand, if numerical coordinates are chosen for the points “at random,” then the rank of this numerical matrix ($O(|E|^3)$) will be the generic value, with probability 1. This problem has a randomized polynomial-time algorithm, but there is no known deterministic algorithm that runs in polynomial, or even exponential, time.

60.1.3 GEOMETRY OF FIRST-ORDER RIGIDITY

GLOSSARY

Special position of a graph G in d -space: Any configuration $p \in \mathbb{R}^{dv}$ such that the rigidity matrix $R_G(p)$, or any submatrix, has rank smaller than the maximum rank (the rank at a configuration with algebraically independent coordinates).

Projective transform of a d -configuration p : A d -configuration q on the same vertices, such that there is an invertible matrix T of size $d+1 \times d+1$ making $T(p_i, 1) = \lambda_i(q_i, 1)$ (where $(p_i, 1)$ is the vector p_i extended with an additional 1 — the affine coordinates of p_i).

Affine spanning set for d -space: A configuration p of points such that every point $q_0 \in \mathbb{R}^d$ can be expressed as an affine combination of the p_i : $q_0 = \sum_i \lambda_i p_i$, with $\sum_i \lambda_i = 1$. (Equivalently, the affine coordinates $(p_i, 1)$ span the vector space $\mathbb{R}^{d+1}$.)

Cone graph: The graph $G * u$ obtained from $G = (V, E)$ by adding a new vertex u and the $|V|$ edges (u, i) for all vertices $i \in V$.

Cone projection from p_0 : For a $(d+1)$ -configuration p on V , a configuration $q = \Pi_0(p)$ in d -space (placed as a hyperplane in $(d+1)$ -space) on the vertices $V \setminus 0$, such that $p_i \neq p_0$ is on the line $q_i p_0$ for all $i \neq 0$.

BASIC RESULTS

THEOREM 60.1.18 *First-order Flex Test*

If the points of a configuration p on the vertices V affinely span d -space, then a

first-order motion p' is nontrivial if and only if there is some pair h, k (not a bar) such that: $(p_h - p_k) \cdot (p'_h - p'_k) \neq 0$.

THEOREM 60.1.19 *Projective Invariance*

If a framework $G(p)$ is first-order rigid (isostatic, independent) and $q = T(p)$ is a projective transform of p , then $G(q)$ is first-order rigid (isostatic, independent, respectively).

The following result provides an alternate proof of projective invariance as well as a corresponding generic result for cones.

THEOREM 60.1.20 *Coning Theorem*

A framework $G(\Pi_0 p)$ is first-order rigid (isostatic, independent) in d -space if and only if the cone $(G * u)(p)$ is first-order rigid (isostatic, independent, respectively) in $(d+1)$ -space.

The special positions of a graph in d -space are rare, since they form a proper algebraic variety (essentially generated by minors of the rigidity matrix with variables for the coordinates of points). For a generically isostatic graph, this set of special positions can be described by the zeros of a single polynomial [WW83].

THEOREM 60.1.21 *Pure Condition*

For any graph G that is generically isostatic in d -space, there is a homogeneous polynomial $C_G(x_{1,1}, \dots, x_{1,d}, \dots, x_{|V|,1}, \dots, x_{|V|,d})$ such that $G(p)$ is first-order flexible if and only if $C_G(p_1, \dots, p_{|V|}) = 0$. C_G is of degree $(\text{val}_i + 1 - d)$ in the variables $(x_{i,1}, \dots, x_{i,d})$ for each vertex i of valence val_i in the graph.

FIGURE 60.1.8

Since Grassmann algebra (Chapter 59) is the appropriate language for these projective properties, these pure conditions C_G are polynomials in the Grassmann algebra. Section 59.4 contains several examples of these polynomial conditions.

THEOREM 60.1.22 *Quadratics for Bipartite Graphs*

For a complete bipartite graph $K_{m,n}$ and $d > 1$, the framework $K_{m,n}(p)$, with $p(A)$ and $p(B)$ each affinely spanning d -space, is first-order flexible if and only if all the points $p(A \cup B)$ lie on a quadric surface of d -space (Figure 60.1.8).

The following classical result describes an important open set of configurations that are not special for triangulated spheres.

THEOREM 60.1.23 *Extended Cauchy Theorem*

If $G(p)$ consists of the vertices and edges of a convex simplicial d -polytope, then

$G(p)$ is first-order rigid in d -space.

If $G(p)$ consists of the vertices and edges of a strictly convex polyhedron in 3-space, then $G(p)$ is independent.

We recall that Steinitz's theorem guarantees that every 3-connected planar graph has a realization as the edges of a strictly convex polyhedron in 3-space, which gives Gluck's theorem. There are numerous example of nonconvex simplicial polytopes that are not first-order rigid. Connelly [Con78] gives a nonconvex (but not self-intersecting) triangulated sphere (with nine vertices) that is flexible (see the definition below). For many graphs, such as a triangulated torus (Theorem 60.1.15), we do not have even one specific configuration that gives a first-order rigid framework, only the guarantee that "almost all" configurations will work.

FIGURE 60.1.9

Recent papers [Str03, HOR⁺02] suggest that pseudotriangulations play a role for planar graphs in plane rigidity analogous to the role of convex polyhedra for planar graphs in 3-space. **Pseudotriangulations** were defined in Chapter 5, as plane-embedded graphs with a convex polygonal boundary, all interior regions being polygons with exactly three interior angles that are $< \pi$ (Figure 60.1.9A,C). A plane-embedded graph is **pointed** if at each vertex there is an angle that is embedded as $> \pi$ (Figure 60.1.9B,C). The following are some of these recent results.

THEOREM 60.1.24 Counts on Pseudotriangulations

For a general position configuration p , the following properties are equivalent:

- (a) $G(p)$ is a pointed pseudotriangulation;
- (b) $G(p)$ is a pseudotriangulation with $|E| = 2|V| - 3$;
- (c) $G(p)$ is a noncrossing pointed graph with $|E| = 2|V| - 3$;
- (d) $G(p)$ is a noncrossing pointed graph and is maximal with this property, with the given vertices.

THEOREM 60.1.25 Rigidity of Pseudotriangulations

A pseudotriangulation $G(p)$, realized as a bar framework, is first-order rigid. A pointed noncrossing graph $G(p)$ is an independent bar framework.

A planar graph G is generically 2-isostatic if and only if it has a realization as a pointed pseudotriangulation.

There are further significant consequences of the underlying projective geometry of first-order rigidity [CW82]. The concepts of first-order rigidity and first-order flexibility, as well as the dual statics, can be expressed in any of the Cayley-Klein metrics that are extracted from the shared underlying projective space. This family includes the spherical metric, the hyperbolic metric, and others. It is possible to

express first-order rigidity in entirely projective terms that are essentially independent of the metric. In this way, the points “at infinity” in the Euclidean space can be fully integrated into first-order rigidity. However, in some metrics such as the hyperbolic metric, there is a singular set (the sphere at infinity, also known as the *absolute*) on which rigidity equations have distinct properties. This transfer goes back to Pogorelov and has been reworked in [SW02].

THEOREM 60.1.26 *Transfer of Metrics*

For a given graph G and a fixed point p in projective space of dimension d , the framework $G(p)$ is first-order rigid in Euclidean space if and only if $G(p)$ is first-order rigid in any alternate Cayley-Klein metric, with p not containing points on the absolute.

The most extreme projective transformation is a polarity, in which points and hyperplanes (e.g., planes in 3-space) switch roles. For Euclidean 3-space, there are translations of first-order rigidity results to these dual “sheet” structures [Whi87]. For other metrics, the duality in three dimensions changes distance constraints on pairs of points into angle constraints on pairs of planes [SW02].

OTHER RELATED STRUCTURES

A number of related structures have also been investigated for first-order rigidity. One, which appears in engineering, robotics, and chemistry, is the “body-and-hinge framework.” Rigid bodies, indexed by V , are connected in pairs along hinges (lines in 3-space), indexed by edges of a graph. The bodies each move, preserving the contacts at the hinges. Such hinged frameworks could be modeled as bar-and-joint frameworks, with each hinge replaced by a pair of joints and each body replaced by a first-order rigid framework on the joints of its hinges (and other joints if desired); cf. Sections 48.1 and 59.4. Unlike the unsolved problems for generic rigidity of frameworks in 3-space, the generic behavior of body-and-hinge structures has been completely solved. We state two sample results and a related conjecture.

THEOREM 60.1.27 *Tay’s Theorem*

For a graph G the following are equivalent:

- (a) *for some hinge assignment of lines $h_{i,j}$ in 3-space to the edges $\{i, j\}$ of G , the body-and-hinge framework $G(h)$ is first-order rigid;*
- (b) *for almost all hinge assignments h , the body-and-hinge framework $G(h)$ is first-order rigid;*
- (c) *if each edge of the graph is replaced by five copies, the resulting multigraph contains six edge-disjoint spanning trees.*

Tay’s theorem extends directly to all dimensions d (finding $\binom{d+1}{2}$ edge-disjoint spanning trees inside $\binom{d+1}{2} - 1$ copies of the graph).

THEOREM 60.1.28 *Spherical Flexes and Stresses*

Given an abstract spherical structure (see Section 60.3) $S = (V, F; \underline{E})$, and an assignment of distinct points $p_i \in \mathbb{R}^3$ to the vertices, the following two conditions are equivalent:

- (a) the bar framework $G(p)$ on $G = (V, E)$ has a nontrivial self-stress;
- (b) the body-and-hinge framework on the dual graph $G^* = (F, E^*)$ with hinge lines $p_i p_j$ for each edge $\{i, j\}$ of G is first-order flexible.

A second “model” treats the atoms of a molecule as the bodies, and the lines of the bond lines as hinges. Such structures are geometrically singular since the lines of all bonds of an atom are concurrent in the center of the atom. This model, and the equivelant bar frameworks, are central to applications of rigidity to protein structures with thousands of atoms [Whi99].

CONJECTURE 60.1.29 *Molecular Conjecture*

If a graph G is realized as the atoms (points) and bonds (lines) of a molecular structure, then the molecular structure is generically rigid if, and only if, when each edge of the graph G is replaced by five copies, the resulting multigraph contains six edge-disjoint spanning trees.

This conjecture is embedded in the FIRST algorithm for protein flexibility [JRKT01]. In polar form, the conjecture states that if each body is realized with all hinges of each body coplanar (plate structures), the generic rigidity is still measured by the existence of six spanning trees.

60.1.4 RIGID AND FLEXIBLE FRAMEWORKS

GLOSSARY

Bar equivalence: Two frameworks $G(p)$ and $G(q)$ such that all bars have the same length in both configurations: $|p_i - p_j| = |q_i - q_j|$ for all bars $\{i, j\} \in E$.

Analytic flex: An analytic function $p(t) : [0, 1) \rightarrow \mathbb{R}^{v_d}$ such that $G(p(0))$ is bar-equivalent to $G(p(t))$ for all t (i.e., all bars have constant length).

Flexible framework: A bar framework $G(p)$ in $\mathbb{R}^d$ with an analytic flex $p(t)$ such that $p(0) = p$ but p is not congruent to $p(t)$ for all $0 < t$ (Figure 60.1.1B).

Rigid framework: A bar framework $G(p)$ in d -space that is not flexible (Figure 60.1.1A,D).

BASIC CONNECTIONS

Because the constraints $|p_i - p_j| = |q_i - q_j|$ are algebraic in the coordinates of the points (after squaring), many alternate definitions of a “rigid framework” are equivalent. These connections depend on results such as the curve selection theorem of algebraic geometry or the inverse function theorem.

THEOREM 60.1.30 *Alternate Rigidity Definitions*

For a bar framework $G(p)$ the following conditions are equivalent:

- (a) the framework is rigid;

- (b) for every continuous path, or **continuous flex** of $G(p)$, $p(t) \in \mathbb{R}^{vd}$, $0 \leq t < 1$ and $p(0) = p$, such that $G(p(t))$ is bar-equivalent to $G(p)$ for all t , $p(t)$ is congruent to p for all t ;
- (c) there is an $\epsilon > 0$ such that if $G(p)$ and $G(q)$ are bar-equivalent and $|p - q| < \epsilon$, then p is congruent to q .

Essentially, the first derivative of a nontrivial analytic flex is a nontrivial first-order flex: $D_t((p_i(t) - p_j(t))^2 = c_{ij})|_{t=0} \Rightarrow 2(p_i - p_j) \cdot (p'_i - p'_j) = 0$. (If this first derivative is trivial, then the earliest nontrivial derivative is a first-order motion.) This result is related to general forms of the inverse function theorem.

THEOREM 60.1.31 *First-order Rigid to Rigid*

If a bar framework $G(p)$ is first-order rigid, then $G(p)$ is rigid.

Some first-order flexes are not the derivatives of analytic flexes (Figures 60.1.1D and 60.1.2B). However, a nontrivial first-order flex for a framework does guarantee a pair of nearby noncongruent, bar-equivalent frameworks.

THEOREM 60.1.32 *Averaging Theorem*

If the points of a configuration p affinely span d -space, then the assignment p' is a nontrivial first-order flex of $G(p)$ if and only if the frameworks $G(p + p')$ and $G(p - p')$ are bar-equivalent and not congruent.

Rigidity and first-order rigidity are equivalent in some situations.

THEOREM 60.1.33 *Rigid to First-order Rigid*

If bar framework $G(p)$ is independent, then $G(p)$ is first-order rigid if and only if $G(p)$ is rigid.

The recent solution of the Carpenter's Rule problem on straightening plane-embedded polygonal paths and convexifying plane-embedded polygons [CDR03, Str03] uses independence of appropriate bar frameworks, and resulting paths. The independence is proven using Maxwell's theorem (see Section 60.3). See Chapter 9 for more connections. The following is one form of this connection [RSS03].

THEOREM 60.1.34 *Expansive Motions*

If one edge of the boundary polygon of a pointed pseudotriangulation $G(p)$ is removed, and its two vertices are spread apart in a motion, then the resulting path (unique up to congruences) is expansive—all pairs of joints are either moving apart or remaining at a constant distance.

Whereas first-order rigidity is projectively invariant, rigidity itself is not projectively invariant—or even affinely invariant. It is a purely Euclidean property.

THEOREM 60.1.35 *Generic Rigidity Theorem II*

For a graph G and a fixed dimension d the following are equivalent:

- (a) G is generically rigid in d -space;
- (b) for all $q \in U \subset \mathbb{R}^{dv}$, U some nonempty open set, $G(q)$ is rigid;
- (c) for all $q \in W \subset \mathbb{R}^{dv}$, W some open dense set, $G(q)$ is first-order rigid.

60.1.5 TENSEGRITY FRAMEWORKS

In a tensegrity framework, we replace some (or all) of the equalities for bars with inequalities for the distances—corresponding to *cables* (the distance can shrink but not expand) and *struts* (the distance can expand but not shrink). The study of these inequalities introduces techniques from linear programming.

GLOSSARY

Signed graph: A graph with a partition of the edges into three classes, written $G_{\pm} = (V; E_-, E_0, E_+)$.

Tensegrity framework $G_{\pm}(p)$ in $\mathbb{R}^d$: A signed graph $G_{\pm} = (V; E_-, E_0, E_+)$ and a configuration p on V .

Cables, bars, struts: For a tensegrity framework $G_{\pm}(p)$, the members of E_- , of E_0 , and of E_+ , respectively. In figures, cables are indicated by dashed lines, struts by double thin lines, and bars by single thick lines (see Figure 60.1.10).

FIGURE 60.1.10

$G_{\pm}(p)$ **dominates** $G_{\pm}(q)$: For each edge, the appropriate condition holds:

$$\begin{aligned} |p_i - p_j| &\geq |q_i - q_j| && \text{when } \{i, j\} \in E_- \\ |p_i - p_j| &= |q_i - q_j| && \text{when } \{i, j\} \in E_0 \\ |p_i - p_j| &\leq |q_i - q_j| && \text{when } \{i, j\} \in E_+. \end{aligned}$$

Rigid tensegrity framework $G_{\pm}(p)$: For every analytic path $p(t)$ in $\mathbb{R}^{vd}$, $0 \leq t < 1$, if $p(0) = p$ and $G(p)$ dominates $G(p(t))$ for all t , then p is congruent to $p(t)$ for all t .

First-order flex of a tensegrity framework $G_{\pm}$: An assignment $p' : V \rightarrow \mathbb{R}^d$ of velocities to the vertices such that, for each edge $\{i, j\} \in E$ (Figure 60.1.10),

$$\begin{aligned} (p_j - p_i) \cdot (p'_j - p'_i) &\leq 0 && \text{for cables } \{i, j\} \in E_- \\ (p_j - p_i) \cdot (p'_j - p'_i) &= 0 && \text{for bars } \{i, j\} \in E_0 \\ (p_j - p_i) \cdot (p'_j - p'_i) &\geq 0 && \text{for struts } \{i, j\} \in E_+. \end{aligned}$$

Trivial first-order flex: A first-order flex p' of a tensegrity framework $G_{\pm}(p)$ such that $p'_i = Sp_i + t$ for all vertices i , with a fixed skew-symmetric matrix S and vector t .

First-order rigid: A tensegrity framework $G_{\pm}(p)$ is first-order rigid if every first-order flex is trivial, and **first-order flexible** otherwise.

Proper self-stress on a tensegrity framework $G_{\pm}(p)$: An assignment ω of scalars to the edges of G such that:

$$(a) \quad \omega_{ij} \geq 0 \text{ for cables } \{i, j\} \in E_-;$$

- (b) $\omega_{ij} \leq 0$ for struts $\{i, j\} \in E_+$; and
 (c) for each vertex i , $\sum_{\{j \mid \{i, j\} \in E\}} \omega_{ij}(p_j - p_i) = 0$.

Strict self-stress: A proper self-stress ω with the inequalities in (a) and (b) strict.

Underlying bar framework: For a tensegrity framework $G_{\pm}(p)$, the bar framework $G(p)$ on the unsigned graph $G = (V, E)$, where $E = E_- \cup E_0 \cup E_+$ (Figure 60.1.11A,B).

FIGURE 60.1.11

BASIC RESULTS

The equivalent definitions of “rigidity” and the basic connections between rigidity and first-order rigidity all transfer directly to tensegrity frameworks [RW81].

THEOREM 60.1.36 First-order Stress Test

A tensegrity framework $G_{\pm}(p)$ is first-order rigid if and only if the underlying bar framework $G(p)$ is first-order rigid and there is a strict self-stress on $G_{\pm}(p)$ (Figure 60.1.11A,B).

This connection to self-stresses means that any first-order rigid tensegrity framework with at least one cable or strut has $|E| > d|V| - \binom{d+1}{2}$ edges.

THEOREM 60.1.37 Reversal Theorem

A tensegrity framework $G_{\pm}(p)$ is first-order rigid if and only if the reversed framework $G_{\pm}^r(p)$ is first-order rigid, where the graph $G_{\pm}^r$ interchanges cables and struts (Figure 60.1.11A,C).

There is no single “generic” behavior for a signed graph $G_{\pm}$. If some configuration produces a first-order rigid framework for a graph $G_{\pm}$, then the set of all such configurations is open but not dense. The algebraic variety of “special positions” of the underlying unsigned graph divides the configuration space into open subsets, in some of which all configurations are rigid, and in others, none are. The required sign pattern for a self-stress can change as you cross such a boundary [WW83].

The first-order rigidity of a tensegrity framework is projectively invariant, with the proviso that a cable (strut) $\{i, j\}$ is switched to a strut (cable) whenever $\lambda_i \lambda_j < 0$ for the projective transformation.

THEOREM 60.1.38 *Stress Existence*

If a tensegrity framework $G_{\pm}(p)$ with at least one cable or strut is rigid, then there is a nonzero proper self-stress.

A number of results relate minima of quadratic energy functions to the rigidity of tensegrity frameworks. These energy results are not invariant under projective transformations, but such rigidity is preserved under “small” affine transformations. This is one result, drawn from results on second-order rigidity [CW96].

THEOREM 60.1.39 *Rigidity Stress Test*

A tensegrity framework $G_{\pm}(p)$ is rigid if, for each nontrivial first-order motion p' of $G_{\pm}(p)$, there is a proper self-stress $\omega^{p'}$ making $\sum_{ij} \omega_{ij}^{p'} (p'_i - p'_j) \cdot (p'_i - p'_j) > 0$.

A special result for modified frameworks—with some vertices fixed or pinned—further illustrates the role of tensegrity frameworks. A **spiderweb** is a partitioned graph $G_- = (V_0, V_1, E_-)$, with pinned vertices V_0 , with $E_- \cap V_1 \times [V_0 \cup V_1]$ and a configuration p for $V_0 \cup V_1$. A **spiderweb self-stress** for $G_-(p)$ is an assignment ω of nonnegative scalars to E_- such that for each unpinned vertex $i \in V_1$, $\sum_{\{j|\{i,j\} \in E_-\}} \omega_{ij} (p_j - p_i) = 0$. A **spiderweb flex** for $G_-(p)$ is a flex $p(t)$ of the induced tensegrity framework on the spiderweb, with all pinned vertices fixed ($p_k(t) = p_k$) (Figure 60.1.12).

FIGURE 60.1.12

THEOREM 60.1.40 *Spiderweb Rigidity*

Any spiderweb $G_-(p)$ in d -space with a spiderweb self-stress, positive on all cables, is rigid in d -space.

All critical points of functions of squared edge lengths correspond to proper self-stresses of a tensegrity framework, with members E_- for positive coefficients and E_+ for negative coefficients in the energy function. As a corollary, graph drawing programs (Chapter 52) that use minima (or critical points) of such energy functions will generate polyhedral pictures for planar graphs.

In the spiderweb energies, there is a global minimum of energy. This means that the configuration is globally rigid—no other realizations have the same edge lengths. In general, global rigidity has a distinct theory with some specific overlaps to the theory presented here.

Related to sphere packings (Chapter 61) are “reversed spiderwebs”: tensegrity frameworks with vertices at the centers of the spheres (fixed joints for external pressures or constraints) and struts when two spheres contact. Such strut frameworks are rigid (corresponding to locally maximal density of the packing) if and only if they are first-order rigid (again with vertices in V_0 fixed) [Con88].

60.2 SCENE ANALYSIS

The problem of reconstructing spatial objects (polyhedra or polyhedral surfaces) from a single plane picture is basic to several applications. This section summarizes the combinatorial results for “generic pictures” (Section 60.2.1). Section 60.2.2 presents a polar “parallel configurations” interpretation of the same abstract mathematics and Section 60.2.3 presents connections to other fields of discrete geometry.

60.2.1 COMBINATORICS OF PLANE POLYHEDRAL PICTURES

GLOSSARY

Polyhedral incidence structure S : An abstract set of *vertices* V , an abstract set of *faces* F and a set of *incidences* $I \subset V \times F$.

d -scene for an incidence structure $S = (V, F; I)$: A pair of location maps, $p : V \rightarrow \mathbb{R}^d$, $p_i = (x_i, \dots, z_i, w_i)$ and $P : F \rightarrow \mathbb{R}^d$, $P^j = (A^j, \dots, C^j, D^j)$, such that, for each $(i, j) \in I$: $A^j x_i + \dots + C^j z_i + w_i + D^j = 0$. (We assume that no hyperplane is vertical, i.e., is parallel to the vector $(0, 0, \dots, 0, 1)$.)

$(d-1)$ -picture of an incidence structure S : A location map $r : V \rightarrow \mathbb{R}^{d-1}$, $r_i = (x_i, \dots, z_i)$ (Figure 60.2.1A).

Lifting of a $(d-1)$ -picture $S(r)$: A d -scene $S(p, P)$ with vertical projection $\Pi(p) = r$ (Figure 60.2.1B). (I.e., if $p_i = (x_i, \dots, z_i, w_i)$, then $r_i = (x_i, \dots, z_i) = \Pi(p_i)$).

FIGURE 60.2.1

Lifting matrix for a picture $S(r)$: The $|I| \times (|V| + d|F|)$ coefficient matrix $M_S(r)$ of the system of equations for liftings of a picture $S(r)$: for each $(i, j) \in I$, $A^j x_i + \dots + C^j z_i + w_i + D^j = 0$, where the variables are ordered:

$$\dots, w_i, \dots ; \dots, A^j, \dots, C^j, D^j, \dots$$

Sharp picture: A $(d-1)$ -picture $S(r)$ that has a lifting $S(p, P)$ with a distinct hyperplane for each face (Figure 60.2.1A,B).

BASIC RESULTS

Since the incidence equations are linear, there is no distinction between “continuous liftings” and “first-order liftings.” Since the rank of the lifting matrix is determined

by a polynomial process on the entries, “generic properties” of pictures have several characterizations.

THEOREM 60.2.1 *Generic Pictures*

For a structure S and a dimension d , the following are equivalent:

- (a) the structure is generically sharp in d -space (an open dense subset of configurations r produce sharp d -pictures);
- (b) $S(r)$ is sharp for a configuration r with algebraically independent coordinates.

The generic properties of a structure are robust: all small changes in such a sharp picture are also sharp pictures and small changes in the points of a sharp picture require only small changes in the sharp lifting. Even special positions of such structures will always have nontrivial liftings, although these may not be sharp. However, up to numerical round-off, all pictures “are generic.” Other structures that are not generically sharp (Figure 60.2.2A) may have sharp pictures in special positions (Figure 60.2.2B), but a small change in the position of even one point can destroy this sharpness.

FIGURE 60.2.2

The incidence equations allow certain “trivial” changes to a lifted scene that will preserve the picture—generated by adding a single plane H^0 to all existing planes: $P_*^j = H^0 + P^j$; and by changes in vertical scale in the scene: $w_i^* = \lambda w_i$. This space of **lifting equivalences** has dimension $d+1$, provided the points of the scene do not lie in a single hyperplane.

THEOREM 60.2.2 *Picture Theorem*

A generic picture of an incidence structure $S = (V, F; I)$ with at least two faces has a sharp lifting, unique up to lifting equivalence, if and only if $|I| = |V| + d|F| - (d+1)$ and, for all subsets I' of incidences on at least two faces, $|I'| \leq |V'| + d|F'| - (d+1)$ (Figure 60.2.1A,C).

A generic picture of an incidence structure $S = (V, F; I)$ has independent rows in the lifting matrix if and only if for all nonempty subsets I' of incidences, $|I'| \leq |V'| + d|F'| - d$ (Figure 60.2.2A).

ALGORITHMS

Any part of a structure with $|I'| = |V'| + d|F'| - d$ independent incidences will be forced to be coplanar over a picture with algebraically independent coordinates for the points. If the structure is not generically sharp, then an effective, robust lifting algorithm consists of selecting a subset of vertices for which the incidences

are sharp, then “correcting” the position of the other vertices based on calculations in the resulting scene. This requires effective algorithms for selecting such a set of incidences. Sugihara and Imai have implemented $O(|I|^2)$ algorithms for finding generically sharp (independent) structures using modified bipartite matching on the incidence structure [Sug86].

60.2.2 PARALLEL DRAWINGS

The mathematical structure defined for polyhedral pictures has another, dual interpretation: the polar of a “point constrained by one projection” is a “hyperplane constrained by an assigned normal.” Two configurations sharing the prescribed normals are “parallel drawings” of one another. These geometric patterns, used by engineering draftsmen in the nineteenth century, have reappeared in a number of branches of discrete geometry. This dual interpretation also establishes a basic connection between the geometry and combinatorics of scene analysis and the geometry and combinatorics of first-order rigidity of frameworks.

GLOSSARY

Parallel d -scenes for an incidence structure: Two d -scenes $S(p, P)$, $S(q, Q)$ such that for each face j , $P^j \parallel Q^j$ (that is, the first $d-1$ coordinates are equal) (Figure 60.2.3). (For convenience, not necessity, we stick with the “nonvertical” scenes of the previous section.)

Nontrivially parallel d -scene for a d -scene $S(p, P)$: A parallel d -scene $S(q, Q)$, such that the configuration q is not a translation or dilatation of the configuration p (Figure 60.2.3B for $d=2$).

FIGURE 60.2.3

Directions for the faces: An assignment of d -vectors $D^j = (A^j, \dots, C^j)$ to $j \in F$.

d -scene realizing directions D : A d -scene $S(p, P)$ such that for each face $j \in F$, the first $d-1$ coordinates of P^j and D^j coincide.

Parallel drawing matrix for directions D in d -space: The $|I| \times (|V| + d|F|)$ matrix $M_S(D)$ for the system of equations for each incidence $(i, j) \in I$: $A^j x_i + B^j y_i + \dots + C^j z_i + w_i + D^j = 0$, where the variables are ordered:

$$\dots, D^j, \dots; \dots, x_i, y_i, \dots, z_i, w_i, \dots$$

BASIC RESULTS

All results for polyhedral pictures dualize to parallel drawings. Again, for parallel drawings there is no distinction between continuous changes and first-order changes. The trivially parallel drawings, generated by d translations and one dilatation towards a point, form a vector space of dimension $d + 1$, provided there are at least two distinct points (Figure 60.2.3A). (A trivially parallel drawing may even have all points coincident, though the faces will still have assigned directions (Figure 60.2.3A).)

THEOREM 60.2.3 *Parallel Drawing Theorem*

For generic selections of the directions D in d -space for the faces, a structure $S = (V, F; I)$ has a realization $S(p, P)$ with all points p distinct if and only if, for every nonempty set I' of incidences involving at least two points $V(I')$ and faces $F(I')$, $|I'| \leq d|V(I')| + |F(I')| - (d + 1)$ (Figure 60.2.3A).

In particular, a configuration p, P with distinct points realizing generic directions for the incidence structure is unique, up to translation and dilatation, if and only if $|I| = d|V| + |F| - (d + 1)$ and $|I'| \leq d|V'| + |F'| - (d + 1)$.

Of course other nontrivially parallel drawings will also occur if the rank is smaller than $d|V'| + |F'| - (d + 1)$ (Figure 60.2.3 B, with a generic rank 1 less than required for $d = 2$, and a geometric rank, as drawn, 2 less than required).

Figure 60.2.3 may also be interpreted as the parallel drawings of a “cube in 3-space.” For spherical polyhedra, there is an isomorphism between the nontrivially parallel drawings in 3-space (the parallel drawings modulo the trivial drawings) and the nontrivially parallel drawings in a plane projection [CW94]. Only the dimension (4 vs. 3) of the trivially parallel drawings will change with the projection.

60.2.3 CONNECTIONS TO OTHER FIELDS

FIRST-ORDER RIGIDITY

For any plane framework, if we turn the vectors of a first-order motion 90° (say clockwise), they become the vectors joining p to a parallel drawing q of the framework (Figure 60.2.4A,B). The converse is also true.

THEOREM 60.2.4

A plane framework $G(p)$ has a nontrivial first-order flex if and only if the configuration $G(p)$ has a nontrivially parallel drawing $G(q)$ (Figure 60.2.4C,D).

Because of this connection, combinatorial and geometric results for plane first-order rigidity and for plane parallel drawings have numerous deep connections. For example, Laman’s theorem (Theorem 60.1.12b) is a corollary of the parallel drawing theorem, for $d = 2$. In higher dimensions, the connection is one-way: a nontrivially parallel drawing of a “framework” (the “direction of an edge” is represented by $d - 1$ facets through the two points) induces one (or more) nontrivial first-order motions of the corresponding bar framework. The theory of parallel drawing in higher

FIGURE 60.2.4

dimensions is more complete and has simpler algorithms than the theory of first-order rigidity in higher dimensions, generalizing almost all results for plane first-order rigidity and plane parallel drawings, including combinatorial characterizations using counts, tree partitions, and inductive constructions of maximal independent sets.

MINKOWSKI DECOMPOSABILITY

By a theorem of Shephard, a polytope is decomposable as the Minkowski sum of two simpler polyhedra if and only if the faces and vertices of the polytope (or the edges and vertices of the polytope) have a nontrivially parallel drawing. Many characterizations of Minkowski indecomposable polytopes can be deduced directly from results for parallel d -scenes (or equivalently, for polyhedral pictures of the polar polytope).

ANGLES IN CAD

In plane computer-aided design, many different patterns of constraints (lengths, angles, incidences of points and lines, etc.) are used to design or describe configurations of points and lines, up to congruence or local congruence. With distances between points, the geometry becomes that of first-order rigidity. If angles and incidences are added, even the problems of “generic rigidity” of constraints are unsolved (and perhaps not solvable in polynomial time). However, special designs, mixing lengths, distances of points to lines, and trees of angles have been solved, using direct extensions of the techniques and results for plane frameworks and plane parallel drawings [SW99].

There is another connection between angles of intersections and rigidity. A recent manuscript [SW02] describes a correspondence between the first-order theory of circles of variable radius and intersection angles as constraints and distance constraints between points in Euclidean (and hyperbolic) 3-space, as well as spheres and angles in 3-space and points and distances in 4-space. As a result, the full complexity of distance constraints in 4-space is embedded inside general dimensioning in 3-space CAD. In general, geometric systems of constraints do not yield simple combinatorial counting algorithms of the type found for plane first-order rigidity.

60.3 RECIPROCAL DIAGRAMS

The reciprocal diagram is a single geometric construction that has appeared, independently over a 140-year span, in areas such as “graphical statics” (drafting techniques for resolving forces), scene analysis, and computational geometry.

GLOSSARY

Abstract spherical polyhedron $S = (V, F; \underline{E})$: For a 2-connected planar graph $G_S = (V, E_S)$, drawn without self-intersection on a sphere (or in the plane), we record the vertices as V and the regions as faces F , and rewrite the directed edges $\underline{E}$ as ordered 4-tuples $\underline{e} = \langle h, i; j, k \rangle$, where the edge from vertex h to vertex i has face j on the right and face k on the left. (The reversed edge $-\underline{e} = \langle i, h; k, j \rangle$ runs from i to h , with k on the right.)

FIGURE 60.3.1

Dual abstract spherical polyhedron: The abstract spherical polyhedron S^* formed by switching the roles of V and F , and switching the pairs of indices in each ordered edge $\underline{e} = \langle h, i; j, k \rangle$ into $\underline{e}^* = \langle j, k; i, h \rangle$. (Also the abstract spherical polyhedron formed by the dual planar graph $G^S = (F, E^S)$ of the original planar graph (Figure 60.3.1A,C).)

Proper spatial spherical polyhedron: An assignment of points $p_i = (x_i, y_i, z_i)$ to the vertices and planes $P^j = (A^j, B^j, D^j)$ to the faces of an abstract spherical polyhedron $(V, F; \underline{E})$, such that if vertex i and face j share an edge, then the point lies on the plane: $A^j x_i + B^j y_i + z_i + D^j = 0$; and at each edge the two vertices are distinct points and the two faces have distinct planes.

Projection of a proper spatial polyhedron $S(p, P)$: The plane framework $G_S(r)$, where r is the vertical projection of the points p (i.e., $r_i = \Pi p_i = (x_i, y_i)$) (Figure 60.3.2).

Gradient diagram of a proper spatial polyhedron $S(p, P)$: The plane framework $G^S(s)$, where $s_j = (A^j, B^j)$ is (minus) the gradient of the plane P^j (Figure 60.3.2).

Reciprocal diagrams: For an abstract spherical polyhedron S , two frameworks $G_S(r)$ and $G^S(s)$ on the graph and the dual graph of the polyhedron, such that for each directed edge $\langle h, i; j, k \rangle \in \underline{E}$, $(r_h - r_i) \cdot (s_j - s_k) = 0$ (Figure 60.3.1D,E).

BASIC RESULTS

Reciprocal diagrams have deep connections to both of our previous topics:

- (a) Given a spatial scene on a spherical structure, with no faces vertical, the vertical projection and the gradient diagram are reciprocal diagrams. (This follows because the difference of the gradients at an edge is a vector perpendicular to the vertical plane through the edge.)
- (b) Given a pair of reciprocal diagrams on $S = (V, F; E)$, then for each edge $\underline{e} = \langle h, i; j, k \rangle$ the scalars ω_{ij} defined by $\omega(r_h - r_i) = (s_j - s_k)^\perp$ (where $^\perp$ means rotate by 90° clockwise) form a self-stress on the framework $G_S(r)$. (This follows because the closed polygon of a face in $G^S(s)$ is, after $^\perp$, the vector sum for the “vertex equilibrium” in the self-stress condition.)

These facts can be extended to other oriented polyhedra and their projections. The real surprise is that, for spherical polyhedra, the converses hold and all these concepts are equivalent (an observation dating back to Clerk Maxwell and the drafting techniques of graphical statics).

FIGURE 60.3.2

THEOREM 60.3.1 *Maxwell's Theorem*

For an abstract spherical polyhedron $(V, F; \underline{E})$, the following are equivalent:

- (a) The framework $G_S(r)$, with the vertices of each edge distinct, has a self-stress nonzero on all edges;
- (b) $G_S(r)$ has a reciprocal framework $G^S(s)$ with the vertices of each edge distinct;
- (c) $G_S(r)$ is the vertical projection of a proper spatial polyhedron $S(p, P)$;
- (d) $G_S(r)$ is the gradient diagram of a proper spatial polyhedron $S^*(q, Q)$.

There are other refinements of this theorem, that connect the space of self-stresses of $G_S(r)$ with the space of parallel drawings (and first-order flexes) of $G^S(s)$, the space of polyhedra $S(p, P)$ with the same projection, and the space of

parallel drawings of $S^*(q, Q)$ [CW94] (Figure 60.3.2). A second refinement connects the local convexity of the edge of the polyhedron with the sign of the self-stress.

THEOREM 60.3.2 *Convex Self-stress*

The vertical projection of a strictly convex polyhedron, with no faces vertical, produces a plane framework with a self-stress that is < 0 on the boundary edges (the edges bounding the infinite region of the plane) and > 0 on all edges interior to this boundary polygon.

A plane Delaunay triangulation also has a basic “reciprocal” relationship to the plane Voronoi diagram: the edges joining vertices at the centers of the regions are perpendicular to edges of the polygon of the Voronoi regions surrounding the vertex. This pair of reciprocals is directly related to the projection of a spatial convex polyhedral cap, as are generalized Voronoi diagrams. See Section 23.1.

This pattern of “reciprocal constructions” and the connection to liftings to polytopes in the next dimension generalizes to higher dimensions [CW94]. For example, for Voronoi diagrams and Delaunay simplicial complexes, the edges of one are perpendicular to facets of the other, in all dimensions. Moreover, for appropriate sphere-like homology, the existence of a reciprocal corresponds to the existence of nontrivial liftings [CW94, ERR01, Ryb99]. Such geometric structures are also related to k -rigidity and to combinatorial proofs of the g -theorem in polyhedral combinatorics [TW00]. Finally, [BGH02] makes a related connection between parallel drawings and group actions on complex manifolds.

60.4 SOURCES AND RELATED MATERIALS

SURVEYS AND BASIC SOURCES

All results not given an explicit reference can be traced through these surveys:

[CW96]: A presentation of basic results for concepts of rigidity between first-order rigidity and rigidity for tensegrity frameworks.

[CW]: A thorough introduction to a number of topics on the rigidity of frameworks, in manuscript form only.

[GSS93]: A monograph devoted to combinatorial results for the graphs of generically rigid frameworks, with an extensive bibliography on many aspects of rigidity.

[Ros00]: A recent thesis that explores in depth both topics of this chapter and their connections.

[Sug86]: A monograph on the reconstruction of spatial polyhedral objects from plane pictures.

[Whi93]: A survey of results relating first-order rigidity to matroid theory and related matroids for scene analysis, and to multivariate splines.

[Whi96]: An expository article presenting matroidal aspects of first-order rigidity, scene analysis, and multivariate splines.

61 SPHERE PACKING AND CODING THEORY

G.A. Kabatiansky and J.A. Rush

INTRODUCTION

Consider a metric space equipped with some measure (natural in all examples) in which all balls of the same radius have the same “volume” (measure). A set of metric balls of the same radius is called a sphere packing if the intersection of any two balls has measure zero. In the case where the space has finite measure the density of a sphere packing is defined as the ratio of the measure of the union of the balls to the measure of the whole space. In the other case one can consider some natural “large subspace” of the space, such as a ball of large radius, and define the density of a sphere packing as the limit of the ratio of the corresponding volumes. The most famous instance of this problem is sphere packing in Euclidean n -dimensional space, where one asks how densely it is possible to fill $\mathbb{R}^n$ with nonoverlapping balls of a fixed (and by homogeneity, irrelevant) radius.

In posing a code-theoretic analogue to the previous question, one specifies a finite alphabet A of q elements and a metric $d(x, y)$ on the set A^n of q -ary n -tuples; often d is the Hamming metric, and A^n is then called the Hamming space. One then asks for the size $A_q(n, d)$ of a maximal subset (code) of A^n for which any two points are at distance at least d apart. For $d = 2t + 1$, in particular, this is equivalent to finding the largest sphere packing (of radius t) in the Hamming space.

One frequently requires the centers of a sphere packing in $\mathbb{R}^n$ to form a lattice. The analogous code-theoretic requirement is that the centers be not merely a *subset* but more stringently a *subspace*, i.e., that the codes be *linear*.

In Section 61.1 we consider sphere packing, and in Section 61.2 we consider sphere packing in connection with spherical codes. We look at error-correcting codes (including nonlinear codes and codes in metrics other than the Hamming) in Section 61.3, and at the construction of sphere packings, as well as packings of more general bodies, from error-correcting codes, in Section 61.4.

61.1 SPHERE PACKING AND QUADRATIC FORMS

SPHERE PACKING IN $\mathbb{R}^n$

The word “sphere,” as used in packing theory, usually denotes a solid ball. This is in contrast to the usage in the rest of mathematics, where “sphere” almost always refers to the outer surface alone. For historical reasons, the subject seems destined always to be called “sphere packing,” even though the terms “sphere” and “ball” are interchangeable within the sphere-packing literature.

GLOSSARY

The **ball of radius r** around the origin is

$$B^n(r) = \{x = (x_1, \dots, x_n) \in \mathbb{R}^n \mid x_1^2 + \dots + x_n^2 \leq r^2\}.$$

Its volume is $V_n r^n$, where

$$V_n = \int_{x \in B^n} dx_1 \cdots dx_n = \frac{2^n \Gamma(\frac{n+1}{2}) \pi^{(n-1)/2}}{\Gamma(1+n)} = \frac{\pi^{n/2}}{\Gamma(1+n/2)}$$

is the volume of a unit ball $B^n = B^n(1)$.

Sphere packing: An arrangement of balls of the same radius, whose interiors are disjoint.

Lattice: The integral span of a basis of $\mathbb{R}^n$. Equivalently, a nonsingular linear transform of the points $\mathbb{Z}^n$ with integer coordinates.

Lattice packing of spheres: The centers of the balls in the packing are all the points of a lattice.

Density of a sphere packing: Let $\overline{P}$ be the union of balls in the packing P . The density of P is

$$\delta(P) = \lim_{r \rightarrow \infty} \frac{\text{Vol}(\overline{P} \cap B^n(r))}{V_n r^n}.$$

Maximum packing density of the sphere: This is $\delta(n) = \sup \delta(P)$, where the supremum is over packings P of B^n .

Determinant of a lattice: The volume of the parallelepiped spanned by a basis for the lattice Λ , written $\det \Lambda$; it is independent of the basis. (Some authors call the determinant of a lattice the *square* of that volume. We refer to the squared volume as the **determinant of the quadratic form associated with the lattice**; see below.)

Density of a lattice packing of spheres: If the minimum distance between points of the lattice Λ is $2r$, then Λ provides a packing for balls of radius r , and its density is $\delta(\Lambda) = V_n r^n / \det \Lambda$.

Maximum lattice-packing density of the sphere: The quantity $\delta_L(n) = \sup \delta(\Lambda)$, the supremum being taken over lattice packings of B^n .

The **center density** $\delta^*(P)$ of a packing P is $\delta(P)/V_n$, the number of ball centers per unit volume of space when the minimum distance between the centers is normalized to 2. Analogously, $\delta^*(n) = \sup \delta^*(P) = \delta(n)/V_n$ and $\delta_L^*(n) = \delta_L(n)/V_n$.

The main problem in the theory of sphere packing is the determination of the quantities δ and δ_L in a given dimension n . Dense packing was Problem 18 of Hilbert's famous problem list [Hil01]. Some authors express results in terms of center density $\delta^*(n)$ instead, or in terms of $\log_2 \delta^*(n)$.

QUADRATIC FORMS IN n VARIABLES

GLOSSARY

Quadratic form associated with a lattice: If a lattice Λ is the integral span of the vectors $\mathbf{l}_1, \dots, \mathbf{l}_n$, which are the rows of the $n \times n$ matrix $L = (l_{ij})$, then this is the positive definite quadratic form

$$f_L(x_1, \dots, x_n) = \left(\sum_{i=1}^n x_i \mathbf{l}_i, \sum_{i=1}^n x_i \mathbf{l}_i \right) = \sum_{i,j=1}^n a_{ij} x_i x_j,$$

where $A = (a_{ij}) = LL^T$. (Here T means transpose.) The symmetric positive definite matrix A is called an **inner product matrix** for the lattice Λ , and $\det f = \det A$ is the determinant of the quadratic form associated with the lattice.

The **arithmetic minimum** of the positive definite quadratic form $f(x_1, \dots, x_n)$ is $M(f)$ = the smallest value taken on by f on $\mathbb{Z}^n \setminus \{O\}$.

Hermite's constant is $\gamma_n = \sup(M(f)/\sqrt[n]{\det f})$, the supremum taken as f varies over positive definite quadratic forms in n variables.

If $M(f)/\sqrt[n]{\det f} = \gamma_n$, then f is called **absolutely extreme**.

Hermite's constant is related to the maximum center lattice-packing density of a sphere by

$$\left(\frac{\sqrt{\gamma_n}}{2} \right)^n = \delta_L^*(n).$$

Thus, the geometric problem of finding the densest lattice packing of a sphere is equivalent to the number-theoretic problem of maximizing the arithmetic minimum of a positive definite quadratic form of fixed determinant. This well-known equivalence is often unstated; papers on arithmetic minima frequently don't mention sphere packing, and vice versa. The historical trend is toward stating results in terms of sphere packing.

LAMINATED LATTICES

Define Λ_0 as the trivial lattice consisting of one point. For $n = 1, 2, 3, \dots$, we understand a **laminated lattice** Λ_n to be any n -dimensional lattice with these three properties: First, its minimum distance is 2. Second, some Λ_{n-1} is a sublattice. And third, Λ_n has minimal determinant among lattices satisfying the first two conditions.

Notice that it is not apparent from the definition how many laminated lattices there are. It turns out that there are two Λ_{11} 's, three Λ_{12} 's, and three Λ_{13} 's. For all the other values of n in $0 \leq n \leq 24$, there is exactly one Λ_n . There are exactly 23 different Λ_{25} 's, and for $n \geq 26$ there are probably a great many.

The **Leech lattice**, Λ_{24} , has a profound influence on all smaller dimensions, and indeed all of the closest lattice packings of spheres that have been found to date are sections of the Leech lattice. These dense lattices are the lattices Λ_n for $1 \leq n \leq 24$ excepting $n = 11, 12, 13$, for which there are denser cross sections of Λ_{24} , called K_{11} , K_{12} , and K_{13} in [CS99].

It seems reasonable to consider the dimensions up to 24 separately.

DIMENSIONS UP TO 24

The values of $\delta_L(n)$ are known (i.e., proved) in dimensions $n \leq 8$, and conjectured with modest conviction in dimensions $9 \leq n \leq 24$. It is a theorem due to Thue [Thu10] that $\delta_L(2) = \delta(2) = \pi/\sqrt{12}$. This is the density of the usual hexagonal packing of circles in the plane, shown in [Figure 61.1.1](#).

FIGURE 61.1.1
Closest packing of circles in the plane.

Gauss proved that $\delta_L(3) = \pi/\sqrt{18} = .7404\dots$. This is the density of the so-called **face-centered cubic lattice**, shown in Figure 61.1.2, which is generated by three equal vectors, each of which makes an angle of $\pi/3$ with the other two. For almost four centuries the Kepler Conjecture that $\delta(3) = \delta_L(3) = \pi/\sqrt{18}$ remained open.¹ The Rogers bound gives $\delta(3) \leq .7796\dots$, which was improved by Lindsey [Lin86] $\delta(B^3) \leq .7784$ and then by Muder [Mud93], who found that $\delta(B^3) \leq .773055\dots$. Finally, the Kepler Conjecture was proved by Hales in 1998 (see his nicely written overview [Hal00])

FIGURE 61.1.2
The densest lattice packing of spheres in three dimensions, which is also the densest packing.

It is interesting to see when the best known value of $\delta(n)$ is bigger than $\delta_L(n)$ for $n \leq 24$ (see Table 61.1.1.). The recent progress in constructing nonlattice packings denser than lattice ones started from Vardy’s 20-dimensional packing [Var95]. Immediately afterward, Conway and Sloane [CS96] found that Vardy’s nonlattice packing had analogues in dimension 22 (and dimensions 44 through 47), which also set new density records.

TABLE 61.1.1 Comparison of known values of δ^* and δ_L^* .

DIMENSION n	$\delta_L^*(n)$	$\delta^*(n)$	δ/δ_L
10	$\frac{1}{16\sqrt{3}}$	$\frac{5}{128}$	1.08523
11 and 13	$\frac{1}{18\sqrt{3}}$	$\frac{9}{256}$	1.09696
18	$\frac{1}{8\sqrt{3}}$	$\frac{3^9}{4^9}$	1.04040
20	$\frac{1}{8}$	$\frac{7^{10}}{2^{31}}$	1.05230
22	$\frac{1}{2\sqrt{3}}$	$\frac{11^{11}}{2^{23}3^{10}\sqrt{3}}$	1.15198

¹Generating the famous joke that “all physicists KNOW and all mathematicians BELIEVE that...”

The densest lattice packings known in dimensions up to $n = 10$ can be obtained from their predecessors merely by adjoining a new basis vector of the same length as all the others. Unfortunately the 11-dimensional dense lattice is not obtainable in this way; one must start from scratch.

Let $A = (a_{ij})$ be the following ten-by-ten matrix:

$$\begin{pmatrix} 4 & 2 & 2 & 0 & 0 & 2 & 0 & 0 & 0 & 0 \\ 2 & 4 & 2 & 2 & 2 & 2 & 0 & 0 & 0 & 0 \\ 2 & 2 & 4 & 2 & 2 & 2 & 0 & 0 & 0 & 0 \\ 0 & 2 & 2 & 4 & 2 & 2 & 0 & 0 & 0 & 1 \\ 0 & 2 & 2 & 2 & 4 & 2 & 0 & 0 & 0 & 1 \\ 2 & 2 & 2 & 2 & 2 & 4 & 2 & 2 & 1 & 2 \\ 0 & 0 & 0 & 0 & 0 & 2 & 4 & 2 & 2 & 1 \\ 0 & 0 & 0 & 0 & 0 & 2 & 2 & 4 & 2 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 2 & 2 & 4 & 1 \\ 0 & 0 & 0 & 1 & 1 & 2 & 1 & 1 & 1 & 4 \end{pmatrix}.$$

Our ability to build by adding fixed-length basis vectors through dimension ten is reflected algebraically in a property of this quadratic form due to Chaundy [Cha46]:

$$\begin{aligned} f(x_1, \dots, x_{10}) &= \sum_{i,j=1}^{10} a_{ij} x_i x_j \\ &= 2(x_2 + x_3 + x_4 + x_5 + \tfrac{1}{2}x_6)^2 + 2(x_1 + x_2 + \tfrac{1}{2}x_6)^2 + 2(x_1 + x_3 + \tfrac{1}{2}x_6)^2 \\ &\quad + 2(x_4 + \tfrac{1}{2}x_6 + \tfrac{1}{2}x_{10})^2 + 2(x_5 + \tfrac{1}{2}x_6 + \tfrac{1}{2}x_{10})^2 + 2(x_7 + \tfrac{1}{2}x_6 + \tfrac{1}{2}x_{10})^2 \\ &\quad + 2(x_8 + \tfrac{1}{2}x_6 + \tfrac{1}{2}x_{10})^2 + 2(x_7 + x_8 + x_9 + \tfrac{1}{2}x_6)^2 + 2(x_9 + \tfrac{1}{2}x_{10})^2 + \tfrac{3}{2}x_{10}^2. \end{aligned}$$

The property is that

$$g(x_1, \dots, x_i) = f(x_1, \dots, x_i, 0, \dots, 0)$$

is an absolutely extreme quadratic form in i variables for $1 \leq i \leq 8$, and very probably is one for $i = 9, 10$ as well. Thus each new inner product matrix can be obtained from the previous one by adding a new column to the right, and its transpose to the bottom, of the previous matrix.

Although it is not possible to get past $n = 10$ in the manner described above, it is nonetheless possible, as stated in the previous section, to obtain all the best lattice packings known up to $n = 24$ by taking intersections of the 24-dimensional Leech lattice Λ_{24} (to be constructed in Section 61.4) with certain subspaces. Moreover, the highest known center densities attained for lattice packings of B^n are symmetric about $n = 12$. Let us write $\xi(x)$ for the reciprocal of the presumably optimal center density for a lattice in dimensions $12 \pm x$ for $0 \leq x \leq 12$. Its values are summarized in [Table 61.1.2](#).

DIMENSIONS UP TO 2048

The best packings known in these dimensions are still fairly good, but less likely to be optimal than those of lower dimension. (See [Table 61.1.3](#).) The success in these dimensions is due to the residual influences of combinatorial accidents such as the

TABLE 61.1.2 Reciprocal center densities of the densest known lattice packings of B^n in dimensions up to 24.

61.2 SPHERICAL CODES AND GENERAL BOUNDS ON SPHERE-PACKING DENSITY

PACKING IN THE UNIT SPHERE, OR SPHERICAL CODES

Consider the unit sphere S^n in $(n+1)$ -dimensional Euclidean space $\mathbb{R}^{n+1}$ as a metric space with angular distance (the Riemann sphere) and its packing by metric balls of “radius” φ , i.e., by spherical caps of angular radius φ . The centers of any such packing form a so-called **spherical code** C with minimal angular distance 2φ (in brief, a 2φ -spherical code), since the angle between any two distinct points of C is at least 2φ . The **density** of a packing C with caps of angular radius φ is defined as $\sigma_n^{-1}|C|\sigma_n(\varphi)$, where

$$\sigma_n(\varphi) = (\sin \varphi)^n \sigma_{n-1} \int_0^1 \frac{x^{n-1} dx}{\sqrt{1 - x^2 \sin^2(\varphi)}}$$

is the measure of a cap of angular radius φ and $\sigma_n = 2\sigma_n(\pi/2) = (n+1)V_{n+1}$ is

the measure of the surface of S^n . Let $M(n, \varphi)$ be the largest possible cardinality of a φ -spherical code and

$$\delta(n, \varphi) = \frac{M(n, 2\varphi)\sigma_n(\varphi)}{\sigma_n}$$

be the largest possible packing density in S^n with caps of angular radius φ . There is a natural relationship between dense sphere packing in Euclidean space and packing in the sphere, namely,

$$\delta(n) = \lim_{\varphi \rightarrow 0} \delta(n, \varphi).$$

The value $\tau(n) = M(n-1, \pi/3)$ is known as the **kissing**, or **contact number**, and equals the maximal number of equal spheres in $\mathbb{R}^n$ that touch one sphere of the same radius without overlapping. For 3-dimensional space it was the subject of discussion between Newton ($\tau(3) := 12$) and Gregory ($\tau(3) := 13$) at the end of the 17th century. Spherical codes also have many applications in communications as sets of signals for various modulation schemes.

For $\varphi \geq \pi/2$ the problem of spherical codes (or packing of caps in S^n) is solved completely, due to the following **Rankin upper bounds** [Ran55]:

$$M(n, \varphi) \leq -\frac{1 - \cos \varphi}{\cos \varphi}, \quad \text{if } \cos \varphi < 0$$

$$M(n, \varphi) \leq 2(n+1) \frac{1 - \cos \varphi}{1 - (n+1) \cos \varphi}, \quad \text{if } \cos \varphi < 1/(n+1),$$

which show that the regular simplex on $n+1$ vertices ($i = 1, \dots, n+1$) and the set of vertices of the octahedron $\{\pm \mathbf{e}_i\}$ are optimal spherical codes.

Hence, for $\varphi \geq \pi/2$ it is not possible to arrange more than a linear number of points (in fact, not more than $2(n+1)$) on S^n in such a way that the angle between any two points is at least φ . However, for any fixed $\varphi < \pi/2$ one can specify exponentially many points on S^n with the desired property. Indeed, any optimal φ -spherical code is at the same time a covering of S^n by caps of angular radius φ . Since the density of any covering is at least 1 it follows that [Sha59]

$$M(n, \varphi) \geq \sigma_n / \sigma_n(\varphi) > (\sin \varphi)^{-n} \quad \text{for } \varphi < \pi/2,$$

or, equivalently,

$$n^{-1} \log M(n, \varphi) \geq -\log \sin \varphi.$$

On the other hand, upper bounds of Rankin and Coxeter state that

$$n^{-1} \log M(n, \varphi) \leq -\log \sin(\varphi/2) - 0.5 + o(1).$$

The best known asymptotic bound (the KL bound [KL78]) was obtained by establishing a deep relationship between the size of a spherical code (and its combinatorial properties—see [Lev98]), on the one hand, and zonal spherical functions of $SO(n+1)$, on the other hand.

It follows from the theory of group representations that a continuous and invariant (under the action of the group $SO(n+1)$) kernel $F(x, y)$ is positive semidefinite (or nonnegative definite), i.e.,

$$F(x, y) = f((x, y)) = a_0 + \sum_{i=1}^N u_i(x)u_i(y), \quad a_0 > 0$$

if and only if

$$f(t) = \sum_{i=0} f_i C_i^m(t),$$

where $f_i \geq 0$ for all $i \geq 1$, $f_0 > 0$, $m = (n-1)/2$, and

$$C_i^m(t) = \sum_{j=0}^{i/2} (-1)^j \binom{i-j}{j} \binom{i-j+m-1}{i-j} (2t)^{i-2j}$$

are the **Gegenbauer**, or **ultraspherical polynomials**. Consider a polynomial $f(t)$ with the following properties:

1) $f_0 > 0$ and $f_i \geq 0$ for all $i \geq 1$;

2) $f(t) \leq 0$ for $-1 \leq t \leq \cos \varphi$.

Then for an arbitrary φ -spherical code C we have

$$S = \sum_{x,y \in C} f((x,y)) = f_0 |C|^2 + \sum_i \sum_{x \in C} |u_i(x)|^2 \geq f_0 |C|^2.$$

On the other hand,

$$S = \sum_{x=y \in C} f((x,y)) + \sum_{x \neq y \in C} f((x,y)) \leq |C| f(1).$$

Hence we obtain the following inequality, often called the **linear programming bound** (see [CS99]):

$$M(n, \varphi) \leq f(1)/f_0.$$

The optimal choice of polynomial $f(t)$ is an open problem. With the polynomial

$$f(t) = (C_{k+1}^m(t) C_k^m(s) - C_k^m(t) C_{k+1}^m(s))^2 / (t-s)$$

it was shown in [KL78] that

$$M(n, \varphi) \geq 4 \binom{k+n-1}{k} (1 - \xi_{k+1}^{(m)})^{-1} \quad \text{if} \quad \cos \varphi < \xi_k^{(m)},$$

where $\xi_k^{(m)}$ is the largest root of $C_k^m(t)$ on $(-1, +1)$, $m = (n-1)/2$. Then the asymptotic formula for $\xi_k^{(m)}$ [KL78] leads to the aforementioned **KL bound**:

$$n^{-1} \log M(n, \varphi) \leq \frac{1 + \sin \varphi}{2 \sin \varphi} \log \left(\frac{1 + \sin \varphi}{2 \sin \varphi} \right) - \frac{1 - \sin \varphi}{2 \sin \varphi} \log \left(\frac{1 - \sin \varphi}{2 \sin \varphi} \right) + o(1).$$

Since

$$(\sin(\varphi/2))^n M(n, \varphi) \leq (\sin(\theta/2))^n M(n, \theta) \quad \text{for} \quad \varphi < \theta,$$

the KL bound can be improved to

$$n^{-1} \log M(n, \varphi) \leq -\log \sin(\varphi/2) - 0.599 + o(1)$$

for $\varphi \leq \varphi^*$, where $\varphi^* \approx 63$ is the root of $\cos \varphi (\ln(1 + \sin \varphi) - \ln(1 - \sin \varphi)) + (1 + \cos \varphi) \sin \varphi = 0$.

For the particular case of the kissing number ($\varphi = \pi/3$), the lower and upper bounds have the following form:

$$1 - \frac{\log_2 3}{2} + o(1) = 0.2075... + o(1) \leq n^{-1} \log_2 \tau(n) \leq 0.401 + o(1).$$

Let us note that it is unknown if the kissing number $\tau_L(n)$ for lattices can be exponentially large. The best known result is that $\tau_L(n) \geq 2^{\Omega(\log^2(n))}$. On the other hand, Alon [Alo97] has constructed, on the basis of error-correcting codes, a finite packing of balls in $\mathbb{R}^n$ whose minimum kissing number is at least $2\sqrt{n}$. It follows from the recent result [ABV01] that the corresponding algebro-geometric codes form a finite packing of balls in which every ball touches the same number, $2^{\Omega(n)}$, of “neighbors,” and this construction can be easily extended to an infinite packing of balls with the same property.

A better choice of polynomials was found by Levenshtein [Lev79]. The corresponding polynomial of odd degree (a simpler case) has the following form:

$$f_{2k-1}^{(s)} = (t-s) \left(\sum_{i=0}^{k-1} r_i (P_k(s) - P_i(s)) P_i(t) \right)^2,$$

where $P_i(t) = C_i^m(t)/C_i^m(1)$, $m = (n-1)/2$, and $r_i = \binom{i+n-1}{i} + \binom{i+n-2}{i-1}$. With these polynomials it was shown [Lev79] that

$$M(n, \varphi) \leq 2 \binom{k+n-1}{k-1} \quad \text{if} \quad \cos \varphi < \xi_{k-1}^{(m+1)}.$$

Despite the fact that these bounds are asymptotically the same as the KL bound, they are always (also for k even) better than those coming from [KL78], and enable one to prove the optimality or asymptotic optimality of some known packings in the sphere. First of all, these bounds led [Lev83] to the first two infinite families of spherical codes that are asymptotically optimal (by cardinality for a given angle φ). Both families are constructed from known binary error-correcting codes (see Section 61.3) by embedding them into S^{n-1} via the mapping $X_i = (-1)^{x_i} n^{-1/2}$. The first family is based on the well-known Kerdock codes (see [MS78]) and yields the following parameters: $n = 2^{2l}$, $M = n^2$, $\cos \varphi = n^{-1/2}$. The second family, based on the Sidelnikov codes [Sid71], has the parameters $n = (2^{4l} - 1)/(2^l + 1)$, $M = 2^{4l} \approx n^{4/3}$, $\cos \varphi = n^{-2/3}$.

The most impressive results derived from these bounds are for the kissing numbers, where it was proved independently [Lev79, OS79] that $\tau_8 = 240$ (achieved on the lattice E_8) and $\tau_{24} = 196560$ (achieved on the Leech lattice Λ_{24}). There are also eleven other examples (see Chapter 2) of point arrangements on the unit sphere S^n (for rather small $n \leq 23$) whose optimality follows from the new bounds. It is worth mentioning that these bounds give an analytic proof that the maximal value of the minimal separation angle for 12 points on S^2 is $\arccos 1/\sqrt{5}$.

GENERAL BOUNDS ON SPHERE-PACKING DENSITY

Clearly $\delta(n) \geq \delta_L(n)$. It was shown elegantly by K.M. Ball [Bal93] that

$$\delta_L(n) \geq (n-1)2^{1-n}\zeta(n).$$

The right-hand side is $2^{-n(1+o(1))}$ for large n , and bounds of that form have been known for a long time [Min69]. Note that the simple observation that any maximal packing of spheres should be a covering by spheres of twice larger radius immediately leads to $\delta(n) \geq 2^{-n}$. Ball's result was a refinement, for spheres, of the **Minkowski-Hlawka bound** [Hla43],

$$\delta_L(G) \geq 2^{1-n}\zeta(n),$$

which is applicable to all compact, convex, O -symmetric bodies G . In the other direction, Yaglom's inequality allows us to "transform" upper bounds on the size $M(n, \varphi)$ of spherical codes into an upper bound on $\delta(n)$. This states that

$$\delta(n) \leq \left(\sin \frac{\varphi}{2}\right)^n M(n, \varphi) \quad \text{for } 0 < \varphi < \pi/2.$$

For $\varphi = \pi/3$ this inequality can be slightly strengthened: $\delta(n) \leq 2^{-n} \tau(n)$. Then an application of the improved KL bound, or, in particular, the upper bound for the kissing numbers, gives the **Kabatiansky-Levenshtein bound** [KL78]

$$\delta(n) \leq 2^{-(.599\dots)n(1+o(1))}.$$

For $n \leq 42$, the Kabatiansky-Levenshtein bound is not as good as the **Rogers bound** [Rog64], which is given by $\delta(n) \leq \eta_n$, where η_n is the fraction of a solid regular simplex of edge 2 in R^n that is covered by the $n+1$ unit balls centered at its vertices. The quantity η_n is bounded above by

$$\frac{n^{\frac{n+3}{2}} \sqrt{\pi} 2^{u-n}}{e^{1+\frac{n}{2}} \Gamma(1 + \frac{n}{2})},$$

where $u \leq 21/(4n+10)$. For large n , we have $\eta_n = (n/e)2^{-n/2}(1+o(1))$.

61.3 ERROR-CORRECTING CODES

Known results on constructions of error-correcting codes mostly address the case where the size q of the alphabet A is a power of a prime; in this case A will be considered below as a finite field $\mathbb{F}_q$, unless otherwise specified.

GLOSSARY

A **q -ary n -dimensional Hamming space** $\mathbb{H}_q^n$ is the set of n -tuples over a q -ary alphabet A with the **Hamming distance** $d(x, y)$ defined as the number of positions where x and y are distinct.

The **volume (cardinality) of the ball of radius t** around a point $a \in \mathbb{H}_q^n$ equals $V_n(t; q) = \sum_{j=0}^t \binom{n}{j} (q-1)^j$.

A **q -ary code of length n** is a subset of H_q^n . Elements of the code are called **codewords**. **Binary codes** have $q = 2$.

The **(minimum) Hamming distance** $d(C)$ of a code C is the minimum of $d(x, y)$ for $x \neq y \in C$. Hence, a code with Hamming distance $d(C) \geq 2t+1$ is the same as a packing of balls of radius t in the Hamming space. In other words, a code C can correct t errors iff $d(C) \geq 2t+1$. $A_q(n, d)$ denotes the maximum possible cardinality of a code C with $d(C) \geq d$.

A **q -ary linear $[n, k]$ -code** is a k -dimensional subspace of $\mathbb{F}_q^n$. An $[n, k]$ -linear code C can be conveniently described by the generator $k \times n$ -matrix G_C whose columns form a basis of C , or by a parity-check $(n-k) \times n$ -matrix H_C whose columns form a basis of the dual space $C^\perp$. Any s columns of H_C are linearly independent iff $d(C) \geq s+1$. Hence, $d(C) \leq n-k+1$ for any linear $[n, k]$ -code C (the **Singleton bound**).

The **Hamming code** has length $n = (q^m - 1)/(q - 1)$, where q is a prime power and $m = 2, 3, \dots$, and is defined by a parity-check $(n - m) \times n$ -matrix whose columns are all $(q^m - 1)/(q - 1)$ noncollinear vectors of $\mathbb{F}_q^m$ (i.e., all points of $(m-1)$ -dimensional projective space over $\mathbb{F}_q$). A Hamming code has distance $d \geq 3$ (in fact, equal to 3) since any two columns of its parity-check matrix are linearly independent.

Density of a sphere packing in a Hamming space: Let C be a sphere packing in $\mathbb{H}_q^n$ of radius t , i.e., a code with distance $d(C) \geq 2t + 1$. The density of C is $\delta(C) = |C|V_q(t, n)/q^n$. The maximum packing density in the Hamming space is $\delta_q(n, t) = A_q(n, 2t + 1)V_q(t, n)/q^n$.

The obvious inequality $\delta(C) \leq 1$ is known in coding theory as the **Hamming bound**. In contradistinction to Euclidean space, there are sphere packings with density 1 in a Hamming space. Such packings (codes) are called **perfect codes**. There are only two perfect codes with $t > 1$, namely the binary and ternary Golay codes (see below). For $t = 1$ and q a prime power, the known perfect codes include the infinite family of q -ary Hamming codes (see [MS78]).

It is an open question whether packings of radius $t = 1$ with density 1 in a Hamming space (i.e., perfect single-error correcting codes) exist in the case where q is not a prime power.

For x real we write $\binom{x}{j} = x(x-1)(x-2)\cdots(x-j+1)/(j!)$ and define the **Krawtchouk polynomial**

$$K_k^{(n)}(x) = \sum_{j=0}^k (-1)^j \binom{x}{j} \binom{n-x}{k-j} (q-1)^{k-j}.$$

The role of Krawtchouk polynomials in a Hamming space is analogous to that of Gegenbauer polynomials in Euclidean space

CYCLIC CODES

GLOSSARY

Let $\mathbb{F}_q[x]$ be the ring of polynomials in x with coefficients in $\mathbb{F}_q$ and $\mathbb{F}_q[x]/\langle x^n - 1 \rangle$ be its quotient ring modulo $x^n - 1$. It is convenient to identify a vector $\mathbf{a} = (a_0, \dots, a_{n-1})$ in $\mathbb{F}_q^n$ with a polynomial $a(x) = a_0 + a_1x + \cdots + a_{n-1}x^{n-1}$ in $\mathbb{F}_q[x]/\langle x^n - 1 \rangle$. Then the polynomial $xa(x)$ corresponds to a cyclic shift of the vector $\mathbf{a}$. Let $g(x) \in \mathbb{F}_q[x]$ divide $x^n - 1$. The ideal $\langle g(x) \rangle$ in $\mathbb{F}_q[x]/\langle x^n - 1 \rangle$ is called a **cyclic code** since all its vectors are invariant under the cyclic shifts. It has **length** n and **dimension** $k = n - \deg g$. The polynomial $g(x)$ is called the **generator polynomial** of the code.

Let $n = (q^m - 1)/(q - 1)$ and let β be a primitive n th root of unity in $GF(q^m)$. Assume that m and $q - 1$ are relatively prime. Let $g(x) \in GF(q)[x]$ be the minimal polynomial of β . Then the ideal $\langle g(x) \rangle$ is equivalent to a **Hamming code** in the sense that one code can be obtained from the other by applying a fixed permutation to each codeword.

Let α be a primitive n th root of unity in some extension field $\mathbb{F}_{q^m}$ of $\mathbb{F}_q$. Consider the generator polynomial $g(x)$ that has roots $\alpha^L, \alpha^{L+1}, \alpha^{L+2}, \dots, \alpha^{L+s-2}$ and is such that $g(x)$ is the LCM of the minimal polynomials of those powers of α . Then $\langle g(x) \rangle$ is called a **BCH code of designed distance s** because up to $\lfloor (s-1)/2 \rfloor$ errors can be corrected efficiently (with complexity $\Omega(n^2)$) by the *Berlekamp-Massey algorithm* (see [MS78]). For $L = 1$ it is called a **narrow-sense BCH code**. If $n = q^m - 1$, so that α is a primitive element of $\mathbb{F}_{q^m}$, the code is called a **primitive BCH code**.

A primitive BCH code with $m = 1$, i.e., with $n = q - 1$, is called a **Reed-Solomon code**. These codes are optimal since they achieve the Singleton bound $d(C) \leq n - k + 1$.

Let p be a prime that we reserve for the size of the symbol field. We assume that the code length n is also prime and require that n divides $p^{(n-1)/2} - 1$ so that p is a quadratic residue mod n . (If $p = 2$ this implies that n is of the form $8j \pm 1$.) Let Q_+ be the set of quadratic residues (i.e., squares) mod n and let Q_- be the set of nonresidues. Let α be a primitive n th root of unity in some extension field of $GF(p)$, and let

$$q_+(x) = \prod_{j \in Q_+} (x - \alpha^j) \in GF(p)[x], \quad q_-(x) = \prod_{j \in Q_-} (x - \alpha^j) \in GF(p)[x].$$

Then $(x-1)q_+(x)q_-(x) = x^n - 1$. Define four cyclic codes as follows:

$$C_1 = \langle q_+(x) \rangle, \quad C_2 = \langle (x-1)q_+(x) \rangle, \quad C_3 = \langle q_-(x) \rangle, \quad C_4 = \langle (x-1)q_-(x) \rangle.$$

These are called **quadratic residue (QR) codes**.

The **Golay codes** G_{23}, G_{11} are special quadratic residue codes over $GF(2)$ and $GF(3)$, respectively. Their error correction capacity is three errors for G_{23} and two errors for G_{11} . These codes are the only two perfect codes that are capable of correcting more than one error.

The parameters of these codes are found in [Table 61.3.1](#) below.

OTHER LINEAR CODES FOR THE HAMMING METRIC

GLOSSARY

The **extended Golay codes** G_{24}, G_{12} are obtained from the Golay codes by appending a digit, that is, an element of $\mathbb{F}_q$, to each codeword to make the sum of the n digits of each codeword equal to zero mod q . (Thus $n = 24$ and $q = 2$ for G_{24} , while $n = 12$ and $q = 3$ for G_{12} .)

The **binary Reed-Muller code of order r** , where $0 \leq r \leq m$, consists of the vectors that correspond to (and form the outputs of) all Boolean polynomials of degree at most r over $\mathbb{F}_2$ in the binary variables $v_1, v_2, \dots, v_r$.

A **Goppa code** is a linear code

$$C = \left\{ v = (v_1, \dots, v_n) \in F_q^n \mid \sum_{i=1}^n \frac{v_i}{z - P_i} \equiv 0 \pmod{G(z)} \right\}$$

where $v_i \in \mathbb{F}_q$, $P_i \in \mathbb{F}_{q^m}$, and $G(z)$ is a polynomial over $\mathbb{F}_{q^m}$ for which $G(P_i) \neq 0$, all of these holding for $1 \leq i \leq n$.

Algebraic-geometric codes are constructed as follows. Let X be a smooth, projective, algebraic curve over $\mathbb{F}_q$, absolutely irreducible over $\mathbb{F}_q$. Let $X(\mathbb{F}_q) = \{P_1, \dots, P_n\}$ be the set of $\mathbb{F}_q$ points of X , so that $n = |X(\mathbb{F}_q)|$. Let g be the genus of X , that is, the genus of the compact Riemann surface associated with X in the sense of the Riemann-Roch theorem. Choose a divisor D of X whose associated vector space $L(D)$ has dimension k over $\mathbb{F}_q$. Our code $C \subset \mathbb{F}_q^n$ is the image of $L(D)$ under the evaluation map $\text{Ev} : L(D) \rightarrow \mathbb{F}_q^n$, $\text{Ev} : f \mapsto (f(P_1), \dots, f(P_n))$.

The parameters of these codes can be found in Table 61.3.1.

TABLE 61.3.1 Comparison of parameters for certain types of codes for the Hamming metric. Distances and dimensions are at least as large as stated.

TYPE	BLOCK LENGTH n	DIMENSION k	DISTANCE d
Hamming	$\frac{q^m - 1}{q - 1}$	$n - m$	3
Primitive BCH	$q^m - 1$	$n - \deg g(x)$	$d \geq s$
Reed-Solomon	$q - 1$	$n - s + 1$	$d = s$
QR codes C_1, C_3	prime	$(n + 1)/2$	$d \geq \sqrt{n}$
QR codes C_2, C_4	prime	$(n - 1)/2$	$d \geq \sqrt{n}$
Ternary Golay G_{11}	11	6	5
Binary Golay G_{23}	23	12	7
Ext. Golay G_{12}	12	6	6
Ext. Golay G_{24}	24	12	8
Reed-Muller	2^m	$1 + \binom{m}{1} + \dots + \binom{m}{r}$	2^{m-r}
Goppa	n	$n - m \deg G$	$1 + \deg G$
Algebraic-geometric	$n = \text{no. of } GF(q)\text{-points on curve, so that } n \leq q + 1 + 2g\sqrt{q}$	$k = \dim L(D)$	$n + 1 - g - k$, where $g = \text{genus of curve}$

GENERAL BOUNDS ON CODE SIZE FOR THE HAMMING METRIC

There are many analogies between spherical codes and error-correcting codes, especially in the binary case, when the mapping $\lambda : \mathbb{H}_2^n \rightarrow S^{n-1}$ given by $\lambda(x_1, \dots, x_n) = (X_1, \dots, X_n)$ with $X_i = (-1)^{x_i} n^{-1/2}$ embeds the n -dimensional binary Hamming space into S^{n-1} and $(X, Y) = 1 - 2d(x, y)/n$.

Clearly any optimal code of Hamming distance d is at the same time a covering of the Hamming space with spheres of radius $d - 1$. This implies that

$$A_q(n, d) \geq q^n / V_n(d - 1; q)$$

since the density of a covering is at least 1 (the **Gilbert bound**). This bound is also valid for linear codes, in which case it has a slightly stronger form (the **Varshamov bound**):

$$A_q^{(Lin)}(n, d) \geq q^{n - \lceil \log_q V_n(d - 2; q) \rceil}.$$

It is common for asymptotic problems of coding theory to consider one of the two following asymptotic processes: $d = \text{const}$ and $d/n = \Delta = \text{const} > 0$. For the latter case it is convenient to consider the code rate $R(C) = n^{-1} \log_q |C|$. The **optimal**

code rate $R_q(\Delta)$ is defined as

$$R_q(\Delta) = \lim_{n \rightarrow \infty} n^{-1} \log_q A_q(n, \Delta n).$$

Then both bounds have the same form called, known as the **VG bound**:

$$R(\Delta) \geq 1 - H_q(\Delta) - \Delta \log_q(q-1) \quad \text{for } \Delta \leq (q-1)/q,$$

where $H_q(x) = -(x \log_q(x) + (1-x) \log_q(1-x))$ is the q -ary **entropy function**. One of the longest-standing open problems in coding theory is whether a family of cyclic codes of a fixed rate R can have Hamming distance that grows linearly with n , i.e., the relative distance $\Delta > 0$. S. Berman proved that for any family of cyclic codes C_i whose length n has only a fixed number of prime divisors in its factorization the Hamming distance is bounded above by some absolute constant that depends on the number of divisors.

Surprisingly, the VG bound is known not to be tight as $n \rightarrow \infty$ for a fixed $\Delta = d/n$ and for q an even power of a prime greater than or equal to 49, a result due to Tsfasman, Vlăduț, and Zink [TVZ82]. Namely, the parameters of AG codes asymptotically approach the **AG bound**:

$$R_q(\Delta) \geq 1 - \Delta - \frac{1}{\sqrt{q}-1}.$$

Note that these codes are polynomially constructible (the first construction with polynomial complexity was due to S. Vlăduț; by a recent result of [SAK⁺01] the construction complexity is $O((n \log_q n)^3)$) and even polynomially decodable. The VG bound only guarantees the existence of such codes, whereas their construction and decoding have complexity $\exp(\Omega(n))$.

The Hamming bound for the optimal code rate has the form

$$R_q(\Delta) \leq 1 - H_q\left(\frac{\Delta}{2}\right) - \log_q(q-1) \frac{\Delta}{2}.$$

The simple recursion $A_q(n, d) \leq q^{n-n'} A_q(n', d)$ leads to the **Singleton bound** (for arbitrary codes) $\log_q A_q(n, d) \leq n - d + 1$. Asymptotically we obtain

$$R(\Delta) \leq 1 - \Delta.$$

The **Plotkin bound**

$$A_q(n, d) \leq d(d - (1 - q^{-1})n)^{-1} \quad \text{if } d - (1 - q^{-1})n > 0$$

is an analog of the Rankin bound for spherical codes. It is attained on codes dual to the Hamming codes (which are mapped by the embedding λ to right simplexes in $\mathbb{R}^n$, $n = 2^m - 1$, $m = 2, 3, \dots$). The same recursion, $A_q(n, d) \leq q^{n-n'} A_q(n', d)$, leads to a more general form of the Plotkin bound: $A_q(n, d) \leq dq^{n - \lfloor q(d-1)/(q-1) \rfloor}$. Asymptotically this gives

$$R_q(\Delta) \leq 1 - \frac{q}{q-1} \Delta.$$

Note that the Plotkin bound implies (analogously to the Rankin bound) that for $d \geq n(q-1)/q$ it is not possible to find more than a linear (in n) number of points in H_q^n with the property that the Hamming distance between any two points is at

least d . On the other hand, the VG bound guarantees that for any fixed $\Delta < 1 - 1/q$ there exists a code of cardinality $\exp(\Omega(n))$ with Hamming distance $d \geq \Delta n$. Note that “critical points” $\varphi = \pi/2$ for S^{n-1} and $\Delta = 1/2$ for H_2^n are identified by the embedding λ .

Almost all known upper bounds for codes can be obtained by an application of the linear programming (LP) bound approach introduced by P. Delsarte [Del73], namely,

$$A_q(n, d) \leq f(1)/f_0$$

for any polynomial $f(x) = \sum_{i=0}^n f_i K_i^{(n)}(x)$ with the following properties:

1) $f_0 > 0$ and $f_i \geq 0$ for all $i \geq 1$;

2) $f(x) \leq 0$ for $x \geq d$.

The best asymptotic bound was obtained in [MRRW77]. For binary codes, in particular, it gives

$$R_2(\Delta) \leq H_2(1/2 - \sqrt{\Delta(1-\Delta)}) \quad \text{for } 0.273 < \Delta \leq 1/2.$$

It was proved recently [Sam01] that the LP approach is limited by the arithmetic mean of this bound and the VG bound.

Of course all the bounds mentioned above for the code rate can be rewritten as bounds for the maximum packing density of Hamming spheres of radius t in H_q^n . For instance, the VG bound for binary codes states that $n^{-1} \log_2 \delta(n, \tau n) \geq H(\tau) - H(\tau/2)$ for $\tau = \text{const}$. For the case of fixed radius t the Hamming bound is tighter. It is known [KP88] that for q a prime power,

$$\lim_{n \rightarrow \infty} \delta_q(n, 1) = 1.$$

In the binary case, the existence of the BCH codes implies that the maximum packing density of Hamming spheres of fixed radius t is separated from zero:

$$\delta_2(n, t) \geq 1/t! + o(n).$$

For $t = 2$, the existence of the Preparata codes (see [MS78]) implies that

$$\limsup \delta_2(n, 2) = 1.$$

In the nonbinary case much less is known. It is an open problem whether the maximum packing density is separated from zero, or in a slightly weaker form whether

$$\lim_{n \rightarrow \infty} \frac{n - \log_q A_q(n, 2t+1)}{\log_q n} = t.$$

This conjecture is known to be true for $t = 2$ and $q = 3, 4$. For $t = 2$ and arbitrary prime power q the best known result [Dum95] states that

$$\frac{n - \log_q A_q(n, 5)}{\log_q n} \leq 7/3.$$

CODES FOR EXOTIC METRICS

Let G be a compact convex O -symmetric body in $\mathbb{R}^n$, and fix an odd prime p . Regard $\mathbb{F}_p$ as lying in $\mathbb{R}^n$ by making the identification

$$\mathbb{F}_p = \{-(p-1)/2, \dots, -1, 0, 1, \dots, (p-1)/2\}.$$

Thus $\mathbb{F}_p^n = \mathbb{Z}^n \cap pQ$, where Q is the unit hypercube

$$\{x \in \mathbb{R}^n \mid \max(|x_1|, \dots, |x_n|) \leq \tfrac{1}{2}\}.$$

The ***G*-norm** of a point x of $GF(p)^n$ is

$$\|x\|_G = \inf\{\mu \geq 0 \mid x \in p\mathbb{Z}^n + \mu G\}.$$

An $[n, k, d, p, G]$ **code** C is a k -dimensional subspace of $GF(p)^n$ such that $\|x - y\|_G \geq d$ whenever $x, y \in C$ with $x \neq y$. For $x \in GF(p)^n$, let

$$B_{d;p,G}^n(x) = \{y \in GF(p)^n \mid \|y - x\|_G \leq d\}$$

be a metric ball and let $V_n(d; p, G) = |B_{d;p,G}^n(x)|$ be its volume. (Note that $V_n(d; p, G)$ does not depend on x .) It can be shown that $V_n(d; p, G) \leq |\mathbb{Z}^n \cap dG|$. An ordinary (in coding theory) count of “bad” parity-check matrices proves the following analogue of the VG bound for these codes: an $[n, k, d, p, G]$ code exists provided $k \leq n - \lceil \log_p V_n(d - 1; p, G) \rceil$.

The second author [Rus89] used $[n, k, d, p, G]$ codes and Construction A of Leech and Sloane (described in the next section) with $G = B^n$ to produce packings of the sphere with density $2^{-n(1+o(1))}$ as $n \rightarrow \infty$.

61.4 CONSTRUCTIONS OF PACKINGS

While we know that $\delta(B^n) \geq \delta_L(B^n) \geq 2^{-n(1+o(1))}$, we don’t know explicit arrangements nearly so dense when n is large. In principle, Minkowski reduction theory makes finding the densest lattice packing of B^n a finite problem (and those imbued with a pure enough mathematical spirit may be satisfied with this) but still it is nice to have explicit arrangements. Typically, there is a tradeoff: the more explicit, or “constructive,” the method is, the worse it fares as $n \rightarrow \infty$.

We mention, below, five constructions of packings from codes. Constructions A, B, and C are due to Leech and Sloane; D to Bos, Conway, and Sloane; and E to Barnes and Sloane. For more details, see [CS99].

CONSTRUCTION A

If C is a binary $[n, k, d]$ code, its Construction A lattice is $\Lambda_A(C) = 2\mathbb{Z}^n + C$. (If C is nonlinear, this gives a periodic but nonlattice arrangement.) We have $\det \Lambda_A(C) = 2^{n-k}$, and the lattice provides a packing for spheres of radius $\min(1, \frac{1}{2}\sqrt{d})$.

If C is an $[n, k, d, p, B^n]$ code, then its Construction A lattice is $\Lambda(C) = p\mathbb{Z}^n + C$. Then $\det \Lambda(C) = p^{n-k}$, and the lattice packs spheres of radius $\frac{1}{2} \min(d, p)$. If C is an $[n, k, d, p, G]$ code, and $d \leq p$, then $\Lambda(C)$ packs the body $\frac{1}{2}dG$.

CONSTRUCTION B

Let C be a binary $[n, k, d]$ code for which every codeword has even Hamming weight. The Construction B lattice of C consists of all those points $(x_1, \dots, x_n)$ of the Construction A lattice for which $x_1 + \dots + x_n$ is divisible by 4. We can call it

$\Lambda_B(C)$. We have $\det \Lambda_B(C) = 2^{n-k+1}$, and the lattice packs spheres of radius $\frac{1}{2} \min(\sqrt{d}, \sqrt{8})$. (If C is a nonlinear even-weight code, this gives a periodic but nonlattice arrangement.)

CONSTRUCTION C

Since this produces nonlattice packings, and Construction D applied to nested linear codes produces lattice packings of equal density, we omit a description of Construction C.

CONSTRUCTION D

Let C_i be a binary $[n, k_i, d_i]$ code, with $C_{i-1} \supset C_i$ and $d_i \geq 4^i/u$ for $1 \leq i \leq t$, where $u \in \{1, 2\}$. Let $C_0 = GF(2)^n$, so that $k_0 = n$ and $d_0 = 1$. Let $C_{t+1} = \{(0, \dots, 0)\}$, so that $k_{t+1} = 0$ and $d_{t+1} = \infty$. Take a row-vector basis

$$c_1 = (c_{11}, c_{12}, \dots, c_{1n}), c_2 = (c_{21}, c_{22}, \dots, c_{2n}), \dots, c_n = (c_{n1}, c_{n2}, \dots, c_{nn})$$

spanning $GF(2)^n$, selected so that these row vectors can be permuted with one another to produce an upper triangular matrix, and so that $c_1, c_2, \dots, c_{k_i}$ span C_i for $0 \leq i \leq t$. The Construction D lattice for this nested set of codes is

$$\Lambda_D(\{C_i\}) = \left\{ x + y \mid x \in 2\mathbb{Z}^n \text{ and } y \in \sum_{i=1}^t \sum_{j=1}^{k_i} b_{ij} \frac{c_{ij}}{2^{i-1}}, \text{ where each } b_{ij} \in \{0, 1\} \right\}.$$

The lattice has determinant $2^{n-(k_1+k_2+\dots+k_t)}$ and can pack spheres of radius $1/\sqrt{u}$.

There is a similar construction, Construction D', which uses parity checks rather than generators, and produces lattices of the same density as those of Construction D. We omit the description.

CONSTRUCTION E

This is a sort of nonbinary version of Construction D. In this subsection only, we permit codes to have nonfield symbol sets. Thus a “linear code” is merely an additive abelian group, not a vector space over the symbol field as elsewhere in this chapter.

Let $\Lambda \subset \mathbb{R}^n$ be a lattice with minimum Euclidean distance d between its points. Let D be a dilatation composed with an orthogonal transformation. Fix integers $p \geq 1$ and $r \geq 0$. Suppose $D\Lambda \subset \Lambda$, and that $pD^{-1} = a_0D^0 + a_1D^1 + \dots + a_rD^r$ for certain integers $a_0, \dots, a_r$. Suppose all the $p^b - 1$ nonzero congruence classes of $D^{-1}\Lambda/\Lambda$ have minimum distance from the origin at least $d/\sqrt[r]{|\det D|}$.

Let C_i be a p^{k_i} -element subgroup of E^m , where $E = \Lambda/D\Lambda \cong (\mathbb{Z}/p\mathbb{Z})^b$, and $C_{i-1} \supset C_i$, for $1 \leq i \leq t$. Endowing these with the Hamming metric, we regard C_i as an $[m, k_i, d_i]$ code. We assume that the largest code, C_0 , has parameters $[m, m, 1]$.

Let $x \in \{0, 1, 2, \dots, p-1\}$ belong to the congruence class $\bar{x} \in \mathbb{Z}/p\mathbb{Z}$. Let $V: E \rightarrow \Lambda$ be the map

$$\bar{x}_1 v_1 + \cdots + \bar{x}_b v_b \mapsto x_1 v_1 + \cdots + x_b v_b,$$

and use the same symbol V to denote the map $V : E^m \rightarrow \Lambda^m$ that operates componentwise.

Let row vectors $c_1, c_2, \dots, c_{bk_i}$ be selected,

$$c_1 = (c_{1,1}, c_{1,2}, \dots, c_{1,bk_i}), \dots, c_{bk_i} = (c_{n,1}, c_{n,2}, \dots, c_{bk_i,bk_i}),$$

so that a typical codeword of C_i can be written $\bar{x}_1 c_1 + \cdots + \bar{x}_{bk_i} c_{bk_i}$, where each x_j is in $\{0, 1, 2, \dots, p-1\}$, and so that the rows $c_1, c_2, \dots, c_{bk_i}$ can be permuted with one another to form an upper triangular matrix, for $1 \leq i \leq t$.

The Construction E lattice is the mn -dimensional lattice L_t given as follows: Let

$$M_i = \left\{ x_1 D^{-i} V(c_1) + \cdots + x_{bk_i} D^{-i} V(c_{bk_i}) \mid x_1, \dots, x_{bk_i} \in \{0, 1, 2, \dots, p-1\} \right\}.$$

Let $L_0 = \Lambda^m$. For $1 \leq i \leq t$, we define

$$L_i = L_{i-1} + M_i = \{x + y \mid x \in L_{i-1}, \quad y \in M_i\}.$$

Construction E produces a lattice in $\mathbb{R}^{mn}$ whose determinant is

$$\frac{(\det \Lambda)^m}{\exp_p(b(k_1 + k_2 + \cdots + k_t))}$$

and that lattice-packs spheres of radius

$$(1/2) \min_{0 \leq j \leq t} \left(d |\det D|^{-j/n} \sqrt{d_j} \right).$$

E_8 AND THE LEECH LATTICE Λ_{24}

E_8 and Λ_{24} are anomalously dense and symmetrical lattice packings in $\mathbb{R}^8$ and $\mathbb{R}^{24}$, respectively. They have far more constructions than we can mention here.

Let L be the lattice $\{(x_1, \dots, x_8) \in \mathbb{Z}^8 \mid x_1 + \cdots + x_8 \text{ is even}\}$. Then E_8 is

$$L \cup \left(L + \left(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2} \right) \right).$$

Alternatively, one gets E_8 by applying Construction A to the binary extended Hamming code $[8, 4, 4]$, which is the span over $GF(2)$ of the rows of this array:

$$\begin{array}{cccccccc} 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{array}$$

When scaled so that $\det E_8 = 1$, it packs spheres of radius $\sqrt{1/2}$. Each sphere touches 240 others, and that is known to be the maximum number possible.

Our construction of the Leech lattice will be based on the extended Golay code

where f is a superball function. Let G_f denote that superball. In [Rus93] it was shown that

$$\delta_L(G_f) \geq \left(\frac{1}{2} \left(\sup_{A \in GL_n(\mathbf{R})} \frac{\int_{x \in \mathbf{R}^k} \exp(-f(Ax)) dV}{\sum_{x \in \mathbf{Z}^k} \exp(-f(Ax))} \right)^{1/k} \right)^{n(1+o(1))} \quad \text{as } n \rightarrow \infty.$$

The second author conjectures that this holds with equality. In the case $k = 1$ and $f(x) = x^2$, the conjecture is that $\delta_L(n) = 2^{-n(1+o(1))}$.

Finally, the first author conjectures that the “covering (or random) type” lower bounds presented in this chapter, such as the Varshamov-Gilbert bound for *binary* error-correcting codes, its analogue for spherical codes (the Shannon bound), and, consequently, the Minkowski-Hlawka bound, are asymptotically tight.

61.5 VERY RECENT DEVELOPMENTS

Just prior to publication, there were two major developments. One involved Musin’s claim of a proof of the kissing number for 3-spheres in $\mathbb{R}^4$: $\tau(4) = 24$ [Mus03]. The other was the claim by H. Cohn and A. Kumar of a proof that the Leech lattice is the densest lattice in dimension 24. Both results were being checked as this edition of the Handbook went to press.

62 CRYSTALS AND QUASICRYSTALS

Marjorie Senechal

INTRODUCTION

Mathematical crystallography is the branch of discrete geometry that deals with the structure and form of crystals. For over a century the field has been a meeting ground for polytopes, lattices, tilings, and groups. Today, stimulated both by developments internal to mathematics and by the discovery of quasicrystals, the subject is broadening rapidly, and modeling the geometry of crystals requires an ever-expanding mathematical toolbox. In Section 62.1 we survey the classical foundations of the subject; in Section 62.2 we indicate how these foundations are being redesigned to encompass recent developments. *We assume that the reader is familiar with the terminology and results of [Chapter 3](#) of this Handbook.*

62.1 PERIODIC CRYSTALS

The geometrical study of crystals began when Johannes Kepler suggested that snowflakes were comprised of identical spheres arranged in what we now call cubic close-packing. Kepler also noted that if the spheres in such a packing were uniformly compressed, they would assume the forms of rhombic dodecahedra (Figure 62.1.1), and these dodecahedra would tile space. He thus demonstrated the duality between sphere-packing models and tiling models for crystal structure. This close relation between sphere packings and tilings, or more generally between point sets (the centers of the spheres in Kepler's case) and tilings, is exploited in mathematical crystallography to this day.

FIGURE 62.1.1

(a) *Cubic closest packing of spheres.* (b) *When the spheres are uniformly compressed they become space-filling rhombic dodecahedra.*

62.1.1 POINT-SET MODELS

From the middle of the nineteenth century until quite recently, “regular systems of points,” or unions of a finite number of them, have served as the abstract model for crystal structure. The study of crystal geometry amounted to the classification of these point sets by symmetry.

THE CLASSICAL THEORY

Let Γ be a discrete point set in $\mathbb{E}^n$.

GLOSSARY

- Star** (of a point $x \in \Gamma$): The configuration of line segments joining x to each of the other points of Γ .
- Voronoi cell** (of a point $x \in \Gamma$): The set $V(x)$ of points in $\mathbb{E}^n$ that are at least as close to x as to any other point of Γ . (See also [Chapters 3](#) and [23](#).)
- Voronoi tiling** (associated with Γ): The tiling $\mathcal{V}_\Gamma$ whose tiles are the Voronoi cells of the points of Γ .
- Regular system of points:** An infinite discrete point set such that the stars of all its points are congruent; equivalently, a discrete point set that is an orbit of an infinite group of isometries.
- Crystallographic group:** A group of isometries that acts transitively on a regular system of points. Crystallographic groups are discrete subgroups of the nonabelian group of Euclidean motions of $\mathbb{E}^n$.
- Lattice** (of dimension n): A discrete subgroup of $\mathbb{R}^n$, generated by n linearly independent translations.
- Crystal (classical):** The union of a finite number of orbits of a crystallographic group.
- Point lattice:** An orbit of a lattice.

MAIN RESULTS

Table 62.1.1 [BBN⁺78] gives the number of crystallographic groups in $\mathbb{E}^2$, $\mathbb{E}^3$, and $\mathbb{E}^4$, up to isomorphism. For $n \geq 5$ the number of groups is not known.

TABLE 62.1.1 Crystallographic groups.

n	2	3	4
TYPES	17	219	4783

THEOREM 62.1.1 *Bieberbach's Theorem*

A regular system of points is a finite union of translates of congruent lattices (Figure 62.1.2); the symmetry group G of a regular system of points is a product of a translation group T and a finite group of isometries, such that T is the maximal abelian subgroup of G .

(See [Sen96] for a discussion of this theorem and for further references.)

FIGURE 62.1.2

A regular system of points as a union of congruent lattices.

THEOREM 62.1.2 *The Crystallographic Restriction*

The only rotational symmetries possible for a regular system of points are those compatible with a lattice (of the same dimension).

Table 62.1.2 gives the possible orders m , $2 \leq m \leq 13$, of rotational symmetries of a regular system of points and the lowest dimension $d(m)$ in which they can occur. Five-fold rotations, as well as n -fold rotations with $n > 6$, are “forbidden” in $\mathbb{E}^2$ and $\mathbb{E}^3$. (This table is easily computed from the formula given in [Sen96, p. 51].)

TABLE 62.1.2 m -fold rotational symmetries.

m	$d(m)$	m	$d(m)$	m	$d(m)$	m	$d(m)$
2	1	5	4	8	4	11	12
3	2	6	2	9	6	12	4
4	2	7	6	10	4	13	12

DELONE'S REFORMULATION OF THE CLASSICAL FOUNDATIONS

In the 1930s Delone, Aleksandrov, and Padurov reformulated the foundations of mathematical crystallography, replacing the regular systems of points with more general discrete point sets, which they called “ (r, R) -systems.”

GLOSSARY

(r, R) system: A set $\Lambda = \Lambda_{r,R}$ of points in $\mathbb{E}^n$ that is uniformly discrete and relatively dense (r is the infimum of the distances between pairs of points of Λ , and every sphere of radius $\geq R$ contains at least one point of Λ).

Delone (or **Delaunay**) **set:** The modern term for an (r, R) system.

Finite type: A Delone set Λ is said to be of finite type if $\Lambda - \Lambda$ is a discrete closed set.

c -star (of a point x in a Delone set): The configuration of line segments joining x to the points of the Delone set that lie in $B(x, c)$, the ball with center x and radius c .

MAIN RESULTS

The Voronoi cell of any point x of a Delone set $\Lambda_{r,R}$ is contained in the ball $B(x, R)$; thus the cell is completely determined by $\Lambda \cap B(x, 2R)$. (This is an easy exercise.)

If an orbit of a group of isometries of $\mathbb{E}^n$ is a Delone set, then the group is crystallographic and the Delone set is a regular system of points [DLS98].

A Delone set $\Lambda_{r,R}$ is of finite type if and only if it has a finite number of neighborhoods of radius $2R$, up to translation [Lag99].

THEOREM 62.1.3 *The Local Theorem (for point sets)* [DDSG76]

There is a real number k such that if all the $2Rk$ -stars of a Delone set $\Lambda_{r,R}$ are congruent, then Λ is a regular system of points.

(See also [Section 3.2](#).)

PROBLEM 62.1.4

Does the constant k in the Local Theorem depend only on the dimension n ?

62.1.2 TILING MODELS

Crystal growth is modular: beginning with a relatively tiny cluster of atoms, a crystal grows by the accretion of modules (atoms, molecules) to this “seed.” The position a module assumes on the growing crystal is assumed to be determined by local forces, as are subsequent rearrangements that may be required to minimize surface energy. In models of crystal structure consistent with this process, the modules are sometimes represented as spheres, but more commonly as space-filling polyhedra. In particular, it is convenient to think of a crystal as a tiling of space by congruent tiles. The tiles may be the crystallographer’s “unit cells,” the Voronoi cells of the crystal lattice, or stereohedra.

GLOSSARY

(Closed) unit cell (of a lattice in $\mathbb{E}^n$): The Minkowski sum of a set of n generating vectors of the lattice.

Zonotope: The Minkowski sum of an arbitrary number of line segments (or vectors).

***n*-parallelotope:** A convex *n*-polytope that tiles $\mathbb{E}^n$ by translation. (See [Section 3.2](#).) Unit cells and Voronoi cells (of lattice points) are parallelotopes.

Stereohedron: The Voronoi cell of a point of a regular system of points. (A stereohedron is not necessarily a parallelotope.)

MAIN RESULTS

Table 62.1.3 gives the number of combinatorial types of *n*-parallelotopes in $\mathbb{E}^2$, $\mathbb{E}^3$, and $\mathbb{E}^4$. (See [Sen96, p. 45].)

TABLE 62.1.3 *n*-parallelotopes.

<i>n</i>	2	3	4
TYPES	2	5	52

A 2-parallelotope is combinatorially equivalent to a quadrilateral or a hexagon. The 3-parallelotopes are, combinatorially, cubes, hexagonal prisms, truncated octahedra, rhombic dodecahedra, and the “elongated” rhombic dodecahedra (which have four hexagonal and eight rhombic faces). The 2-parallelotopes and 3-parallelotopes are zonotopes, but this is not generally true in higher dimensions.

Every 2-, 3-, and 4-parallelotope is an affine image of the Voronoi cell of a lattice in $\mathbb{E}^2$, $\mathbb{E}^3$, and $\mathbb{E}^4$, respectively.

The number of combinatorial types of stereohedra in $\mathbb{E}^n$ is bounded (see [Section 3.2](#)).

PROBLEM 62.1.5

Is every n-parallelotope an affine image of the Voronoi cell of some full rank lattice point in $\mathbb{R}^n$?

Voronoi proved that the answer is “yes” if exactly $n + 1$ Voronoi cells meet at every vertex of the Voronoi tiling. The answer is also “yes” for zonotopes [Erd99] and for parallelotopes with $2(2^n - 1)$ faces (the maximal number in that dimension) [MRS95].

62.1.3 MODELING X-RAY DIFFRACTION

In 1912 the German physicist Max von Laue demonstrated the light-like nature of X-rays and the plausibility of a lattice structure for crystals by showing that crystals can serve as diffraction gratings for X-rays (this experiment also supported the existence of atoms). X-ray diffraction turned out to be the Rosetta stone that unlocked the solid state. Synthetic pharmaceuticals, electronics, and medical imaging are only three of the many fields of application that have resulted from this discovery.

X-ray diffraction is far-field (Fraunhofer) diffraction. This means that the distances from the X-ray source to the crystal and from the crystal to the photographic plate on which scattered intensities are recorded are sufficiently far that the scattering can be modeled by Fourier transformation [Cow86].

GLOSSARY

Dual lattice: If L is a lattice in $\mathbb{E}^n$, its dual lattice L^* is the group of vectors $\vec{y} \in \mathbb{E}^n$ such that $\vec{y} \cdot \vec{x} \in \mathbb{Z}$ for every $\vec{x} \in L$; here $\cdot$ denotes the usual scalar product.

Dirac delta “function” at x : Intuitively, the generalized function δ_x that assigns unit mass to the point $x \in \mathbb{E}^n$ and vanishes at all other points.

MAIN RESULTS

Assume, for simplicity, that our regular system of points is a point lattice. We associate to the corresponding lattice L the generalized function

$$\rho(x) = \sum_{x_n \in L} \delta_{x_n}(x); \quad (62.1.1)$$

its Fourier transform is the generalized function

$$\hat{\rho}(s) = \sum_{x_n \in L} \exp(-2\pi i x_n \cdot s), \quad (62.1.2)$$

where $s \in \mathbb{E}^n$. The diffraction pattern that we observe (on a photographic plate) when X-rays are passed through this “crystal” is a density map of the crystal’s “intensity function” (the Fourier transform of the autocorrelation $\rho(x) * \overline{\rho(-x)}$). The “Wiener diagram” below [Sen96], in which $\Downarrow$ denotes Fourier transformation, describes the relationship between the crystal and the observed intensities.

$$\begin{array}{ccc} \rho(x) & \xrightarrow{\text{autocorrelation}} & \rho(x) * \overline{\rho(-x)} \\ \Downarrow & & \Downarrow \\ \hat{\rho}(s) & \xrightarrow{\text{squaring}} & |\hat{\rho}(s)|^2 \end{array}$$

The task of the crystallographer is to deduce $\rho(x)$ from the intensity function, a task greatly complicated by the fact that the intensity is real while $\hat{\rho}(s)$ is complex.

This diagram is widely used in crystallography for heuristic purposes, although it is not valid (in any theory of generalized functions) because convolution and multiplication are not defined for infinite sums of deltas. Nevertheless, there is a sense in which it gives correct information [Hof95]. In particular, sharp bright spots in the diffraction pattern correspond to delta functions in the Fourier transform in the case of periodic point sets (and also in the case of model sets, discussed in Section 62.2 below). The Poisson summation formula (see [Sen96]) states, in effect, that the diffraction pattern of a point lattice is a set of sharp bright spots at the points of its dual point lattice.

THEOREM 62.1.6 Poisson Summation Formula

Let L and L^* be dual lattices, and let $\rho(x)$ be as in (62.1.1) above. Then (62.1.2) can be written in the form

$$\hat{\rho}(s) = \sum_{s_n \in L^*} \delta_{s_n}(s). \quad (62.1.3)$$

62.2 GENERALIZED CRYSTALS AND QUASICRYSTALS

After the discovery of X-ray diffraction in 1912, it was unquestioningly accepted that a crystal is a solid with a periodic atomic structure. Only a periodic structure, it was reasoned, could produce diffraction patterns with sharp bright spots, because—roughly speaking—the spots indicate the repetition, throughout the crystal’s atomic pattern, of congruent c -stars for all $c > 0$. The “long-range order” created by this repetition, it was assumed, must be periodic. But this classical model began to be questioned in the 1970s when it was found that the structures of so-called modulated crystals could not be accounted for by three-dimensional periodicity. The paradigm that had reigned since Laue’s experiment collapsed completely with the discovery, in the early 1980s, of crystals with “forbidden” icosahedral symmetry. Today it is widely agreed that both periodic and nonperiodic crystals exist, but the structure of nonperiodic crystals is still not fully understood. Rather than repeat the mistake of the past by again defining a crystal in terms of some a priori concept of its structure, the Commission on Aperiodic Crystals of the International Union of Crystallography proposed as a working definition: *a crystal is a solid with an essentially discrete diffraction pattern.*

To put this into mathematical language, we follow the periodic model by associating a sum of Dirac deltas to a Delone set Λ , one delta at each point, and computing the Fourier transform of the autocorrelation (when the autocorrelation exists). This transform is a measure, called the spectrum of Λ ; the spectrum can be uniquely decomposed into a sum of discrete and continuous measures. The discrete component of the spectrum is itself a countable sum of weighted Dirac deltas, located at a set of points that we will call Λ_d (when Λ is a lattice, $\Lambda_d = \Lambda^*$). We always have $0 \in \Lambda_d$; if $\Lambda_d \neq \{0\}$, it is said to be nontrivial. (The set Λ_d need not be discrete as a point set; in general it will be everywhere dense.)

Definition: A (*generalized*) *crystal* is a Delone set Λ with nontrivial Λ_d . A *quasicrystal* is a generalized crystal whose intensity function is invariant under a rotational symmetry forbidden by the Crystallographic Restriction. The *symmetry group* (of a quasicrystal) is the group of isometries under which the intensity function is invariant.

Below, we describe some generalizations of the notions of regular systems of points and stereohedra. It must be emphasized that at this early stage, all definitions are subject to change, and very few theorems have been proved in satisfactory generality.

62.2.1 POINT-SET MODELS

A point-set model for a generalized crystal is a suitable generalization of a regular system of points, but there is no agreement yet on what “suitable” should mean. However, most models assume that the point set is a Delone set satisfying additional conditions, for example as in the definition above. Classification by symmetry group is replaced by local isomorphism classes.

GLOSSARY

c-atlas: The set of congruence classes of *c*-stars of the points of a Delone set Λ .

Repetitive point set: A Delone set Λ such that the stars of every *c*-atlas are relatively dense in Λ (i.e., for each such star s there is an $R_s > 0$ such that every ball of radius R_s contains a copy of s).

Local isomorphism class: Two Delone sets in $\mathbb{R}^n$ belong to the same local isomorphism class if every bounded configuration of each also occurs in the other.

Inflation symmetry: A Delone set Λ is said to possess inflation symmetry if there is a $\lambda > 1$ such that $\lambda\Lambda \subset \Lambda$.

X-ray diffraction patterns of real crystals suggest that point-set models for generalized crystals in $\mathbb{E}^k$ should be subsets of $\mathbb{Z}$ -modules of rank $m \geq k$. A $\mathbb{Z}$ -module whose rank m is greater than its dimension k may be everywhere dense. One way to select the points of the crystal is by means of an “acceptance domain” or “*window*.” A crystal obtained in this way is called a *model set* [Mey95].

Model set: Let L be a lattice of rank $m = k + n$ in $\mathbb{E}^m$; let $p_{\parallel}$ and $p_{\perp}$ be the orthogonal projections into a k -dimensional subspace $\mathcal{E} = \mathbb{E}^k$ and its orthogonal complement $\mathcal{E}^{\perp} = \mathbb{E}^n$, respectively. Assume that $p_{\parallel}$, restricted to L , is one-one and that $p_{\perp}(L)$ is everywhere dense in $\mathbb{E}^n$, and let Ω be a bounded subset of $\mathbb{E}^n$ with nonempty interior. Then the set

$$\Lambda(\Omega) = \{p_{\parallel}(x) \mid x \in L, p_{\perp}(x) \in \Omega\} \quad (62.2.1)$$

is called a model set. When Ω is a translate of the projection of the Voronoi cell of the lattice into the orthogonal space, the window is said to be ***canonical***. *Note:* model sets can be defined in greater generality than is done here [Moo00].

The ingredients for a one-dimensional model set are shown in Figure 62.2.1, in which $m = 2$, $n = k = 1$, and L is a square lattice. The subspace $\mathcal{E}$ is the solid line of positive slope; the window Ω is the thick line segment in $\mathcal{E}^{\perp}$. A lattice point x is projected into $\mathcal{E}$ if and only if $p_{\perp}(x) \in \Omega$ (alternatively, if and only if x lies in the cylinder bounded by the dotted lines). Note that the window in Figure 62.2.1 is *not* canonical.

FIGURE 62.2.1

Ingredients for a one-dimensional model set. The subspace $\mathcal{E}$ is the solid line; the window Ω is the thick line segment in $\mathcal{E}^{\perp}$.

Meyer set: A Meyer set is a Delone set Λ such that $\Lambda - \Lambda$ is also a Delone set.

Poisson comb: A crystal with purely discrete spectrum.

ϵ -dual (of a Delone set Λ): $\Lambda_\epsilon^* = \{y \in \mathbb{E}^n \mid |\exp(2\pi i y \cdot \lambda) - 1| \leq \epsilon, \forall \lambda \in \Lambda\}$.

MAIN RESULTS

Model sets are repetitive Delone sets. By translating Ω we get an infinite family of model sets in the same local isomorphism class. If the subspace $\mathcal{E}$ contains no points of the dual lattice L^* , then the model set is nonperiodic, i.e., it is not invariant under any translation [Sen96, Moo97].

When the window Ω is a translate of the projection, into $\mathcal{E}^\perp$, of the Voronoi cell of the lattice, the relative frequencies of the r -stars of $\Lambda(\Omega)$ are determined by the location of the corresponding points $p_\perp(x)$ in the window (see Figure 62.2.2) [Sen96].

FIGURE 62.2.2

Every point in a one-dimensional model set is the second point in a three-point configuration or star. (a) In this example, there are three translations classes of such stars. (b) Each star is characterized by the interval, in the window Ω , into which the lattice point corresponding to its “center” projects. ($\mathcal{E}$ is the dotted line; the triples of lattice points projecting to the stars are also indicated by dotted lines.)

Every model set is a Meyer set; conversely, every Meyer set is a subset of a set of the form $\Lambda(\Omega) + F$, where $\Lambda(\Omega)$ is a model set and F is finite [Mey95].

Λ is a Meyer set if and only if $\Lambda - \Lambda \subseteq \Lambda + F$, where F is finite [Lag96].

If Λ is a finitely generated Delone set with inflation symmetry, then λ must be an algebraic integer. If Λ is of finite type, then in addition all algebraic conjugates λ' satisfy $|\lambda'| \leq \lambda$. If Λ is a Meyer set, then for all algebraic conjugates λ' , $|\lambda'| \leq 1$ [Lag99].

A Delone set Λ is a Meyer set if and only if for every $\epsilon > 0$, Λ_ϵ^* is relatively dense in $\mathbb{E}^n$ [Moo97].

Every (suitably) repetitive Delone set is a Poisson comb [LP98].

For accounts of other recent results, see [BM03].

OPEN PROBLEMS

CONJECTURE 62.2.1

The converse of the last statement above is also true.

The most important open problem is the one posed by the discovery of nonperiodic crystals:

PROBLEM 62.2.2

What are necessary and sufficient conditions for a discrete point set to be a crystal according to the new definition? (It is not necessary that the set be Delone!)

Partial results have also been obtained [Lag00, LMS03] for the special case of Poisson combs.

PROBLEM 62.2.3

Is there an analogue of the Local Theorem for generalized crystals?

62.2.2 TILING MODELS

Tiling models are useful in the theory of generalized crystals for precisely the same reasons they are useful in the classical periodic case: they give us a clearer picture of how space is partitioned than point-set models do, and they may help us to understand the growth of crystals. Covering models have been proposed as well (see, e.g., [SJS⁺98]) but we will not discuss them here.

Which tilings are appropriate models for generalized crystals? High-resolution electron micrographs of many crystal structures can be interpreted meaningfully as tilings; often these tilings appear to be hierarchical (see [Section 3.4](#)). The hierarchical structure may play a role in crystal formation or stability. Some of the tilings can be derived by the projection method (see below), for which there does not appear to be a physical interpretation. However, the projection method is of great theoretical value.

CANONICALLY PROJECTED TILINGS

Canonically projected tilings are closely related to the model sets defined in [Section 62.2.1](#).

GLOSSARY

Canonical projection method for tilings: Let L be a lattice in $\mathbb{E}^m$, $\mathcal{E}$ a k -dimensional subspace, and $\vec{\gamma} \in \mathbb{E}^m$. Let $\mathcal{V}$ be the Voronoi tiling associated with L , and $\mathcal{D}$ the dual Delone tiling (see [Section 3.1](#)). The canonical projection method for tilings projects, onto $\mathcal{E}$, the $(n-k)$ -dimensional faces of $\mathcal{D}$ that correspond, under duality, to the k -dimensional faces of $\mathcal{V}$ that are cut by $\mathcal{E} + \vec{\gamma}$ ([Figure 62.2.3](#)). Thus, if $\mathcal{E}$ meets the interior of a Voronoi cell $V(x)$ (dimension n), we project x onto $\mathcal{E}$: x is the vertex (dimension 0) of the Delone tiling that corresponds to $V(x)$ in the duality. The vector $\vec{\gamma}$ is the **shift vector** for the projection.

Canonically projected tiling: A tiling that can be constructed by the canonical projection method.

Note: Some authors require “canonical” to mean, in addition to the above, that L is the standard integer lattice.

FIGURE 62.2.3

The line $\mathcal{E}$ cuts a subset of the one- and two-dimensional faces of the Voronoi tiling (Voronoi cells are indicated by squares); we project the corresponding one- and zero-dimensional faces of the Delone tiling (dotted line segments and their endpoints).

MAIN RESULTS

Let $\mathcal{E} + \vec{\gamma}$ be a translate of a k -dimensional subspace of $\mathbb{E}^n$, let L be an n -dimensional lattice with Voronoi tiling $\mathcal{V}$, and let $*$ be the dual map. Denote the set of faces of $\mathcal{V}$ that have nonempty intersection with $\mathcal{E}$ by $\mathcal{V} \wedge \mathcal{E}_\gamma$, and let $p_\parallel$ be as above. Then [Sch93]

$$(\mathcal{V} \cap \mathcal{E}_\gamma)^* = p_\parallel((\mathcal{V} \wedge \mathcal{E}_\gamma)^*). \quad (62.2.2)$$

Some of the best known projected nonperiodic tilings are listed in Table 62.2.1 (see [Sen96]). In all four cases, the lattice L is the standard integer lattice and the window Ω is a projection of a hypercube (the Voronoi cell of L). The vector $\vec{\gamma}$ is chosen so that $\mathcal{E} + \vec{\gamma}$ does not intersect any faces of $\mathcal{V}$ of dimension less than $n - k$ (thus only a subset of the faces of the Delone tiling $\mathcal{D}$ of dimensions $0, 1, \dots, k$ will be projected). The first three tilings are hierarchical; by an unpublished “folk theorem,” the fourth is, too. $\mathcal{E}$ is a subspace that is stable under some finite rotation group; the rotational symmetry reappears in some of the bounded configurations of the tiling, and also in its diffraction pattern.

TABLE 62.2.1 Canonically projected nonperiodic tilings.

TILING FAMILY	L	$\mathcal{E}$
Fibonacci tiling	I_2	line with slope $1/\tau$ ($\tau = (1 + \sqrt{5})/2$)
Ammann-Beenker tiling	I_4	plane stable under 8-fold rotation
Generalized Penrose tiling	I_5	plane stable under 5-fold rotation
Penrose 3D tiling	I_6	3-space stable under icosahedral rotation group

The famous Penrose tilings of $\mathbb{E}^2$ (by rhombs) are precisely those generalized Penrose tilings defined by the flats $\mathcal{E} + \vec{\gamma}$, $\vec{\gamma} \in \mathbb{E}^5$ such that $\vec{\gamma} \cdot \vec{w} \equiv \frac{1}{2} \pmod{1}$, where $\vec{w} = (1, 1, 1, 1, 1)$.

The relative frequencies of the vertex stars of a canonically projected tiling are determined by the window: they are the ratios of volumes of the intersections of the projected faces of $V(0)$ (see Figures 62.2.2 and 62.2.4, and also [Sen96]).

FIGURE 62.2.4

The Ammann-Beenker tiling. (a) A portion of the tiling. (b) The six vertex stars. (c) The projected faces of the 4-cube are hexagons that decompose the window Ω into cells. There are six congruence classes of cells, corresponding to the six classes of stars. (A star of j tiles, $j = 3, \dots, 8$, corresponds to the intersection of the projections of j hexagons.)

THE MULTIGRID METHOD

The multigrid method is an interesting variant of the canonical projection method for tilings. In this version, the tiling is constructed as a dual of an n -grid, which is a superposition of n grids. For special choices of the grids and grid star, the n -grid is precisely the intersection $\mathcal{E}_\gamma \cap \mathcal{V}$ in (62.2.2); in these cases the multigrid and the canonical projection methods produce the same families of tilings. The multigrid method is, however, less studied [Sen97].

GLOSSARY

Grid: A countably infinite family of equispaced parallel $((k-1)$ -dimensional) hyperplanes in $\mathbb{E}^k$.

Grid vector: A vector orthogonal to the grid whose length is the distance between adjacent hyperplanes of the grid.

n -grid (also *multigrid*): A union of n grids (in $\mathbb{E}^k$).

Grid star: The set of grid vectors of an n -grid.

Shift vector (for n -grids in $\mathbb{E}^k$): We think of the n grids as initially passing through the origin, and then shift them so that at most k grids pass through a single point. The shift vector $\vec{\gamma}$ is the n -tuple of the shifts away from the origin; if at most k hyperplanes of the n -grid meet in any point, $\vec{\gamma}$ is said to be *regular*.

Note: We use the same symbol, $\vec{\gamma}$, for shift vectors and for translations of $\mathcal{E}$ to emphasize the fact that they play precisely the same role in the theory.

Pentagrid: A 5-grid in $\mathbb{E}^2$ whose star consists of unit vectors pointing from the center to the vertices of a regular pentagon (Figure 62.2.5). A pentagrid is said to be regular if its shift vector is regular.

n -grid dual: A tiling dual to an n -grid whose edges are parallel to the vectors of the grid star.

MAIN RESULTS

Many of the main results in the subsection on Canonically Projected Tilings above can be reinterpreted in the language of multigrids and thus derived by the multigrid method.

FIGURE 62.2.5

A portion of a pentagrid (a) and the corresponding patch of a generalized Penrose tiling (b).

HIERARCHICAL TILINGS

These tilings are discussed in Section 3.4.

OPEN PROBLEMS

There is a large class of open problems concerned with the generality of these tiling construction methods and the relations among them.

PROBLEM 62.2.4

Which hierarchical tilings are projected tilings, and vice versa?

PROBLEM 62.2.5

Every tiling of $\mathbb{E}^k$ by zonotopes has a pseudogrid dual (a grid in which the hyperplanes are replaced by pseudohyperplanes—see [Chapter 6](#)); which of these pseudogrids are stretchable, and how is this related to the question of whether or not the tiling is a crystal?

PROBLEM 62.2.6

Which tilings can be lifted to a surface (not necessarily contained in a cylinder) of faces of a lattice Delone complex in some higher-dimensional space?

62.2.3 MODELING CRYSTAL “GROWTH”

The classical notion of modeling crystal growth by tilings can be carried over to the more general setting, but now we want the tilings to be nonperiodic. Nonperiodic

tilings can be constructed hierarchically (see [Section 3.4](#)), by projection, and by many other methods. However, if we require that the nonperiodicity be *forced* by “matching rules” of some sort, then there are fewer possibilities. There has been a great deal of progress in matching rule theory during the past decade, but many important problems are still open.

GLOSSARY

Aperiodic prototile set: A set of prototiles that admits only nonperiodic tilings (see [Chapter 3](#)). Some prototiles of aperiodic sets are simple shapes (with or without markings on them), but others can be quite complicated.

Matching rule (for a set of prototiles): A finite atlas, of some finite radius, of allowed configurations of marked or unmarked prototiles, such as face pairs, vertex stars, or face coronas (for definitions, see [Chapter 3](#)).

FIGURE 62.2.6

The matching rules for the Penrose tilings. (a) The tiles can be marked, as shown here; the rule is that both the type (double or single) and direction of the arrows must match. (b) The configurations shown here constitute another (equivalent) matching rule for the Penrose tiles: each tile must be matched to four other tiles in one of these ways.

Definition: A matching rule (for an aperiodic set of prototiles) is:

perfect, if it enforces nonperiodicity and repetitivity, and defines a single local isomorphism class;

strong, if it enforces nonperiodicity and repetitivity, but admits more than one local isomorphism class;

weak, if it enforces nonperiodicity but not repetitivity.

To prove that a prototile set is aperiodic, one must exhibit a matching rule that is at least weak.

There does not seem to be a name for matching rules that force periodic structures, but such rules do exist for certain prototile sets. For example, a tiling by squares will be periodic if we insist on a single vertex star, four squares meeting at a vertex. See also the classification of isohedral tilings in [GS87].

In cases when it is useful to distinguish between the prototiles and their shapes (for example, between marked and unmarked prototiles), it is helpful to make the following further distinctions: a matching rule, if it exists, is said to be **local** if a

finite atlas of configurations of unmarked tiles suffices to characterize the matching rule (as for the Penrose tiles in Figure 62.2.6 above), and *nonlocal* if the tiles of the atlas must be decorated to characterize the rule. The matching rules for the Ammann-Beenker tiling (see [GS87] and Figure 62.2.4) are nonlocal.

MAIN RESULTS

Given any aperiodic prototile set in $\mathbb{E}^2$, it is possible to construct a region homeomorphic to an annulus whose interior cannot be tiled with those prototiles [DS95]. (This property, well-known empirically to anyone who has ever played with Penrose tiles, is thus completely general; it follows that untileable “holes” in Penrose and other aperiodic tilings cannot be avoided by strengthening their matching rules.)

The proofs of the following results rely heavily on various theorems in discrete geometry, for example theorems of Helly type.

The atlas of face coronas of the Penrose tilings (Figure 62.2.6(b)) is a perfect local matching rule [deB96]; the Ammann-Beenker “octagonal” tiling does not have a local matching rule of any radius [Bur88].

Those generalized Penrose tilings for which $\vec{\gamma} \cdot \vec{w} \in \frac{1}{2} + \mathbb{Z}[\tau]$ are in the same mutually locally derivable class as the Penrose tilings, and hence are self-similar and have perfect, local, matching rules [Le97].

Nonlocal rules exist for all canonically projected tilings for which L is the integer lattice, $k = n$, and $\mathcal{E}$ is quadratic [LP93], and for all generalized Penrose tilings such that $\vec{\gamma} \cdot \vec{w} \in Q[\tau]$ [Le95].

OPEN PROBLEMS

Matching rules have been found for a large number of hierarchical tilings; in most cases, they are nonlocal. Do matching rules exist for all hierarchical tilings? Which are local and which are not?

Which tilings constructed by projection can be equipped with matching rules? Which are local and which are not?

62.3 SOURCES AND RELATED MATERIAL

SURVEYS

The following useful surveys contain a wealth of material, much of it beyond the scope of this chapter.

[DS91]: Essays, mostly by physicists, on various aspects of quasicrystals and quasicrystal models.

[Jar89]: A collection of introductory essays on tiling models for quasicrystals.

[AG95]: Proceedings of the conference “Beyond Quasicrystals” held in Les Houches, France, March, 1994.

[Sen96]: A monograph devoted to the geometry of quasicrystal models.

[Moo97]: Proceedings of the NATO Advanced Study Institute “Mathematics of Aperiodic Order,” held in Waterloo, Canada, August, 1995.

[BM00]: This volume is 2000 state-of-the art.

63 BIOLOGICAL APPLICATIONS OF COMPUTATIONAL TOPOLOGY

Herbert Edelsbrunner

INTRODUCTION

Structural molecular biology is a relatively recent application area for computational geometry and topology, but one with enormous potential. We currently observe a bipartition of computational research in this field: the *bioinformatics* branch focuses on strings, which are abstractions of the hereditary information stored in the DNA of living organisms, while the *molecular simulation* branch studies organic molecules in their natural three-dimensional habitat. Perhaps it is not surprising that the application of numerical algorithms is significantly more developed than that of geometric algorithms. One of the goals of this chapter is to raise the general consciousness about the importance of geometric methods in elucidating the mysterious foundations of our very existence. Another goal is the broadening of what we consider a geometric algorithm. There is plenty of valuable no-man's-land between combinatorial and numerical algorithms, and it seems opportune to explore this land with a computational-geometric frame of mind.

63.1 BIOMOLECULES

GLOSSARY

Central dogma: The proven claim that proteins are created in two steps by transcribing genes to RNA and translating RNA to protein.

FIGURE 63.1.1

The DNA gets replicated as a whole. Pieces of DNA referred to as genes are transcribed into pieces of RNA, which are then translated into proteins.

DNA: Deoxyribonucleic acid. The material that carries hereditary information. A double-stranded helix that encodes information into two antiparallel sequences of nucleotides.

Replication: Process in which the two strands of DNA are separated and both strands are complemented to form new double strands.

Genome: Complete set of genetic material of a living organism. For humans, it is divided into twenty-three *chromosomes*, each a long double strand of DNA.

Gene: Subsequence of DNA capable of being transcribed to produce a functional RNA molecule.

Transcription: Process in which the two strands of DNA are locally separated and one strand is copied to a piece of RNA.

RNA: Ribonucleic Acid. A single-stranded structure that is chemically almost identical to DNA.

Translation: Process in which a strand of RNA is read by the *ribosome* and translated into a protein.

Protein: A linear sequence of amino acids connected by peptide bonds.

Amino acid: Consists of a central carbon atom (C_α) linked to an amino group, a carboxyl group, one hydrogen atom, and a side chain. A *residue* is an amino acid whose $CC_\alpha N$ sequence is linked into the polypeptide chain of a protein.

Protein backbone: Polypeptide chain consisting of repeated $CC_\alpha N$ units. The bond between N and C is rigid, but the bonds connecting C_α to C and C_α to N can be rotated around the connecting edges.

Protein folding: Process in which a polypeptide chain folds up to a usually globular shape that is characteristic for the type of protein.

FROM DNA TO PROTEIN

Organic life is based on a surprisingly small number of molecule types. Most prominently, we have *DNA*, *RNA*, and *protein*. Each of them has the simple structure of a linear sequence consisting of a chain or backbone with attached side chains. DNA and RNA each uses an alphabet of only four nucleotides, while proteins use an alphabet of twenty amino acids. As discovered by Watson and Crick [WC53], the natural form of DNA consists of two sequences or strands that are held together by complementary nucleotide pairs. DNA has the ability to *replicate* itself, which is done by separating the two strands and complementing both with the matching strand made from free nucleotides in the surrounding solution. DNA is the memory of evolution that gives coherence to all living species; it forms the material basis of heredity as studied by Mendel in the nineteenth century [Men66]. Apparently, only a small fraction of the DNA in any organism represents used information. The used pieces are the *genes*, which are *transcribed* into RNA in a process similar to replication. RNA remains single-stranded and most of it gets *translated* into protein. This happens in the *ribosome*, which functions as a large molecular machine made of proteins and RNA molecules. A single strand of RNA is fed into the ribosome, and each triplet of nucleotides is translated into an amino acid, which is appended to the growing peptide chain. Upon completion, this chain leaves the ribosome as the final protein. This scenario is reminiscent of the Turing machine model of computing, in which information is read from an input tape and the results of the computations are printed on an output tape.

FROM SEQUENCE TO FUNCTION

When the protein leaves the ribosome, it folds up to form a shape that is characteristic for its sequence of amino acids. The proteins constitute the workforce

that maintains organic life. Specific proteins fulfill specific functions within the organism, and the particular shape it assumes is crucial:

$$\text{Sequence} \implies \text{Form} \implies \text{Function.}$$

This is why geometry is important in molecular biology. It is essential to learn the shapes of all proteins and to understand what is important about them. Most functions are tied up in the interaction of proteins with each other and with other molecules. The replication of DNA, the transcription to RNA, and the translation to protein are but three examples, and each is served by a complicated machine made of different proteins and RNA molecules. In other words, proteins are the pieces of a huge three-dimensional dynamic puzzle whose solution requires, among others things, a good understanding of the shapes involved. A major difficulty in the field of molecular biology is the miniscule scale of space and time at which the processes take place. The actors and their scripts are complicated and observations are indirect. Experimental work is generally complemented by computational simulations, which are referred to as theoretical work in this area.

63.2 GEOMETRIC MODELS

Proteins are complicated objects, which have been abstracted into a number of different models emphasizing different aspects of their behavior. We may think of them as curves in space modeling the backbone, or as collections of balls or spheres representing it at the level of individual atoms.

GLOSSARY

Space-filling diagram: Model that represents a protein by the space it occupies. Most commonly, each atom is represented by a ball (a solid sphere), and the protein is the union of these balls.

FIGURE 63.2.1

A short segment of a DNA double helix in space-filling representation. DNA uses an alphabet of four nucleotides: adenine (A), guanine (G), cytosine (C), and thymine (T). In the picture many of the nucleotides are barely visible since they are packed in the middle, using hydrogen bonds to hold the strands together.

Van der Waals surface: Boundary of space-filling diagram defined as the union of balls with *van der Waals radii*. The sizes of these balls are chosen to reflect the transition from an attractive to a repulsive van der Waals force.

Solvent-accessible surface: Boundary of space-filling diagram in which each van der Waals ball is enlarged by the radius of the solvent sphere. Alternatively, it is the set of centers of solvent spheres that touch but do not otherwise intersect the van der Waals surface.

Molecular surface: Boundary of the portion of space inaccessible to the solvent. It is obtained by rolling the solvent sphere about the van der Waals surface.

Power distance: Square length of tangent line segment from a point x to a sphere with center z and radius r . It is also referred to as the **weighted square distance** and formally defined as $\|x - z\|^2 - r^2$.

Voronoi diagram: Decomposition of space into convex polyhedra. Each polyhedron belongs to a sphere in a given collection and consists of all points for which this sphere minimizes the power distance. This decomposition is also known as the **power diagram** and the **weighted Voronoi diagram**.

Delaunay triangulation: Dual to the Voronoi diagram. For generic collections of spheres, it is a simplicial complex consisting of tetrahedra, triangles, edges, and vertices. This complex is also known as the **regular triangulation**, the **coherent triangulation**, and the **weighted Delaunay triangulation**.

Dual complex: Dual to the Voronoi decomposition of a union of balls. It is a subcomplex of the Delaunay triangulation.

FIGURE 63.2.2

Each Voronoi polygon intersects the union of disks in a convex set, which is the intersection with its defining disk. The drawing shows the Voronoi decomposition of the union and the dual complex superimposed.

Growth model: Rule for growing all spheres in a collection continuously and simultaneously. The rule that increases the square radius r^2 to $r^2 + t$ at time t keeps the Voronoi diagram invariant at all times.

Alpha complex: The dual complex at time $t = \alpha^2$ for a collection of spheres that grow while keeping the Voronoi diagram invariant. The **alpha shape** is the underlying space of the alpha complex.

Filtration: Nested sequence of complexes. The prime example here is the sequence of alpha complexes.

SPACE-FILLING DIAGRAMS

Our starting point is the *van der Waals force*, which is based on quantum mechanical effects. At short range up to a few Angstrom, the force is attractive but significantly weaker than covalent or ionic bonds. At very short range, the force is strongly repulsive. We may assign *van der Waals radii* to the atoms so that the force changes from attractive to repulsive when the corresponding spheres touch

[GR01]. The *van der Waals surface* is the boundary of the space-filling diagram made up of the balls with van der Waals radii. In the 1970s, Richards and collaborators extended this idea to capture the interaction of a protein with the surrounding solvent [LR71, Ric77]. The *solvent-accessible surface* is the boundary of the space-filling diagram in which the balls are grown by the radius of the sphere that models a single solvent molecule. Usually the solvent is water, represented by a sphere of radius 1.4 Angstrom. The *molecular surface* is obtained by rolling the solvent sphere over the van der Waals surface and filling in the inaccessible crevices and cusps. This surface is sometimes referred to as the **Connolly surface**, after the creator of the first software representing this surface by a collection of dots [Con83].

DUAL STRUCTURES

We complement the space-filling representations of proteins with geometrically dual structures. A major advantage of these dual structures is their computational convenience. We begin by introducing the *Voronoi diagram* of a collection of balls or spheres, which decomposes the space into convex polyhedra [Vor07]. Next we intersect the union of balls with the Voronoi diagram and obtain a decomposition of the space-filling diagram into convex *cells*. Indeed, these cells are the intersections of the balls with their corresponding Voronoi polyhedra. The *dual complex* is the collection of simplices that express the intersection pattern between the cells: we have a vertex for every cell, an edge for every pair of cells that share a common facet, a triangle for every triplet of cells that share a common edge, and a tetrahedron for every quadruplet of cells that share a common point [EKS83, EM94]. This exhausts all possible intersection patterns in the assumed generic case. We get a natural embedding if we use the sphere centers as the vertices of the dual complex.

GROWTH MODEL

One and the same Voronoi diagram corresponds to more than just one collection of spheres. For example, if we grow the square radius r_i^2 of the i th sphere to $r_i^2 + t$, for every i , we get the same Voronoi diagram. Think of t as time parametrizing this particular growth model of the spheres. While the Voronoi diagram remains fixed, the dual complex changes. The cells in which the balls intersect the Voronoi polyhedra grow monotonically with time, which implies that the dual complex can acquire but not lose simplices. We thus get a nested sequence of dual complexes,

$$\emptyset = K_0 \subset K_1 \subset \dots \subset K_m = D,$$

which begins with the empty complex at time $t = -\infty$ and ends with the Delaunay triangulation [Del34] at time $t = \infty$. We refer to this sequence as a *filtration* of the Delaunay triangulation and think of it as the dual representation of the protein at all scale levels.

63.3 MESHING

We introduce yet another surface bounding a space-filling diagram of sorts. The *molecular skin* is the boundary of the union of infinitely many balls. Besides

the balls with van der Waals radii representing the atoms, we have balls interpolating between them that give rise to blending patches and, all together, to a tangent-continuous surface. The molecular skin is rather similar in appearance to the molecular surface but uses hyperboloids instead of tori to blend between the spheres [Ede99]. The smoothness of the surface permits a mesh whose triangles are all approximately equiangular [CDES01]. Applications of this mesh include the representation of proteins for visualization purposes and the solution of differential equations defined over the surface by finite-element and other numerical methods.

GLOSSARY

Molecular skin: Surface of a molecule that is geometrically similar to the molecular surface but uses hyperboloid instead of torus patches for blending.

FIGURE 63.3.1

Cutaway view of the skin of a small molecule. We see a blend of sphere and hyperboloid patches. The surface is inside-outside symmetric: it can be defined by a collection of spheres on either of its two sides.

Mixed complex: Decomposition of space into shrunken Voronoi polyhedra, shrunken Delaunay tetrahedra, and shrunken products of corresponding Voronoi polygons and Delaunay edges as well as Voronoi edges and Delaunay triangles. It decomposes the skin surface into sphere and hyperboloid patches.

FIGURE 63.3.2

The skin curve defined by four circles in the plane. The mixed complex decomposes the curve into pieces of circles and hyperbolas.

Maximum normal curvature: The larger absolute value $\kappa(x)$ of the two principal curvatures at a point x of the surface.

ε -sampling: A collection S of points on the molecular skin M such that every point $x \in M$ has a point $u \in S$ at distance $\|x - u\| \leq \varepsilon/\kappa(x)$.

Restricted Delaunay triangulation: Dual to the restriction of the (three-dimensional) Voronoi diagram of S to the molecular skin M .

Shape space: Locally parametrized space of shapes. The prime example here is the $(k-1)$ -dimensional space generated by k shapes, each specified by a collection of spheres in $\mathbb{R}^3$.

TRIANGULATION

The molecular skin has geometric properties that can be exploited to construct a numerically high-quality mesh and to maintain that mesh during deformation. The most important of these is the continuity of the *maximum normal curvature* function $\kappa : M \rightarrow \mathbb{R}$. To define it, consider the 1-parameter family of geodesics passing through x and let $\kappa(x)$ be the maximum of their curvatures at x . We use this function to guide the local density of the points distributed over M that are used as vertices of the mesh. Given such a collection S of points, we construct a mesh using its Voronoi diagram restricted to M . The polyhedra decompose the surface into patches, and the mesh is constructed as the dual of that decomposition [Che93]. As proved in [ES97], the mesh is homeomorphic to the surface if the pieces of the restricted Voronoi diagram are topologically simple sets of the appropriate dimensions. In other words, the intersection of each Voronoi polyhedron, polygon, or edge with M is either empty or a topological disk, interval, or single point. Because of the smoothness of M , this topological property is implied if the points form an ε -sampling, with $\varepsilon = 0.279$ or smaller [CDES01].

DEFORMATION AND SHAPE SPACE

The variation of the maximum normal curvature function can be bounded by the one-sided Lipschitz condition $|1/\kappa(x) - 1/\kappa(y)| \leq \|x - y\|$, where the distance is measured in $\mathbb{R}^3$. The continuity over $\mathbb{R}^3$ and not just over M is crucial when it comes to maintaining the mesh while changing the surface. This leads us to the topic of deformations and shape space. The latter is constructed as a parametrization of the deformation process. The deformation from a shape A_0 to another shape A_1 can be written as $\lambda_0 A_0 + \lambda_1 A_1$, with $\lambda_1 = 1 - \lambda_0$. Accordingly, we may think of the unit interval as a one-dimensional shape space. We can generalize this to a k -dimensional shape space as long as the different ways of arriving at $(\lambda_0, \lambda_1, \dots, \lambda_k)$, with $\sum \lambda_i = 1$ and $\lambda_i \geq 0$ for all i , all give the same shape $A = \sum \lambda_i A_i$. How to define deformations so that this is indeed the case is explained in [CEF01].

63.4 CONNECTIVITY AND SHAPE FEATURES

Protein connectivity is often understood in terms of its covalent bonds, in particular along the backbone. In this section, we discuss a different notion, namely the topological connectivity of the space assigned to a protein by its space-filling diagram. We mention *homeomorphisms*, *homotopies*, *homology groups*, and *Euler characteristics*, which are common topological concepts used to define and talk about connectivity. Of particular importance are the homology groups and their ranks, the *Betti numbers*, as they lend themselves to efficient algorithms. In addition to computing the connectivity of a single space-filling diagram, we study how

the connectivity changes when the balls grow. The sequence of space-filling diagrams obtained this way corresponds to the filtration of dual complexes introduced earlier. We use this filtration to define basic shape features, such as pockets in proteins and interface surfaces between complexed proteins and molecules.

GLOSSARY

Topological equivalence: Equivalence relation between topological spaces defined by *homeomorphisms*, which are continuous bijections with continuous inverses.

Homotopy equivalence: Weaker equivalence relation between topological spaces $\mathbb{X}$ and $\mathbb{Y}$ defined by maps $f : \mathbb{X} \rightarrow \mathbb{Y}$ and $g : \mathbb{Y} \rightarrow \mathbb{X}$ whose compositions $g \circ f$ and $f \circ g$ are homotopic to the identities on $\mathbb{X}$ and on $\mathbb{Y}$.

Deformation retraction: A homotopy between the identity on $\mathbb{X}$ and a retraction of $\mathbb{X}$ to $\mathbb{Y} \subseteq \mathbb{X}$ that leaves $\mathbb{Y}$ fixed. The existence of the deformation implies that $\mathbb{X}$ and $\mathbb{Y}$ are homotopy-equivalent.

FIGURE 63.4.1

Snapshot during the deformation retraction of the space-filling representation of gramicidin to its dual complex. The spheres shrink to vertices while the intersection circles become cylinders that eventually turn into edges.

Homology groups: Quotients of cycle groups and their boundary subgroups. There is one group per dimension. The *k*th **Betti number**, β_k , is the rank of the *k*th homology group.

Euler characteristic: The alternating sum of Betti numbers: $\chi = \sum_{k \geq 0} (-1)^k \beta_k$.

Voids: Bounded connected components of the complement. Here, we are primarily interested in voids of space-filling diagrams embedded in $\mathbb{R}^3$.

Pockets: Maximal regions in the complement of a space-filling diagram that become voids before they disappear. Here, we assume the growth model that preserves the Voronoi diagram of the spheres.

Persistent homology groups: Quotients of the cycle groups at some time t and their boundary subgroups a later time $t + p$. The ranks of these groups are the **persistent Betti numbers**.

Protein complex: Two or more docked proteins. A complex can be represented by a single space-filling diagram of colored balls.

Molecular interface surface: Surface consisting of bichromatic Voronoi polygons that separate the proteins in the complex. The surface is retracted to the region in which the proteins are in close contact.

FIGURE 63.4.2

Molecular interface surface of the neurotoxic vipoxin complex. The surface has nonzero genus, which is unusual. In this case, we have genus equal to three, which implies the existence of three loops from each protein that are linked with each other. The linking might explain the unusually high stability of the complex, which remains for years in solution. The piecewise linear surface has been smoothed to improve visibility.

CLASSIFICATION

The connectivity of topological spaces is commonly discussed by forming equivalence classes of spaces that are connected the same way. Sameness may be defined as being homeomorphic, being homotopy-equivalent, having isomorphic homology groups, or having the same Euler characteristic. In this sequence, the classification gets progressively coarser but also easier to compute. Homology groups seem to be a good compromise as they capture a great deal of connectivity information and have fast algorithms. The classic approach to computing homology groups is algebraic and considers the incidence matrices of adjacent dimensions. Each matrix is reduced to *Smith normal form* using a Gaussian-elimination-like reduction algorithm. The ranks and torsion coefficients of the homology groups can be read off directly from the reduced matrices [Mun84]. Depending on which coefficients we use and exactly how we reduce, the running time can be anywhere between cubic in the number of simplices and exponential or worse.

INCREMENTAL ALGORITHM

Space-filling diagrams are embedded in $\mathbb{R}^3$ and enjoy properties that permit much faster algorithms. To get started, we use the existence of a deformation retraction from the space-filling diagram to the dual complex, which implies that the two have isomorphic homology groups [Ede95]. The embedding in $\mathbb{R}^3$ prohibits nonzero torsion coefficients [AH35]. We therefore limit ourselves to Betti numbers, which we compute incrementally, by adding one simplex at a time in an order that agrees with the filtration of the dual complexes. When we add a k -dimensional simplex σ , the k th Betti number goes up by one if σ belongs to a k -cycle, and the $(k-1)$ st Betti number goes down by one if σ does not belong to a k -cycle. The two cases can be distinguished in a time that, for all practical purposes, is constant per operation, leading to an essentially linear time algorithm for computing the Betti numbers of all complexes in the filtration [DE95].

PERSISTENCE

To get a handle on the stability of a homology class, we observe that the simplices that create cycles can be paired with the simplices that destroy cycles. The ***persistence*** is the time lag between the creation and the destruction [ELZ02]. The idea of pairing lies also at the heart of two types of shape features relevant in the study of protein interactions. A *pocket* in a space-filling diagram is a portion of the outside space that becomes a void before it disappears [Kun92, EFL98]. It is represented by a triangle-tetrahedron pair: the triangle creates a void and the tetrahedron is the last piece that eventually fills that same void. The *molecular interface surface* consists of all bichromatic Voronoi polygons of a protein complex. To identify the essential portions of this surface, we again observe how voids are formed and retain the bichromatic polygons inside pockets while removing all others [BER03]. A different geometric formalization of the same biochemical concept can be found in [VBR⁺95]. Preliminary experiments suggest that the combination of molecular interfaces and the idea of persistence can be used to predict the hot-spot residues in protein-protein interactions [Wel96].

63.5 DENSITY MAPS

Continuous maps over manifolds arise in a variety of settings within structural molecular biology. One is *X-ray crystallography*, which is the most common method for determining the three-dimensional structure of proteins [BJ76, Rho00]. While casting X-rays on a crystal of purified protein, we observe diffraction patterns, from which the electron density of the protein can be obtained via an inverse Fourier transform. Another setting is *molecular mechanics*, whose central object is the force field that drives atomic motions. We may, for example, be interested in the electrostatic potential induced by a protein and visualize it as a density map over three-dimensional space or over a surface embedded in that space. As a third setting, we mention the *protein docking* problem. Given two proteins, or a protein and a ligand, we try to fit protrusions of one into the cavities of the other [Con86]. We make up continuous functions related to the shapes of the surfaces and identify protrusions and cavities as local extremes of these functions. Morse theory is the natural mathematical framework for studying these maps [Mil63, Mat02].

GLOSSARY

Morse function: Generic smooth map on a manifold, $f : M \rightarrow \mathbb{R}$. In particular, the genericity assumption requires that all critical points be nondegenerate and have different function values.

Gradient, Hessian: The vector of first derivatives and the matrix of second derivatives.

Critical point: Point at which the gradient of f vanishes. It is *nondegenerate* if the Hessian is invertible. The *index* of a nondegenerate critical point is the number of negative eigenvalues of the Hessian.

Integral line: Maximal curve whose velocity vectors agree with the gradient of the Morse function. Two integral lines are either disjoint or the same.

Stable manifold: Union of integral lines converging to the same critical point.

We get **unstable manifolds** if we negate f and thus effectively reverse the gradient.

Morse-Smale complex: Collection of cells obtained by intersecting stable with unstable manifolds. We require f to be a **Morse-Smale function** satisfying the additional genericity assumption that these intersections are transversal.

FIGURE 63.5.1

Portion of the Morse-Smale complex of a Morse-Smale function over a 2-manifold. The solid stable 1-manifolds and the dashed unstable 1-manifolds are shown together with two dotted level sets. Observe that all two-dimensional regions of the complex are quadrangular.

Cancellation: Local change of the Morse function that removes a pair of critical points. Their indices are necessarily contiguous.

CRITICAL POINTS

Classic Morse theory applies only to generic smooth maps on manifolds, $f : M \rightarrow \mathbb{R}$. Maps that arise in practice are rarely smooth and generic, or, more precisely, the information we are able to collect about maps is rarely enough to go beyond a piecewise linear representation. To illustrate this point, we discuss critical points, which for smooth functions are characterized by a vanishing gradient: $\nabla f = 0$. If we draw a small circle around a noncritical point u on a 2-manifold, we get one arc along which the function takes on values less than $f(u)$ and a complementary arc along which the function is greater than or equal to $f(u)$. Call the former arc the **lower link** of u . We get different lower links for critical points: the entire circle for a *minimum*, two arcs for a *saddle*, and the empty set for a *maximum*. A typical representation of a piecewise linear map is a triangulation with function values specified at the vertices and linearly interpolated over the edges and triangles. The lower link of a vertex can still be defined and the criticality of the vertex can be determined from the topology of the lower link [Ban67].

MORSE-SMALE COMPLEXES

In the smooth case, each critical point defines a *stable manifold* of points that converge to it by following the gradient flow. Symmetrically, it defines an *unstable manifold* of points that converge to it by following the reversed gradient flow. These manifolds define decompositions of the manifold into simple cells [Tho49].

Extensions of these ideas to construct similar cell decompositions of manifolds with piecewise linear continuous functions can be found in [EHZ03]. In practice, it is essential to be able to simplify these decompositions, which can be done by canceling critical points in pairs in the order of increasing persistence [ELZ02].

63.6 MATCH AND FIT

Proteins can be similar in a variety of ways: they can have similar residue sequences, they can have backbones that are laid out similarly in space, and they can have similar shapes after folding. The first two notions are important in gaining insight into the evolutionary development of proteins. The corresponding computational problems are sequence alignment and structure alignment. The question of shape similarity, and, in particular, of partial shape similarity, is relevant in understanding the interaction between proteins and their substrates, which can be proteins or other molecules. Indeed, many interactions seem to require a high degree of partial shape complementarity, which we interpret as a high degree of partial shape similarity between the protein and the complement of its substrate.

GLOSSARY

Rigid motion: Orientation- and distance-preserving motion. The primary examples here are rigid motions of three-dimensional space, $\mu : \mathbb{R}^3 \rightarrow \mathbb{R}^3$. Each rigid motion can be decomposed into a rotation followed by a translation.

RMSD: Root-mean-square distance. Root of the average square distance between two sets of points with a given bijection.

Dynamic programming: Algorithmic paradigm which computes the optimum from precomputed optimal solutions to subproblems.

Sequence alignment: Collection of monotonically increasing maps to the integers, one per sequence. Each letter gets either matched or skipped.

Structure alignment: Collection of monotonically increasing maps to the integers, one per chain of points modeling a protein backbone.

Protein docking: Process in which a protein forms a complex with another molecule. The complex usually exists only temporarily and facilitates an interaction between the molecules.

STRUCTURE ALIGNMENT

There are two approaches to structure alignment. The first compares the matrices of internal sequences between the points [HS93]. We discuss only the second approach, which is a direct extension of the work on sequence alignments in bioinformatics [Gus97]. Instead of letters representing residues, we align points in space, which are the centers of the alpha carbon atoms along the two backbones. For decomposable score functions, we can find the optimal alignment with dynamic programming in time that is quadratic in the number of points. One such function suggested in [SLL93] penalizes unmatched points and, for every matched pair (u_i, v_j) , adds

$$\delta(u_i, v_j) = \frac{100}{5 + \|u_i - v_j\|^2}$$

to the score. The dynamic programming approach works only for two fixed sequences, and the six degrees of freedom we gain by allowing rigid motions complicate matters considerably. Nevertheless, it is possible to compute an approximation to the optimal alignment in time that is polynomial in the number of points and the tolerated error [KL02].

RIGID MOTIONS

Let $u_1, u_2, \dots, u_n$ and $v_1, v_2, \dots, v_n$ be two sequences of points in $\mathbb{R}^3$. For a given rigid motion μ , the *root-mean-square distance* between the sequences is

$$f(\mu) = \sqrt{\frac{1}{n} \sum_{i=1}^n \|u_i - \mu(v_i)\|^2}.$$

It is perhaps surprising that the dependence of f on μ can be expressed by a quadratic function which, in the generic case, has a unique local minimum. To describe the minimizing rigid motion, we decompose it into a translation followed by a rotation. Under the assumption that the centroid of the u_i lies at the origin, the optimum translation moves the centroid of the v_i to the origin, and the optimum rotation can be computed by solving a straightforward eigenvalue problem. One of the earliest references to this result is Kabsch [Kab78]. A lucid description of the proof using quaternions to represent rotations can be found in Horn [Hor87].

PROTEIN DOCKING

A good local geometric fit is a necessary condition for a complex between two or more proteins to be formed. There are, however, additional factors, such as electrostatic and hydrophobic forces. (Some side chains of proteins are attracted to water molecules, others repelled by them. The former are called ‘hydrophilic,’ the latter ‘hydrophobic.’ This turns out to be a significant factor in the protein folding process.) To further complicate the issue, proteins are somewhat flexible and can sometimes avoid otherwise prohibitive steric clashes [ESM01]. Taking all these factors into account seems prohibitive and most computational approaches to protein docking explore the space of rigid motions using relatively simple geometric score functions [HMWN02]. An example is the number of atoms in close but not too close distance from each other. The space of rigid motions is six-dimensional and exploring it is time-consuming, even with simple score functions. The idea of Connolly to use critical points of Morse functions to identify motions [Con86] seems promising, but is not yet fully explored. It is usually combined with geometric hashing to enumerate the motions suggested by the critical point patterns [NLWN94].

63.7 MEASURES AND DERIVATIVES

Computing the volume and the surface area of a space-filling diagram are two of the most fundamental means to characterize the geometry of a protein. To mention

a specific application, we consider the computation of the *solvation energy*, which is central in the simulation of folding and docking processes. Many simulations use *implicit solvent models* and describe the hydrophobic part of the solvation energy as a weighted sum of the accessible surface area or, alternatively, as a weighted sum of volumes. The weights are experimentally determined *solvation parameters* that assess the contributions of different atom types to the hydrophobic term [EM86]. A molecular dynamics simulation requires the weighted area or volume and its derivative in order to estimate the contribution of the hydrophobic term to the energy that drives the process.

GLOSSARY

Indicator function: Maps a point x to 1 if $x \in P$ and to 0 if $x \notin P$, where P is some fixed set. Here, we are interested in convex polyhedra P and can therefore use the alternating sum of the number of faces of various dimensions visible from x as indicator. (For further details, see [Ede95].)

Inclusion-exclusion: Principle used to compute the volume of a union of bodies as the alternating sum of volumes of k -fold intersections, for $k \geq 1$.

Stereographic projection: Mapping of the 3-sphere minus a point to the three-dimensional Euclidean space. The map preserves spheres and angles.

FIGURE 63.7.1

Stereographic projection from the north pole. The preimage of a circle in the plane is a circle on the sphere, which is the intersection of the sphere with a plane. By extension, the preimage of a union of disks is the intersection of the sphere with the complement of a convex polyhedron.

Atomic solvation parameters: Experimentally determined numbers that assess the hydrophobicity of different atoms.

Weighted volume: Volume of a space-filling diagram in which the contribution of each individual ball is weighted by its atomic solvation parameter. Also a function $V : \mathbb{R}^{3n} \rightarrow \mathbb{R}$ obtained by parametrizing a space-filling diagram by the coordinates of its n ball centers.

Weighted-volume derivative: The linear map $DV_{\mathbf{z}} : \mathbb{R}^{3n} \rightarrow \mathbb{R}$ defined by $DV_{\mathbf{z}}(\mathbf{t}) = \langle \mathbf{v}, \mathbf{t} \rangle$, where $\mathbf{z} \in \mathbb{R}^{3n}$ specifies the space-filling diagram, $\mathbf{t} \in \mathbb{R}^{3n}$ lists the coordinates of the motion vectors, and $\mathbf{v} = \nabla V(\mathbf{z})$ is the gradient of V at $\mathbf{z}$. It is also the map $DV : \mathbb{R}^{3n} \rightarrow \mathbb{R}^{3n}$ that maps $\mathbf{z}$ to $\mathbf{v}$.

GEOMETRIC INCLUSION-EXCLUSION

Work on computing the volume and the area of a space-filling diagram $F = \bigcup_i B_i$ can be divided into approximate [Row63] and exact methods [Ric74]. According to the principle of inclusion-exclusion, the volume of F can be expressed as an

alternating sum of volumes of intersections:

$$\text{vol } F = \sum_{\Lambda} (-1)^{\text{card } \Lambda + 1} \text{vol} \bigcap_{i \in \Lambda} B_i,$$

where Λ ranges over all nonempty subsets of the index set. The size of this formula is exponential in the number of balls, and the individual terms can be quite complicated. Most of the terms are redundant, however, and a much smaller formula based on the dual complex K of the space-filling diagram F has been given [Ede95]:

$$\text{vol } F = \sum_{\sigma \in K} (-1)^{\dim \sigma} \text{vol} \bigcap \sigma,$$

where $\bigcap \sigma$ denotes the intersection of the $\dim \sigma + 1$ balls whose centers are the vertices of σ . The proof is based on the Euler formula for convex polyhedra and uses stereographic projection to relate the space-filling diagram in $\mathbb{R}^3$ with a convex polyhedron in $\mathbb{R}^4$. Precursors of this result include the existence proof of a polynomial size inclusion-exclusion formula [Kra78] and the presentation of such a formula using the simplices in the Delaunay triangulation [NW92]. We note that it is straightforward to modify the formula to get the weighted volume: decompose the terms $\text{vol} \bigcap \sigma$ into the portions within the Voronoi cells of the participating balls and weight each portion accordingly.

DERIVATIVES

The relationship between the weighted- and unweighted-volume derivatives is less direct than that between the weighted and unweighted volumes. Just to state the formula for the weighted-volume derivative requires more notation than we are willing to introduce here. Instead, we describe the two geometric ingredients, both of which can be computed by geometric inclusion-exclusion [EK03]. The first ingredient is the area of the portion of the disk spanned by the circle of two intersecting spheres that belongs to the Voronoi diagram. This facet is the intersection of the disk with the corresponding Voronoi polygon. The second ingredient is the weighted average vector from the center of the disk to the boundary of said facet. The weight is the infinitesimal contribution to the area as we rotate the vector to sweep out the facet.

GEOMETRIC SOFTWARE

64 SOFTWARE

Michael Joswig

INTRODUCTION

This survey is intended as a guide through the ever growing jungle of geometry software. Software comes in many guises. There are the fully-fledged systems consisting of a hundred thousand lines of code which meet professional standards in software design and user support. But there are also the tiny code fragments scattered over the Internet which can nonetheless be valuable for research purposes. And, of course, the very many individual programs and packages in between.

Likewise today we find a wide group of users of geometry software. On the one hand, there are researchers in geometry, teachers, and their students. On the other hand, geometry software has found its way into numerous applications in the sciences as well as industry. Because it seems impossible to cover every possible aspect, we focus on software packages which are interesting from the researcher's point of view, and, to a lesser extent, from the student's.

This bias has a few implications. Most of the packages listed are designed to run on UNIX/Linux¹ machines. Moreover, the researcher's genuine desire to understand produces a natural inclination toward open source software. This is clearly reflected in the selection below. Major exceptions to these rules of thumb will be mentioned explicitly.

In order to keep the (already long) list of references as short as possible, in most cases only the Web address of each software package is listed rather than manuals and printed descriptions found elsewhere. At least for the freely available packages, this allows one to access the software directly. On the other hand, this may seem careless, since some Web addresses do not last long. This disadvantage usually can be compensated by relying on modern search engines.

The chapter is organized as follows. We start with a discussion of some technicalities (independent of particular systems). Since, after all, a computer is a technical object, the successful use of geometry software may depend on such things. The main body of the text consists of two halves. First, we browse through the topics of this handbook. Each of its major parts is linked to related software systems. Remarks on the algorithms are added mostly in areas where many implementations exist. Second, some of the software systems mentioned in the first part are listed in alphabetical order. We give a brief overview of some of their features. The libraries CGAL [F⁺02] and LEDA [led] are discussed in depth in [Chapter 65](#).

This survey is a snapshot as of Summer 2003. It is unlikely that it is complete in any sense. Even worse, the situation is changing so rapidly that the information given will be outdated soon. All this makes it almost impossible for the non-expert

¹No attempt is made to comment on differences between various UNIX platforms. Today's default UNIX is probably between Sun's Solaris and any Linux distribution. FreeBSD and its derivative MacOS X come quite close. Many (text-based) UNIX programs can also be ported to various flavors of Windows via Cygwin [cyg03].

to get any impression of what software is available. Therefore, this is an attempt to provide an overview in spite of the obvious complications.

Nina Amenta authored the chapter on software in the first edition of this Handbook. Although much has changed during the last five years, her chapter still provided a good starting point for this survey. Moreover, this version of the chapter benefits from her constructive criticism.

GLOSSARY

Software can have various forms from the technical point of view. In particular, the amount of technical knowledge which is required by the user to use software varies considerably. The notions explained below are intended as guidelines.

Stand-alone software: This is a program which usually comes “as-is” and can be used immediately if properly installed. No programming skills are required.

Libraries: A collection of software components which can be accessed by writing a main program that calls functions implemented in the library. Good libraries come with example code that illustrates how (at least some of) the functions can be used. However, in order to exploit all the features, the user is expected to do some programming work. On the other hand, libraries have the advantage that they can be integrated into existing code. Some stand-alone programs can also be used as libraries; if they appear in this category, too, then there are substantial differences between the two versions, or the library has additional functionality.

Modules for general-purpose systems: Computer algebra and symbolic computation systems like *Mathematica* [mat03a], *Maple* [map03], *Matlab* [mat03b], *MuPAD* [mup03], and *REDUCE* [H⁺99] are integrated systems with an elaborate user interface which incorporate numerous algorithms from essentially all areas of mathematics. In this survey only functionality or extensions are listed which the author finds particularly noteworthy.

Additional Web pages: There are very many software overviews on the Web. A few of them that are focused on a specific topic are mentioned in the main text. Sometimes these pages have additional pieces of source code which may be useful. A short list of more comprehensive Web pages is given further below.

GENERAL SOURCES

There are several major web sites which are of general interest to the discrete and computational geometry community. Some of them also collect references to software, which are updated more or less frequently. We mention Amenta’s “Directory of Computational Geometry Software” [Ame97], Eppstein’s “Geometry Junkyard” [Epp03b], and Erickson’s “Computational Geometry Code” [Eri99].

For each of the major general-purpose computer algebra systems there exists a Web site with many additional packages and individual solutions. See the Web addresses of the respective products.

For those who are beginning to learn how to develop geometry software it will probably be too hard to do so by reading the source code of mature systems only. O’Rourke’s book [O’R98] can help fill this gap. Its numerous example programs in

C and Java are also electronically available [O'R00].

"The Stony Brook Algorithm Repository" maintained by Skiena [Ski01] gives an extensive overview of algorithms from several areas. Section 1.6 is dedicated to computational geometry and it contains links to implementations.

Although aging, the **Graphics Gems** by Kirk, Heckberth, Paeth, and many others [KHP⁺95], remains a useful resource. The **Gems** form a large collection of C source code examples for basic (and some more advanced) problems in computational geometry and computer graphics, originally published in a series of books [Gla93, Kir92, Arv91, Hec94].

ARITHMETIC

Depending on the application, issues concerning the arithmetic used for implementing a geometric algorithm can be essential. Using any kind of exact arithmetic is expensive, but the overhead induced also strongly depends on the application. A principal choice for exact arithmetic is *unlimited precision integer* or *rational* arithmetic as implemented in the GNU **Multiprecision Library** (GMP) [gmp03]. However, some problems require nonrational constructions. To cover such instances libraries like **Core** [YD03] and **LEDA** ([led], Chapter 65) offer special data types which allow for exact computation with certain radical expressions.

Geometric algorithms often rely on a few primitives like: Decide whether a point is on a hyperplane or, if not, on which side. Thus exact coordinates for geometric objects are sometimes less important than their true relative position. It is therefore natural to use techniques like interval arithmetic. ***Floating-point filters*** can be understood as an improved kind of interval arithmetic which employs higher precision or exact methods if needed. For more detailed information see [Chapter 41](#).

Yet another arithmetic concept is the following: Compute with machine size integers but halt (or trigger an exception) if an overflow occurs. Typically such an implementation depends on the hardware and thus requires at least a few lines of assembler code. Useful applications for such an approach are situations where the overflow signals that the computation is expected to become too large to finish in any reasonable amount of time. For instance, **t_homology** from **polymake**'s [GJ03] **TOPAZ** module implements Smith-Normal-Form in this way. Similarly, **hull** [Clab] uses exact integer arithmetic for convex hull computation and signals an overflow.

Instead of using a form of exact arithmetic, some implementations perform combinatorial post-processing in order to repair flawed results coming from rounding errors. An example is the convex hull code **qhull** by Barber, Dobkin, and Huhdanpaa [BDH01b]. Usually, this is only partially successful; see the discussion on the corresponding Web page [BDH01a] in **qhull**'s documentation.

FURTHER TECHNICAL REMARKS

While the programming language in which a software package is implemented often does not affect the user, this can obviously become an issue for the administrator who does the installation. Many of the software systems listed below are distributed as source code written in C or C++. Additionally, some of the larger packages are offered as precompiled binaries for common platforms.

C is usually easy. If the source code complies with the ANSI standard, it should be possible to compile it with any C compiler. The situation is quite different for C++. In spite of the fact that there is also an ANSI C++ standard, this standard is considerably more involved and thus far more difficult for the compiler constructors to implement. In fact, *none* of the currently existing C++ compilers fully conforms with the standard. They differ quite a bit in how much and in what respect they deviate; the main issue is template code. Therefore, at the moment it is quite unreasonable to expect that modern C++ code can be compiled with every C++ compiler. To the contrary: For the successful installation of C++ libraries it is often of the utmost importance to use the proper compiler, as specified in the respective installation instructions.

64.1 SOFTWARE SORTED BY TOPIC

This section should give a first indication of what software to use for solving a given problem. The subsections reflect the overall structure of the whole Handbook. References to CGAL [F⁺02] and LEDA [led] usually are omitted, since these large projects are covered in detail in [Chapter 65](#).

64.1.1 COMBINATORIAL AND DISCRETE GEOMETRY

This section deals with software handling the combinatorial aspects of finitely many objects, such as points, lines, or circles, in Euclidean space. Polytopes are described in Section 64.1.2.

STAND-ALONE SOFTWARE

The simplest geometric objects are clearly points. Therefore, essentially all geometry software can deal with them in one way or another. A key concept to many nontrivial properties of finite point sets in $\mathbb{R}^d$ is the notion of an *oriented matroid*. For oriented matroid software and the computation of the set of all triangulations of a given point set see TOPCOM by Rambau [Ram03]. Bokowski's *omawin* [Bok99] can be used for low rank oriented matroid visualization. In order to have correct combinatorial results, arbitrary precision arithmetic is essential.

Stephenson's *CirclePack* [Ste02] can create, manipulate, store, and display circle packings.

Lattice points in convex polytopes are related to volume computations and, via Gröbner bases, to problems in commutative algebra. A specialized implementation in this area is *Erhart* by Clauss, Loechner, and Wilde [CLW99]. There is also *intpoint* by Emiris [Emi01] in the context of mixed volumes. Various volume computation algorithms for polytopes, using exact and floating point arithmetic, are implemented in *vinci* by Büeler, Enge, and Fukuda [BEF03].

Dynamic geometry software allows the creation of geometrical constructions from points, lines, circles, and so on, which later can be rearranged interactively. Objects depending, e.g., on intersections, change accordingly. Among other features, such systems can be used for visualization purposes and, in particular, also for working with polygonal linkages. Commercial products include Laborde

and Bellemain's **Cabri** [LB93] as well as **Cinderella** [RGK] by Kortenkamp and Richter-Gebert. Current dynamic geometry software systems seem to be restricted to planar constructions.

Graph theory certainly is a core topic in discrete mathematics and therefore naturally plays a role in discrete and computational geometry. There is an abundance of algorithms and software packages, but they are not especially well suited to geometry, and so they are skipped here. Often symmetry properties of geometric objects can be reduced to automorphisms of certain graphs. While the complexity status of the graph isomorphism problem remains open, McKay's **nauty** [McK03] works quite well for many practical purposes.

Theorem 14.2.3 establishes the existence of a center point in any Lebesgue measurable subset of $\mathbb{R}^d$. The discrete analogue has a nice approximative algorithmic solution [CEM⁺96] which has been implemented by Clarkson [Claa].

LIBRARIES

Ehrhart polynomials and integer points in polytopes are also accessible via Loecherer's **PolyLib** [Loe02].

MODULES FOR GENERAL PURPOSE SYSTEMS

Parts of **TOPCOM**'s [Ram03] functionality are also available in De Loera's **Maple** package **Puntos** [DL96].

ADDITIONAL WEB PAGES

Huson's Web page [Hus03] contains information on tilings and related software.

Circle packings are related to several other topics in discrete geometry and complex analysis. Boll maintains a Web page [Bol00] on the subject with additional code and many links.

For polyominoes, see Eppstein's Geometry Junkyard [Epp03a] and [Chapter 15](#).

The **LatTE** project by De Loera, Hemmecke et al. [LH⁺] offers an email service for computing lattice points in convex polytopes.

64.1.2 POLYTOPES AND POLYHEDRA

In this section we discuss software related to the computational study of convex polytopes. The distinction between polytopes and unbounded polyhedra is not essential since, up to a projective transformation, each polyhedron is the product of an affine subspace and a polytope.

A key problem in the algorithmic treatment of polytopes is the convex hull problem, which is addressed in the next section.

STAND-ALONE SOFTWARE

polymake [GJ03] is a comprehensive framework for dealing with polytopes in terms of vertex or facet coordinates as well as on the combinatorial level. The system offers a wide functionality which is augmented by interfacing to many other programs operating on polytopes. Among the combinatorial algorithms implemented is the recent method for enumerating all the faces of a polytope given in terms of the

vertex-facet incidences by Kaibel and Pfetsch [KP02].

Triangulations of polytopes can be rather large and intricate. Rambau's TOPCOM [Ram03] is primarily designed to examine the set of all triangulations of a given polytope (or arbitrary point configurations). Pfeifle and Rambau [PR03] combined TOPCOM with `polymake` to compute secondary polytopes; see also [Section 17.6](#).

The combinatorial equivalence of polytopes can be reduced to a graph isomorphism problem. As mentioned above, graph isomorphism can be checked by McKay's `nauty` [McK03].

The Geometry Center's `Geomview` [Geo02] and `JavaView` [PKP⁺02], by Polthier et al., can both be used for (much more than) the visualization of 3-polytopes and (Schlegel diagrams of) 4-polytopes.

LIBRARIES

`PolyLib` [Loe02] by Loechner is a library for working with rational polytopes; it is primarily designed for computing Ehrhart polynomials.

`polymake` [GJ03] comes with an C++ template library that is compatible with the `Standard Template Library` (STL). This allows one to access all the functionality, including the interfaced programs, from the programmer's own code. Further, the library offers a variety of container classes suitable for the manipulation of polytopes.

MODULES FOR GENERAL PURPOSE SYSTEMS

`convex` by Franz [Fra03] is a package for the investigation of rational polytopes and polytopal fans in `Maple`.

64.1.3 FUNDAMENTAL GEOMETRIC OBJECTS

The computation of convex hulls and Delaunay triangulations/Voronoi diagrams is of key importance. For correct combinatorial output it is crucial to rely on arbitrary-precision arithmetic. On the other hand, some applications, e.g., volume computation, are content with floating point arithmetic for approximate results. Some algorithmically more advanced but theoretically yet basic topics in this section are related to topology and real algebraic geometry.

In our terminology the *convex hull problem* asks for enumerating the facets of the convex hull of finitely many points in $\mathbb{R}^d$. The dual problem of enumerating the vertices and extremal rays of the intersection of finitely many halfspaces is equivalent by means of cone polarity. There is the related problem of deciding which points among a given set are extremal, that is, vertices of the convex hull. This can be solved by means of linear optimization.

STAND-ALONE SOFTWARE

`XYZGeoBench` for the Macintosh is an implementation of many fundamental algorithms by Schorn [Sch99]. For many of these algorithms there is an animated visualization.

Many convex hull algorithms are known, and there are several implementations. However, there is currently no algorithm for computing the convex hull which is

polynomial in the combined input and output size, unless the dimension is considered constant. The behavior of each known algorithm depends greatly on the specific combinatorial properties of the polytope on which it is working. One way of summarizing the computational results from Avis, Bremner, and Seidel [ABS97] and [Jos03] is: Essentially for each known algorithm there is a family of polytopes for which the given algorithm is superior to any other, and there is a second family for which the same algorithm is inferior to any other. For these families of polytopes we do have a theoretical, asymptotic analysis which explains the empirical results; see Chapter 22. Moreover, there are families of polytopes for which none of the existing algorithms performs well. Which algorithm or implementation works best for certain purposes will thus depend on the class of polytopes which is typical in those applications. For an overview of general convex hull codes see Table 64.1.1.²

Additionally, there are a few specialized codes: **Zerone** by Lübbecke [Lüb99] is designed to compute the vertices of a polytope with 0/1-coordinates from an inequality description by iteratively solving linear programs. There is a parallel computation version of **lrs** based on Marzetta's **ZRAM** library [Mar98]. The same library is also used in Fukuda's very recent code **rs_topo** [Fuk02] which enumerates (also in parallel) the vertices of a zonotope defined by a vector configuration.

TABLE 64.1.1 Overview of convex hull codes.

Exact arithmetic		
PROGRAM	ALGORITHM	REMARKS
beneath_beyond	Beneath-beyond method [Ede87, 8.3.1]	Part of polymake [GJ03] Dimension ≤ 3
cddr+ [Fuk03a]	Dual Fourier-Motzkin elimination [Zie95, 1.2]	
ch3d [Emi01]	Beneath-beyond method	
lrs [Avis01]	Reverse search [AF92]	
porta [CL03]	Fourier-Motzkin elimination	
pd [Mar97]	Primal-dual method [BFM98]	
Non-exact arithmetic		
PROGRAM	ALGORITHM	REMARKS
2dch [Cla96]	Horizontal sweep	dimension 2 Assumes input in gen. pos.; Exact computation unless Overflow signaled
cddf+ [Fuk03a]	Dual Fourier-Motzkin elimination	
chD [Emi01]	Beneath-beyond method	
hull [Clab]	Randomized incremental [CMS93]	
qhull [BDH01b]	Quickhull [BDH96]	

The computation of Delaunay triangulations in d dimensions can be reduced to a $(d+1)$ -dimensional convex hull problem; see Section 23.1. Thus, in principle, each of the convex hull implementations can be used to generate Voronoi diagrams. Additionally, however, some codes directly support Voronoi diagrams, no-

²We call an implementation *exact* if it, intentionally (but there may be programming errors, of course), gives correct results for *all* possible inputs. The non-exact convex hull codes use floating-point arithmetic or more advanced methods, but for each of them input is known which makes them fail. The quality of the output of the non-exact convex hull codes varies considerably.

tably Clarkson’s `hull` [Clab], `qhull` by Barber, Dobkin, and Huhdanpaa [BDH01b], and, among the programs with exact rational arithmetic, `lrs` by Avis [Avis01].

The following codes are specialized for 2-dimensional Voronoi diagrams: Shewchuk’s `Triangle` [She96] and Fortune’s `voronoi` [For01]. See also `cdt` by Lischinski [Lis98] for incremental constrained 2-dimensional Delaunay triangulation. For 3-dimensional problems there is `Detri` by Mücke [Müc95] and `tess` by Hazlewood [Haz94]. Delaunay triangulations and, in particular, constrained Delaunay triangulations, play a significant role in meshing. Therefore, several of the Voronoi/Delaunay packages also have features for meshing and vice versa.

Alpha shapes form a technique to describe subsets of Euclidean space by means other than convex hulls of finitely many points (Chapter 63). There is a dedicated software package named `Alpha shapes` by Fu, Edelsbrunner et al. [FE⁺96] which deals with 2- and 3-dimensional alpha shapes in exact arithmetic. `hull` computes alpha shapes in arbitrary dimension.

For the special case of triangulating a simple polygon (Chapter 26), there is Seidel’s randomized algorithm with almost linear running time. The implementation by Narkhede and Manocha is part of the `Graphics Gems` [KHP⁺95, Part V]. This archive and also Skiena’s collection of algorithms [Ski01] contain more specialized code and algorithms for polygons.

Mesh generation is a vast area with numerous applications; see Chapter 25. This is reflected by the fact that there is an abundance of commercial and noncommercial implementations. We mention only a few. From the theoretical point of view the main categories are formed by 2-dimensional triangle meshes, 2-dimensional quadrilateral meshes, 3-dimensional tetrahedral meshes, 3-dimensional cubical (also called hexahedral) meshes, and other structured meshes. A focus on the applications leads to entirely different categories, which here is completely ignored. `Triangle` produces triangle meshes. `QMG` is a program for quadtree/octree 2- and 3-dimensional finite element meshing written by Vavasis [Vav00]. `CUBIT` [cub03] can do many different variants of 2- and 3-dimensional meshing; it is a commercial product which is free for scientific use. Note that, depending on the context, triangle or tetrahedra meshes are also called triangulations.

In applications geometric objects are sometimes given as point clouds meant to represent a curve or surface. With the introduction of 3D-scanners and similar devices, appropriate techniques and related software became increasingly important. Obviously, this problem is directly related to mesh generation. `Cocone` by Dey et al. [DGG⁺02] and `PowerCrust` by Amenta, Choi, and Kolluri [ACK02] are designed to produce “water tight” surfaces; see Chapter 30. `Studio` [stu02] is a commercial product dedicated to generating meshes from 3D-scans.

`VisPak` by Wismath et al. [W⁺98] is built on top of `LEDA` and can be used for the generation of visibility graphs of line segments and several kinds of polygons.

Smallest enclosing balls of a point set in arbitrary dimension can be computed with Gärtner’s `Miniball` [Gär99b].

Recent years saw an increasing use of methods from combinatorial topology in discrete and computational geometry. A basic operation is to compute the homology of a finite simplicial complex. Although polynomial time methods (in the size of the boundary matrices) are known for most problems, the (worst case exponential) elimination methods seem to be superior in practice; see Dumas et al. [HDSW03]. Implementations include `homology` by Heckenbach [Hec98] (see also the more recent implementation as a GAP package by Dumas et al. [DHS⁺03]) and `t_homology` which is part of `polymake`’s [GJ03] combinatorial topology module `TOPAZ`.

As for the opposite direction, more computational tools become available for the study of topological objects: Lutz's **BISTELLAR** [Lut02] is the implementation of a heuristic approach to find (vertex) minimal triangulations of a given space by applying bistellar flips. **SnapPea** by Weeks [Wee00] is a program for creating and examining hyperbolic 3-manifolds. **Geomview**'s [Geo02] extension package **Maniview** can be used to visualize 3-manifolds from within.

The computer algebra system **Magma** by Cannon et al. [C⁺03] has some support for real algebraic geometry. Visualization of curves and surfaces can be done with **surf** by Endrass [End03] and **spicy** [Lab03] by Labs.

LIBRARIES

cddlib [Fuk03b] and **lrslib** [Avi01] are the C library versions of Fukuda's **cdd** and Avis' **lrs**, respectively. They offer exact convex hull computation and exact linear optimization. **cddlib** uses the **GMP** [gmp03] arithmetic, while **lrslib** can be compiled with **GMP** arithmetic, but also has its own implementation. **polymake**'s [GJ03] functionality is available as a C++ library. This includes interfaces to **cdd/cddlib** and **lrs/lrslib**.

There is a C library version of **qhull** [BDH01b] which performs convex hulls and Voronoi diagrams in floating point arithmetic. Moreover, **cddlib** and **polymake** also have a limited support for floating point arithmetic.

The computation of Voronoi diagrams, arrangements, and related information is a particular strength of **CGAL** [F⁺02] and **LEDA** [led]. See [Chapter 65](#).

For triangle meshes in $\mathbb{R}^3$ there is the **GNU Triangulated Surface Library** [gts03] written in C. Its functionality comprises dynamic Delaunay and constrained Delaunay triangulations, robust set operations on surfaces, and surface refinement and coarsening for the control of level-of-detail.

Bhaniramka and Wenger have a set of C++ classes for the construction of isosurface patches in convex polytopes of arbitrary dimension [BW03]. These can be used in marching cubes like algorithms for isosurface construction.

MODULES FOR GENERAL PURPOSE SYSTEMS

Plain **Maple** [map03] and **Mathematica** [mat03a] only offer 2-dimensional convex hulls and Voronoi diagrams. Higher dimensional convex hulls can be computed via the **Maple** package **convex** [Fra03].

Mitchell [Mit] has implemented some of his algorithms related to mesh generation in **Matlab** [mat03b]. The finite element meshing program **QMG** by Vavasis can also be used with **Matlab**.

The **REDUCE** [H⁺99] package **REDLOG** by Dolzmann and Sturm [DS99] can do quantifier elimination over the reals (and other domains).

ADDITIONAL WEB PAGES

Emiris maintains a Web page [Emi01] with several programs which address problems related to convex hull computations and applications in elimination theory.

Web based surface reconstruction is available from INRIA's project page [CSD02].

A Web page [Owe03] by Owen contains a quite comprehensive survey on software related to meshing. See also Schneiders' page [Sch].

Morris provides interactive visualization of algebraic surfaces on-line: The pro-

gram **SingSurf** [Mor03] uses **JavaView** [PKP⁺02] for the visualization.

The recently announced **EXACUS** project [M⁺02a] deals with the exact computation of arrangements of planar algebraic curves as well as surfaces in $\mathbb{R}^3$. Currently there are only partial prototype implementations.

64.1.4 GEOMETRIC DATA STRUCTURES AND SEARCHING

LIBRARIES

Geometric data structures form the core of the C++ libraries **CGAL** [F⁺02] and **LEDA** [led]. The algorithms implemented include several different techniques for point location, collision detection, and range searching. See [Chapter 65](#).

As already mentioned above, graph theory plays a role for some of the more advanced geometric algorithms. Several libraries for working with graphs have been developed over the years. It is important to mention in this context the **Boost Graph Library** [SLL02]. This is part of a general effort to provide free peer-reviewed portable C++ source libraries which extend the **STL**.

ZRAM by Marzetta [Mar98] is a library of parallel search algorithms and the corresponding data structures. The implementation is application-independent and machine-independent. It is used in parallel versions of the convex hull codes **lrs** by Avis [Avi01] and **rs.tope** (for zonotopes) by Fukuda [Fuk02].

64.1.5 APPLICATIONS

Applications of computational geometry are abundant and so are the related software systems. Here we list only very few items which may be of interest to a general audience.

STAND-ALONE SOFTWARE

For linear programming problems, essential choices for algorithms include Simplex type algorithms or interior point methods. While commercial solvers tend to offer both, the freely available implementations seem to be restricted to either one. Additionally, there are implementations of a few special algorithms for low dimensions which belong to neither category.

Exact rational linear programming can be done with **cdd** [Fuk03a]. It uses either a dual simplex algorithm or the criss-cross method. An alternative exact linear programming code is **lrs** [Avi01] which implements a primal simplex algorithm.

SoPlex by Wunderling et al. [W⁺02] implements the revised Simplex algorithm both in primal and dual form. For an implementation of interior point methods see **PCx** by Czyzyk et al. [CMW⁺98]. These codes rely on floating-point arithmetic.

CPLX [cpl02], **OSL** [osl01], and **XPress** [xpr03] are widespread commercial solvers for linear, integer, and mixed integer programming. Each program offers a wide range of optimization algorithms. However, none of the commercial products can do exact rational linear optimization.

Clarkson's **opt** [Cla95] is the floating point implementation of a Las Vegas type algorithm which runs in expected linear time (for fixed dimension). See also Hohmeyer's code **linprog** [Hoh96] for an implementation of Seidel's algorithm.

These algorithms are described in Section 45.4.

Another topic with many applications is graph drawing. **GraphViz** [gra02] is an extensible package which offers tailor made solutions for a wide range of applications in this area. **Tulip** [AB⁺03] specializes in the visualization of large graphs. For commercial graph drawing software see **yFiles** [yfi03]; previous versions of yFiles used the **LEDA** and **AGD** [M⁺02c] libraries.

LIBRARIES

cddlib [Fuk03b] and **lrs** offer C libraries for exact LP solving. **CPLEX**, **OSL**, **PCx**, and **XPress** can also be used as C libraries, while **SoPlex** has a C++ library version. Other free C libraries for linear and mixed integer programming include **GLPK** [Mak03] and **lpsolve** [Ber03].

AGD [M⁺02c] and **GDToolkit**[gdt00] both are C++ libraries for graph drawing which are built on top of **LEDA**. Both are free for academic use.

In order to meet certain quality criteria post-processing of mesh data is important. **QSLim** by Garland [Gar99a] is a C++ library for the automatic simplification of polygonal surfaces with the goal to reduce the number of polygons.

MODULES FOR GENERAL PURPOSE SYSTEMS

The linear optimization package **PCx** comes with an interface to **Matlab** [mat03b].

ADDITIONAL WEB PAGES

For more information about linear programming there is an FAQ [Fou03] maintained by Fourer.

Recently, IBM started to foster various open source software projects; see the COIN Web page [coi] for optimization related software packages.

One of the topics related to computational geometry that we have not discussed in this survey is computer graphics. We refer the reader to O'Rourke's FAQ for the Usenet newsgroup **comp.graphics.algorithms** [O'R03].

The **Prisme** project [B⁺01] studies a variety of applications of computational geometry methods. **Galaad** [M⁺02b] is a related project with a focus on curves and surfaces. See also **EXACUS** [M⁺02a].

64.2 FEATURES OF SELECTED SOFTWARE SYSTEMS

All the software packages listed here have been mentioned previously. In many cases, however, we list features not accounted for so far.

AGD [M⁺02c]: C++ library for graph drawing based on **LEDA**. **AGD** offers many different layout algorithms, including planarization based methods, planar straight-line methods, hierarchical layouts, and various specialized applications. Graph layout visualization possible via **Graphlet** [B⁺99], **LEDA/GraphWin**, and other systems. Free for academic use. Also available for Windows 95/98/NT.

Boost Graph Library [SLL02]: C++ library for graphs and graph algorithms. The library is *generic* in the sense that the implementations of the algorithms do not rely on specific implementation details of the data structures. It is developed

in the spirit of the **Standard Template Library** (STL) as described in the ANSI C++ Standard. Similar software design concepts are used in **CGAL** and **polymake**.

cdd [Fuk03a, Fuk03b]: convex hull code which is based on the double description method which is dual to Fourier-Motzkin elimination. It also implements a dual simplex algorithm and the criss-cross method for linear optimization. **cdd** comes as a stand-alone program; its C library version is called **cddlib**. The user can choose between exact rational arithmetic (based on the **GMP**) or floating point arithmetic.

Cinderella [RGK]: commercial dynamic geometry software written in Java. It supports standard constructions with point, lines, and quadrics. **Cinderella** is based on a sound mathematical model by computing in the complex projective plane. Special features include loci of moving points which are constrained by a geometric construction and a randomized theorem prover. Runs on platforms supporting Java. Constructions can be integrated into Web pages as applets.

Cocone [DGG⁺02] is a set of programs related to the reconstruction of surfaces from point clouds in $\mathbb{R}^3$ via discrete approximation to the medial axis transform: **Tight Cocone** produces “water-tight” surfaces from arbitrary input, while **Cocone/SuperCocone** is responsible for detecting the surface’s boundary. **Geomview** output. Based on **CGAL** and **LEDA**. Not available for commercial use.

Computational Geometry in C [O’R98, O’R00]: collection of C and Java programs including 2- and 3-dimensional convex hull codes, Delaunay triangulations, and segment intersection.

CUBIT [cub03] is a commercial meshing tool for surfaces and 3-dimensional objects to be used in finite element analysis. Mesh generation algorithms include quadrilateral and triangular paving, 2- and 3-dimensional mapping, hex sweeping and multi-sweeping, and others. There is also a Windows version. Free for noncommercial research.

Geomview [Geo02] is a tool for interactive visualization. It can display objects in hyperbolic and spherical space as well as Euclidean space. **Geomview** comes with several external modules for specific visualization purposes. The user can write additional external modules in C. **Geomview** can be used as a visualization back end, e.g., for **Maple** [map03] and **Mathematica** [mat03a]. The extension package **Maniview** can visualize 3-manifolds.

GraphViz [gra02]: package with various graph layout tools. This includes hierarchical layouts and spring embedders. The system comes with a customizable graphical interface. Also runs on Windows.

GMP [gmp03]: The **GNU Multiprecision Library** is the standard implementation for long integer, exact rational, and arbitrary precision floating-point arithmetic. Four different algorithms for the multiplication of integers are implemented including the asymptotically optimal method due to Schönhage and Strassen [SS71, Sch82]. Highly optimized back-ends for many common microprocessors written in assembler.

hull [Clab] computes the convex hull of a point set in general position. The program can also compute Delaunay triangulations, alpha shapes, and volumes of Voronoi regions. The program uses exact machine floating-point arithmetic, and it signals overflow. **Geomview** output.

JavaView [PKP⁺02]: visualization package for Euclidean, spherical, and hyperbolic space which — as the name suggests — is written in **Java**. Wide functionality with a focus on applications in differential geometry. There is also an applet version **jav_lite** which allows for interactive visualization embedded in HTML pages. **JavaViewLib** is an add-on package for interfacing with **Maple**. Likewise, access to **Mathematica** is supported via **J/Link**. Runs on platforms supporting **Java**.

lrs [Avi01]: convex hull code based on the reverse search algorithm due to Avis and Fukuda [AF92]. Exact rational arithmetic, e.g. via the **GMP**. In addition to convex hull computations, **lrs** can do linear optimization (via a primal Simplex algorithm), volume computation, and Voronoi diagrams. Also comes as a C library.

nauty [McK03] can compute a permutation group representation of the automorphism group of a given finite graph. As one interesting application this gives rise to an effective method for deciding whether two graphs are isomorphic or not. Such a check for isomorphism can be performed directly.

PolyLib [Loe02] — a library of polyhedral functions. Allows for basic geometric operations on parametrized polyhedra. As a key feature **PolyLib** can compute Ehrhart polynomials, which permits counting the number of integer points in a given polytope.

polymake [GJ03] is a system for examining the geometrical and combinatorial properties of polytopes. It offers convex hull computation, standard constructions, and visualization. Some of the functionality relies — via interfaces — on external programs including **cdd**, **Geomview**, **Graphlet**, **JavaView**, and **lrs**. STL compatible C++ library; computations in exact rational arithmetic based on **GMP**. Separate module **TOPAZ** for simplicial complexes. Its functionality so far includes simplicial homology computation and intersection forms of 4-manifolds.

Power Crust [ACK02] performs surface reconstruction via a discrete approximation of the medial axis transform. The key concept for the algorithm are *power diagrams*, which are certain weighted Voronoi diagrams. **PowerCrust** uses **hull** for Voronoi diagrams, and it offers **Geomview** output.

qhull [BDH01b] computes convex hulls, Delaunay triangulations, Voronoi diagrams, furthest-site Delaunay triangulations, and furthest-site Voronoi diagrams. The algorithm implemented is Quickhull [BDH96]. **qhull** uses floating-point arithmetic only, but the authors incorporated several heuristics to improve the quality of the output. This is discussed in detail on a special Web page [BDH01a] in **qhull**'s documentation; it is an important source for everyone interested in using or implementing computational geometry software based on floating-point arithmetic.

SoPlex [W⁺02] — The sequential object-oriented simplex (C++) class library. Also available as stand-alone. **SoPlex** implements the revised Simplex linear optimization algorithm in primal and dual form.

TOPCOM [Ram03]: package for examining point configurations via oriented matroids. The main purpose is to investigate the set of all triangulations of a given point configuration. Symmetric point configurations can be treated more efficiently if the user provides information about automorphisms. **TOPCOM** can check whether a given triangulation is regular.

Triangle [She96] produces 2-dimensional meshes. It generates exact Delaunay triangulations, constrained Delaunay triangulations, and quality conforming Delaunay triangulations. The latter can be generated while avoiding small angles, and are thus suitable for finite element analysis. There is an add-on **ShowMe** for the visualization of triangulations.

vinci [BEF03] can be seen as an experimental framework for comparing volume computation algorithms. Exact and floating-point arithmetic. Implemented are Cohen & Hickey-triangulations [CH79], Delaunay triangulations (via **cdd** or **qhull**), and others.

XYZGeoBench [Sch99] is an interactive program for the Apple Macintosh (OS version $\geq 6.0.5$). Many basic algorithms for planar (and a few higher-dimensional) problems are implemented and can be animated.

65 TWO COMPUTATIONAL GEOMETRY LIBRARIES: LEDA AND CGAL

Lutz Kettner and Stefan Näher

INTRODUCTION

In the last decade, two major software libraries that support a wide range of geometric computing have appeared: LEDA, the **L**ibrary of **E**fficient **D**ata **T**ypes and **A**lgorithms, and CGAL, the **C**omputational **G**eometry **A**lgorithms **L**ibrary. We start with an introduction of common aspects of both libraries and major differences. We continue with two sections that describe each library in detail.

Both libraries are written in C++. LEDA is based on the object-oriented paradigm and CGAL is based on the generic programming paradigm. They provide a collection of flexible, efficient, and correct software components for computational geometry. Users should be able to easily include existing functionality into their programs. Additionally, both libraries have been designed to serve as platforms for the implementation of new algorithms.

Of course, correctness is of crucial importance for a library, even more so in the case of geometric algorithms where correctness is harder to achieve than in other areas of software construction. Two well-known reasons are the *exact arithmetic assumption* and the *nondegeneracy assumption* that are often used in computational geometry algorithms. However, both assumptions usually do not hold: floating point arithmetic is not exact and inputs are frequently degenerate. See [Chapter 41](#) for details.

EXACT ARITHMETIC

There are basically two scientific approaches to the exact arithmetic problem. One can either design new algorithms that can cope with inexact arithmetic or one can use exact arithmetic. Instead of requiring the arithmetic itself to be exact, one can guarantee correct computations if the so-called *geometric primitives* are exact. So, for instance, the predicate for testing whether three points are collinear must always give the right answer. This allows an efficient implementation of these exact primitives by using floating-point filters or lazy evaluation techniques.

This approach is known as exact geometric computing paradigm and both libraries, LEDA and CGAL, advocate this approach. However, they also offer straight floating point implementations.

DEGENERACY HANDLING

An elegant (theoretical) approach to the degeneracy problem is *symbolic perturbation*. However, this method of forcing input data into general position can cause

some serious problems in practice. In many cases, it increases the complexity of (intermediate) results considerably; and furthermore, the final limit process turns out to be difficult in particular in the presence of combinatorial structures. For this reason, both libraries follow a different approach. They cope with degeneracies directly by treating the degenerate case as the “normal” case. This approach proved to be effective for many geometric problems.

However, symbolic perturbation is used in some places. For example, in CGAL the 3D Delaunay triangulation uses it to realize consistent point insert and removal functions in the degenerate case of more than four points on a sphere [DT03].

LIBRARY STRUCTURE

CGAL and LEDA both support a style of coding which we call *geometric programming*. This is a type of higher level programming that deals with geometric objects and their corresponding primitives rather than working directly on coordinates or numerical representations. In this way the machinery for solving the exact arithmetic problem can be encapsulated in the implementation of the basic geometric operations.

COMMON ROOTS AND DIFFERENCES

LEDA is a general-purpose library of algorithms and data structures, whereas CGAL is focused on geometry. They have a different look and feel and different design principles, but they are compatible with each other and can be used together. A LEDA user can benefit from more geometry algorithms in CGAL, and a CGAL user can benefit from the exact number types and graph algorithms in LEDA, as will be detailed in the individual sections on LEDA and CGAL. There are also joint developments that work with both libraries, e.g., GeoWin for visualization and demos [BN02].

CGAL started six years after LEDA. CGAL learned from the successful decisions and know-how in LEDA (also supported by the fact that LEDA’s founding institute is also a partner in developing CGAL). So CGAL followed LEDA in priority on correctness, geometric programming style, and layout principles for the reference manuals.

The later start allowed CGAL to rely on a better C++ language support, e.g., with templates and traits classes, which led the developers to adopt successfully the new *generic programming paradigm* and shift the design focus more toward flexibility.

A successful spin-off company¹ has been created around LEDA. After an initial free licensing for academic institutions, all LEDA licenses are now fee-based.

A new spin-off company² has been created around CGAL. CGAL also started with a free academic license, but has in contrast now moved with the CGAL release 3.0 to a dual license model with a free open-source license and a commercial license for companies that do not want their developments to become open source.

²GeometryFactory Sarl <www.geometryfactory.com>.

GLOSSARY

Exact arithmetic: Foundation layer of the *exact computation paradigm* in computational geometry software that builds correct software layer by layer. Exact arithmetic can be as simple as a built-in integer type as long as its precision is not exceeded or can involve more complex number types, such as, `leda::real` from LEDA [BFMS00] or `Expr` from CORE [KLPY99].

Floating point filter: Technique to speed up exact computations for common easy cases; a fast floating-point interval arithmetic is used unless the error intervals overlap, in which case the computation is repeated with exact arithmetic.

Coordinate representation: Cartesian and homogeneous coordinates are supported by both libraries. Homogeneous coordinates are used to optimize exact rational arithmetic with a common denominator, and not for projective geometry.

Geometric object: Atomic part of a geometric kernel. Examples are points, segments, lines, and circles in the 2D case, and planes, tetrahedra, and spheres in the 3D case. The corresponding data types have value semantics; variants with and without reference-counted representations exist.

Predicate: Geometric primitive returning a value from a finite domain that expresses a geometric property of the arguments (geometric objects), for example, `CGAL::do_intersect(p,q)` returning a Boolean or `leda::orientation(p,q,r)` returning the sign of the area of the triangle (p,q,r) . A *filtered predicate* uses a floating-point filter to speed up computations.

Construction: Geometric primitive constructing a new object, such as the point of intersection of two straight lines.

Geometric kernel: The collection of geometric objects together with the related predicates and constructions. A *filtered kernel* uses filtered predicates.

Program checkers: Technique for writing programs that check their work. A checker for a program computing a function f takes an instance x and an output y . It returns true if $y = f(x)$ and false, otherwise.

65.1 LEDA

LEDA aims at being a comprehensive software platform for the entire area of combinatorial and geometric computing. It provides a sizable collection of data types and algorithms. This collection includes most of the data types and algorithms described in the textbooks of the area ([AHU74, Meh84, Tar83, CLR90, O'R98, Woo93, Sed91, Kin90, van88, NH93]). LEDA supports a broad range of applications. It has already been used in such diverse areas as code optimization, VLSI design, graph drawing, graphics, robot motion planning, traffic scheduling, geographic information systems, machine learning, and computational biology.

The LEDA project was started in the fall of 1988 by Kurt Mehlhorn and Stefan Näher. The first six months was devoted to the specification of different data types and on selecting the implementation language. At that time the item concept

arose as an abstraction of the notion “pointer into a data structure.” Items provide direct and efficient access to data and are similar to iterators in the standard template library. The item concept worked successfully for all test cases and is now used for most data types in LEDA. Concurrently with searching for the correct specifications, several languages were investigated for their suitability as an implementation platform. Among the candidates were Smalltalk, Modula, Ada, Eiffel, and C++. The language had to support abstract data types and type parameters (genericity) and should be widely available. Based on the experiences with different example programs, C++ was selected because of its flexibility, expressive power, and availability.

We next discuss some of the general aspects of the LEDA system.

EASE OF USE

The LEDA library is easy to use. In fact, only a small fraction of the users are algorithms experts and many users are not even computer scientists. For these users the broad scope of the library, its ease of use, and the correctness and efficiency of the algorithms in the library are crucial. The LEDA manual [MNSU] gives precise and readable specifications for the data types and algorithms mentioned above. The specifications are short (typically not more than a page), general (so as to allow several implementations) and abstract (so as to hide all details of the implementation).

EXTENSIBILITY

Combinatorial and geometric computing is a diverse area and hence it is impossible for a library to provide ready-made solutions for all application problems. For this reason it is important that LEDA is easily extensible and can be used as a platform for further software development. In many cases LEDA programs are very close to the typical textbook presentation of the underlying algorithms. The goal is the equation: *Algorithm + LEDA = Program*.

LEDA *extension packages* (LEPs) extend LEDA into particular application domains and areas of algorithmics not covered by the core system. LEDA extension packages satisfy requirements, which guarantee compatibility with the LEDA philosophy. LEPs have a LEDA-style documentation, they are implemented as platform independent as possible, and the installation process permits a close integration into the LEDA core library. Currently, the following LEPs are available: PQ-trees, dynamic graph algorithms, a homogeneous d -dimensional geometry kernel, and a library for graph drawing.

CORRECTNESS

Geometric algorithms are frequently formulated under two unrealistic assumptions: computers are assumed to use exact real arithmetic (in the sense of mathematics) and inputs are assumed to be in general position. The naive use of floating point arithmetic as an approximation to exact real arithmetic very rarely leads to correct implementations. In a sequence of papers [BMS94b, See94, MN94b, BMS94a, FGK⁺00], these degeneracy and precision issues were investigated and LEDA was

extended based on this theoretical work. It now provides exact geometric kernels for 2D and higher-dimensional computational geometry [MMN⁺98], and also correct implementations for basic geometric tasks, e.g., 2D convex hulls, Delaunay diagrams, Voronoi diagrams, point location, line segment intersection, and higher-dimensional convex hulls and Delaunay triangulations.

Programming is a notoriously error-prone task; this is even true when programming is interpreted in a narrow sense: translating a (correct) algorithm into a program. The standard way to guard against coding errors is program testing. The program is exercised on inputs for which the output is known by other means, typically as the output of an alternative program for the same task. Program testing has severe limitations. It is usually only performed during the testing phase of a program. Also, it is difficult to determine the “correct” suite of test inputs. Even if appropriate test inputs are known it is usually difficult to determine the correct outputs for these inputs: alternative programs may have different input and output conventions or may be too inefficient to solve the test cases.

Given that program verification—i.e., formal proof of correctness of an implementation—will not be available on a practical scale for some years to come, *program checking* has been proposed as an extension to testing [BK89, BLR90]. The cited papers explored program checking in the area of algebraic, numerical, and combinatorial computing. In [MNS⁺99, MM95, HMN96] program checkers are presented for planarity testing and a variety of geometric tasks. LEDA uses program checkers for many of its implementations.

AVAILABILITY AND USAGE

LEDA is realized in C++ and can be used on many different platforms with many different compilers. LEDA is now used at more than 1500 academic sites. A commercial version of LEDA is marketed by Algorithmic Solutions Software GmbH.

65.1.1 THE STRUCTURE OF LEDA

LEDA uses templates for the implementation of parameterized data types and for generic algorithms. However, it is not a pure template library and therefore is based on a number of object code libraries of precompiled code. Programs using LEDA data types or algorithms have to include the appropriate LEDA header files into their source code and must link to one or more of these libraries. The four object code libraries are built on top of one another. Here, we only give a brief overview. The LEDA user manual ([MNSU] or the LEDA book ([MN00]) includes detailed descriptions.

- The Basic Library (*libL*).
Contains system-dependent code, basic data structures, numbers and types for linear algebra, dictionaries, priority queues, partitions, and many more basic data structures and algorithms.
- The Graph Library (*libG*)
Contains different types of graphs and a large collection of graph and network algorithms
- The 2D Geometry Library (*libP*).

Contains the 2D geometric kernels (Section 65.1.2) advanced geometric data structures, and a large number of algorithms for 2D geometric problems (Section 65.1.4).

- The 3D Geometry Library (*libD3*).
Contains the 3D kernels and some algorithms for 3D problems.
- The Window Library (*libW*).
Supports graphical output and user interaction for both the X11 platform (Unix) and Microsoft Windows systems. It also contains animation support, a powerful graph editor (GraphWin), and GeoWin, a interactive tool for the visualization of geometric algorithms. See Section 65.1.5 for details.

65.1.2 GEOMETRY KERNELS

LEDA offers kernels for 2D and 3D geometry, a kernel of arbitrary dimension is available as an extension package. In either case there exists a version of the kernel based on floating point Cartesian coordinates (called *float-kernel*) as well as a kernel based on rational homogeneous coordinates (called *rat-kernel*). All kernels provide a complete collection of geometric objects (points, segments, rays, lines, circles, simplices, polygons, planes, etc.) together with a large set of geometric primitives and predicates (orientation of points, side-of-circle tests, side-of-hyperplane, intersection tests and computation, etc.). For a detailed discussion and the precise specification, see [Chapter 9](#) of the LEDA book ([MN00]). Note that only for the rational kernel, which is based on exact arithmetic and floating-point filters, all operations and primitives are guaranteed to compute the correct result.

65.1.3 DATA STRUCTURES

In addition to the basic kernel data structures LEDA provides many advanced data types for computational geometry. Examples include:

- A general polygon type (`gen_polygon` or `rat_gen_polygon`) with a complete set of Boolean operations. Its implementation is based on an efficient and robust plane sweep algorithms for the construction of the arrangement of a set of straight line segments (see [MN94a] and [MN00, Ch. 10.7]).
- Two- and higher-dimensional geometric tree structures, such as range, segment, interval and priority search trees.
- Partially and fully persistent search trees.
- Different kinds of geometric graphs (triangulations, Voronoi diagrams, and arrangements).
- A dynamic `point_set` data type supporting update, search, closest point, and different types of range query operations on one single representation based on a dynamic Delaunay triangulation (see [MN00, Ch. 10.6]).

65.1.4 ALGORITHMS

The LEDA project never had the goal of providing a complete collection of the algorithms from computational geometry (nor for other areas of algorithms). Rather, it was designed and implemented to establish a *platform* for combinatorial and geometric computing enabling programmers to implement these algorithms themselves more easily and customized to their particular needs. But of course the library already contains a considerable number of basic geometric algorithms. Here we give a brief overview and refer the reader to the user manual for precise specifications and to [Chapter 10](#) of the LEDA-book ([MN00]) for detailed descriptions and analyses of the corresponding implementations. The current version of LEDA offers different implementation of algorithms for the following 2D geometric problems:

- convex hull algorithms (also 3D)
- halfplane intersection
- (constraint) triangulations
- closest and farthest Delaunay and Voronoi diagrams
- Euclidean minimum spanning trees
- closest pairs
- Boolean operations on generalized polygons

65.1.5 VISUALIZATION (GeoWin)

In computational geometry, visualization and animation of programs are important for the understanding, presentation, and debugging of algorithms. Furthermore, the animation of geometric algorithms is cited as among the strategic research directions in this area. *GeoWin* [BN02] is a generic tool for the interactive visualization of geometric algorithms. *GeoWin* is implemented as a C++ data type. Its design and implementation was influenced by LEDA's graph editor *GraphWin* ([MN00, Ch. 12]). Both data types support a number of programming styles which have shown to be very useful for the visualization and animation of algorithms. The animations use *smooth transitions* to show the result of geometric algorithms on dynamic user-manipulated input objects, e.g., the Voronoi diagram of a set of moving points or the result of a sweep algorithm that is controlled by dragging the sweep line with the mouse (see [Figure 65.1.1](#)).

A GeoWin maintains one or more geometric scenes. A geometric *scene* is a collection of geometric objects of the same type. A collection is simply either a standard C++ list (STL-list) or a LEDA-list of objects. GeoWin requires that the objects provide a certain functionality, such as stream input and output, basic geometric transformations, drawing and input in a LEDA window. A precise definition

FIGURE 65.1.1
GeoWin animating Fortune's sweep algorithm.

of the required operations can be found in the manual pages [MNSU]. GeoWin can be used for any collection of basic geometric objects (geometry kernel) fulfilling these requirements. Currently, it is used to visualize geometric objects and algorithms from both the CGAL and LEDA libraries.

The visualization of a scene is controlled by a number of attributes, such as color, line width, line style, etc. A scene can be subject to user interaction and it may be defined from other scenes by means of an algorithm (a C++ function). In the latter case the scene (also called *result scene*) may be recomputed whenever one of the scenes on which it depends is modified. There are three main modes for recomputation: user-driven, continuous, and event-driven.

GeoWin has both an interactive and a programming interface. The interactive interface supports the interactive manipulation of input scenes, the change of geometric attributes, and the selection of scenes for visualization.

65.1.6 PROGRAM EXAMPLES

We now give two programming examples showing how LEDA can be used to implement basic geometric algorithms in an elegant and readable way. The first example is the computation of the *upper convex hull* of a point set in the plane. It uses points and the orientation predicate and lists from the basic library. The second example shows how the LEDA *graph* data type is used to represent triangulations in the

implementation of a function that turns an arbitrary triangulation into a Delaunay triangulation by edge flipping. It uses points, lists, graphs, and the side-of-circle predicate.

UPPER CONVEX HULL

In our first example we show how to use LEDA for computing the upper convex hull of a given set of points. We assume that we are in LEDA's namespace, otherwise all LEDA names would have to be used with the prefix `leda::`. Function `UPPER_HULL` takes a list L of rational points (type `rat_point`) as input and returns the list of points of the upper convex hull of L in clockwise ordering from left to right. The algorithm is a variant of Graham's Scan [Gra72].

First we sort L according to the lexicographic ordering of the Cartesian coordinates and remove multiple points. If the list contains not more than two points after this step we stop. Before starting the actual Graham Scan we first skip all initial points lying on or below the line connecting the two extreme points. Then we scan the remaining points from left to right and maintain the upper hull of all points seen so far in a list called *hull*. Note however that the last point of the hull is not stored in this list but in a separate variable p . This makes it easier to access the last two hull points as required by the algorithm. Note also that we use the rightmost point as a sentinel avoiding the special case that *hull* becomes empty.

```
list<rat_point> UPPER_HULL(list<rat_point> L) {
    L.sort();
    L.unique();

    if (L.length() <= 2) return L;

    rat_point p_min = L.front(); // leftmost point
    rat_point p_max = L.back();  // rightmost point

    list<rat_point> hull;        // result list
    hull.append(p_max);         // use rightmost point as sentinel
    hull.append(p_min);         // first hull point

    // goto first point p above (p_min,p_max)
    while (! L.empty() && ! left_turn(p_min, p_max, L.front())) L.pop();
    if (L.empty()) {            // upper hull consists of only 2 points
        hull.reverse();
        return hull;
    }

    rat_point p = L.pop();      // second (potential) hull point
    rat_point q;
    forall(q,L) {
        while (! right_turn(hull.back(), p, q)) p = hull.pop_back();
        hull.append(p);
        p = q;
    }
    hull.append(p);             // add last hull point
    hull.pop();                 // remove sentinel
    return hull;
}
```

DELAUNAY FLIPPING

LEDA represents triangulations by bidirected plane graphs (from the graph library) whose nodes are labeled with points and whose edges may carry additional information, e.g., integer flags indicating the type of edge (hull edge, triangulation edge, etc.). All edges incident to a node v are ordered in counterclockwise ordering and every edge has a reversal edge. In this way the faces of the graph represent the triangles of the triangulation. The graph type offers methods for iterating over the nodes, edges, and adjacency lists of the graph. In the case of plane graphs there are also operations for retrieving the reverse edge and for iterating over the edges of a face. Furthermore, edges can be moved to new nodes. This graph operation is used in the following program to implement edge flips.

Function `DELAUNAY_FLIPPING` takes as input an arbitrary triangulation and turns into a Delaunay triangulation by the well-known flipping algorithm. This algorithm performs a sequence of local transformations as shown in Figure 65.1.2 to establish the Delaunay property: for every triangle the circumscribing circle does not contain any vertex of the triangulation in its interior. The test whether an edge has to be flipped or not can be realized by a so-called *side_of_circle* test. This test takes four points a, b, c, d and decides on which side of the oriented circle through the first three points a, b, c the last point d lies. The result is positive or negative if d lies on the left or on the right side of the circle, respectively, and the result is zero if all four points lie on one common circle. The algorithm uses a list of candidates which might have to be flipped (initially all edges). After a flip the four edges of the corresponding quadrilateral are pushed onto this candidate list. Note that $G[v]$ returns the position of node v in the triangulation graph G . A detailed description of the algorithm and its implementation can be found in the LEDA book ([MN00]).

FIGURE 65.1.2

Flipping to establish the Delaunay property.

```

void DELAUNAY_FLIPPING(GRAPH<rat_point, int>& G) {
    list<edge> S = G.all_edges();
    while (! S.empty()) {
        edge e = S.pop();
        edge r = G.rev_edge(e);

        edge e1 = G.face_cycle_succ(r);    // e1,e2,e3,e4: edges of quadrilateral
        edge e2 = G.face_cycle_succ(e1);    // with diagonal e
        edge e3 = G.face_cycle_succ(e);
        edge e4 = G.face_cycle_succ(e3);

        rat_point a = G[G.source(e1)];    // a,b,c,d: corners of quadrilateral
        rat_point b = G[G.target(e1)];
        rat_point c = G[G.source(e3)];
        rat_point d = G[G.target(e3)];

        if (side_of_circle(a,b,c,d) > 0) {
            S.push(e1); S.push(e2); S.push(e3); S.push(e4);
            G.move_edge(e,e2,source(e4)); // flip diagonal
            G.move_edge(r,e4,source(e2));
        }
    }
}

```

65.1.7 PROJECTS ENABLED BY LEDA

A large number of academic and industrial projects from almost every area of combinatorial and geometric computing have been enabled by LEDA. Examples are graph drawing, algorithm visualization, geographic information systems, location problems, visibility algorithms, DNA sequencing, dynamic graph algorithms, map labeling, covering problems, railway optimization, route planning and many more. The page <<http://www.mpi-sb.mpg.de/LEDA/friends>> lists academic projects in detail, and <<http://www.algorithmic-solutions.com/enreferenzen.htm>> describes selected industrial projects based on LEDA.

65.2 CGAL

The development of CGAL, the Computational Geometry Algorithms Library, began in 1995 and the first public release 0.9 appeared in June 1997. The presentation here is based on the CGAL release 3.0 from October 2003, available from CGAL's home page <www.cgal.org>.

CGAL is developed by a consortium consisting of ETH Zürich (Switzerland), Freie Universität Berlin (Germany), INRIA Sophia-Antipolis (France), Martin-Luther-Universität Halle-Wittenberg (Germany), Max-Planck Institut für Informatik, Saarbrücken (Germany), RISC Linz (Austria), Tel-Aviv University (Israel), and Utrecht University (The Netherlands). This work was the central task of two successive ESPRIT IV LTR projects named CGAL and GALIA. It is the goal of these

projects to

make the large body of geometric algorithms developed in the field of computational geometry available for industrial application.

CGAL's main design goals are correctness, flexibility, efficiency, and ease of use. Its focus is on a broad foundation in computational geometry. Important related issues, for example visualization, are supported with standard formats and interfaces.

The design of CGAL and our decision to use the C++ language are thoroughly covered in [FGK⁺00]. Generic programming aspects are discussed in [BKSV00]. New developments in the CGAL kernel are presented in [HHK⁺01], the d -dimensional kernel in [MMN⁺98]. Older descriptions of design and motivation are in [Ove96, FGK⁺96, Vel97]. In particular, precision and robustness aspects are discussed in [Sch96], and the influence of different kernels in [Sch99, BBP01].

LIBRARY STRUCTURE

CGAL is structured in layers: The *core library* with nongeometric support functions and types, the *geometric kernel* for constant-size geometric objects, predicates and constructions, the *basic library* with data structures and algorithms, and the *support library* with number types, geometric object generators, file I/O, visualization, and more nongeometric functions and types. CGAL follows the generic programming paradigm in the spirit of the STL (Standard Template Library) of the C++ Standard. As a consequence, the different parts of CGAL are highly modular and independent of each other.

GENERIC PROGRAMMING IDIOMS

Concept: Set of requirements for a C++ template parameter.

Model for a concept: A type in C++ that fulfills all requirements of that concept and can therefore be used as template argument in places where the concept was requested.

Function object: Implements a function as a C++ class with an `operator()`. It is more efficient and type-safe compared to a C function pointer or object-oriented class hierarchies.

FLEXIBILITY

CGAL has a *modular* design of layers and packages that is transparent in the documentation, although currently only the whole library can be installed. The algorithms and data structure in CGAL are *adaptable* to already existing user code; see the geometric traits class example on page 1453. The library is *extendible*, users can add implementations in the same style as CGAL. The library is *open* and supports important standards, such as the C++ standard with its Standard Template Library STL, or important other libraries, such as LEDA or GMP, the Gnu Multiple Precision Arithmetic Library [Gra02].

CORRECTNESS

CGAL addresses the robustness problems in geometric computing, as formulated in the introduction, by relying on exact predicate evaluation, e.g., with exact arithmetic, and explicit degeneracy handling.

In addition, we have a well-established software process and communication set up for our distributed developers community. We use CVS for revision management and run an automatic test-suite twice a week on all supported platforms and compilers. An editorial board reviews new submissions and supervises design homogeneity. We also had one-round of peer-reviewing and testing for the basic library packages.

EASE OF USE

Users with a base knowledge of C++ and the STL will experience a smooth learning curve with CGAL since many concepts are already known from the STL, and the powerful flexibility is often hidden behind sensible defaults. A novice reader should not be discouraged by some of the advanced examples illustrating CGAL's power.

CGAL has a uniform design, aims for complete and minimal interfaces, yet rich and complete functionality in the area of computational geometry. The extensive manual follows the layout style of the LEDA manuals.

EFFICIENCY

CGAL follows the generic programming paradigm and uses templates in C++ to realize most of its flexibility. Thus, the flexibility is resolved at compile time and does not have any runtime cost. That allows us to realize flexibility at places normally not considered because of runtime costs, e.g., on the number-type level.

Furthermore, the flexibility allows to pick the best of the available choices for a particular application. Tradeoffs between space and time in some data structures, or between different number types of different power and speed can be made at the application level, not in the library. This also encourages experimental research.

65.2.1 GEOMETRIC KERNEL

CGAL offers a wide variety of kernels. The geometric objects, predicates, and constructions—classified according to dimension two, three, and arbitrary d —are summarized in [Table 65.2.1](#). The kernels available in CGAL can be classified along the following orthogonal concepts:

Dimension: The dimension of the affine space. The specializations for dimension two and three offer functionality that would not be available in the arbitrary-dimension kernel.

Number type: CGAL kernels use one number type uniformly to store coordinates and coefficients, and to compute the expressions in predicates and constructions.

CGAL distinguishes four concepts of number types: a *ring* for exact integer arithmetic, an *Euclidean ring* that adds integer division and a *gcd* (greatest

TABLE 65.2.1 Kernel objects, selected predicates and constructions.

DIM	GEOMETRIC OBJECTS	PREDICATES	CONSTRUCTIONS
<i>all</i>	Point, Vector, Direction, Line, Ray, Segment, Aff_transformation	compare_lexicographically, do_intersect, orientation	intersection, midpoint transform, squared_distance
2	Triangle, Iso_rectangle, Bbox, Circle	collinear, left_turn, side_of_oriented_circle	bbox, centroid, circumcenter, squared_radius, rational- rotation_approximation
3	Plane, Tetrahedron, Triangle, Iso_cuboid, Bbox, Sphere	coplanar, left_turn, side_of_oriented_sphere	bbox, centroid, circumcenter, cross_product, squared_radius
<i>d</i>	Hyperplane, Sphere	side_of_oriented_sphere	center_of_sphere, lift_to_paraboloid

common divisor) computation, a *field* with exact division, and a number type that supports the exact sign evaluation for expressions with roots.

Exceptions to the one-number-type principle arise in the homogeneous kernel, where a field type (the quotient type `CGAL::Quotient<Field_type>` by default) is associated with the ring type, and in predicates that are specialized on particular number types. The specialized predicates might use a different arithmetic to evaluate an expression exactly although the number type itself would be too limited. The specialized predicates might also use floating point filters.

Coordinate representation: The Cartesian representation requires a *field* as a number type. The homogeneous representation requires a *Euclidean ring* as a number type. The homogeneous coordinate is used to optimize exact rational arithmetic with a common denominator, and not for projective geometry. CGAL implements strictly affine geometry.

Reference counting: Reference counting is used to optimize copying and assignment of kernel objects. It is recommended for exact number types with larger memory size. The kernel objects have value-semantics and cannot be modified, which simplifies reference counting. However, a copy-on-write strategy is available for modifiable objects elsewhere in CGAL. The nonreference counted kernels are recommended for small and fast number types, such as the built-in `double`.

Let `RT` be a *Euclidean ring*, and `FT` a *field* number type. The kernels in CGAL are:

<code>CGAL::Cartesian<FT></code>	Cartesian, reference counted, 2D and 3D
<code>CGAL::Simple_cartesian<FT></code>	Cartesian, nonreference counted, 2D and 3D
<code>CGAL::Homogeneous<RT></code>	homogeneous, reference counted, 2D and 3D
<code>CGAL::Simple_homogeneous<RT></code>	homogeneous, nonreference counted, 2D and 3D
<code>CGAL::Cartesian_d<FT></code>	Cartesian, reference counted, <i>d</i> -dimensional
<code>CGAL::Homogeneous_d<RT></code>	homogeneous, reference counted, <i>d</i> -dimensional

The geometric objects are local types of a kernel, e.g., `Cartesian<leda::real>::Point_2` is a 2D point with Cartesian coordinates of type `leda::real`. The predicates and constructions are local function objects of a kernel. However, global functions provide a more conventional way of calling predicates and constructions.

CGAL offers three possibilities to create filtered kernels: (1) `CGAL::Lazy_exact_nt<NT>` is a filtered number type using `double` interval arithmetic and the exact number type `NT` given as template argument. It creates an expression DAG, evaluates it with interval arithmetic and, if that fails, switches to the exact number type for evaluation. This allows exact constructions. Some predicates are specialized to avoid the expression DAG construction. (2) `CGAL::Filtered_exact<CT,ET>` is a number type using the type `CT` for representation and constructions. Predicates are specialized for this number type to use interval arithmetic as filter and, if that fails, to use the exact number type `ET`. (3) `CGAL::Filtered_kernel<K>` constructs a new kernel based on the given kernel `K`. All predicates of the new kernel use the interval arithmetic as filter and, if that fails, call the predicates in the kernel `K` [BBP01].

A common misconception should be clarified here: A filter in CGAL can only be applied to predicates, not to constructions. If exact constructions are required one needs an exact number type in the kernel. For example, the Delaunay triangulation can be computed correctly with a filtered kernel, but the center of a circumcircle cannot. A kernel such as `CGAL::Homogeneous<CGAL::Gmpz>` would allow the exact construction. It should be mentioned that an approach as in the LOOK kernel [FM02] does extend filtering to constructions, but is not available in CGAL to date.

DEFAULT CHOICES FOR THE GEOMETRIC KERNEL

To ease the choice of a kernel and a suitable number type for beginners, CGAL offers three default kernels for dimension two and three that cover the most common cases of tradeoffs between speed and exactness requirements. These default choices allow initial exact constructions from `double` values and guarantee exact predicates. They vary in their capability of exact constructions and use of exact square root expressions in predicates. The names speak for themselves.

- `CGAL::Exact_predicates_inexact_constructions_kernel`
- `CGAL::Exact_predicates_exact_constructions_kernel`
- `CGAL::Exact_predicates_exact_constructions_kernel_with_sqrt`

EXAMPLE: ORIENTATION OF TRIPLE

The following example creates three points in the plane and computes their orientation. We use the `CGAL::MP_Float` number type that can represent floating-point values of arbitrary precision with the homogeneous kernel. We obtain an exact kernel that could also work correctly with constructions and with `double` input values.

```
#include <CGAL/MP_Float.h>
#include <CGAL/Homogeneous.h>

typedef CGAL::Homogeneous< CGAL::MP_Float>   Kernel;
typedef Kernel::Point_2                      Point_2;
```

```

int main() {
    Point_2 p(0,0), q(10,3), r(12,19);
    if (CGAL::orientation(p,q,r) == CGAL::LEFT_TURN)
        return 0;
    return 1;
}

```

The above kernel is exact, but needs more space and time than a simple `double` implementation. We want to optimize space and time in the following example using `double` coordinates in a Cartesian representation without reference counting. However, we do not want to sacrifice correctness and use the filtered kernel that has specialized predicate implementations; but note that constructions with `doubles` will be prone to rounding errors.

In the current CGAL release, we cannot use the global functions with the filtered kernels. Instead, we ask the kernel for a predicate function object, which works for all kernels.³

```

#include <CGAL/Simple_cartesian.h>
#include <CGAL/Filtered_kernel.h>

typedef CGAL::Simple_cartesian<double> Kernel;
typedef CGAL::Filtered_kernel<Kernel> Filtered_kernel;
typedef Filtered_kernel::Point_2 Point_2;
typedef Filtered_kernel::Orientation_2 Orientation;

int main()
{
    Point_2 p(0,0), q(10,3), r(12,19);
    Filtered_kernel kernel;
    Orientation orientation = kernel.orientation_2_object();
    if (orientation(p,q,r) == CGAL::LEFT_TURN)
        return 0;
    return 1;
}

```

Again, the above filtered kernel does not support exact constructions, and all the kernels used in these examples are limited to the operations on *field types*. A most flexible but also much slower alternative is the `CGAL::Cartesian<leda::real>` kernel that supports exact constructions of arbitrary depth including expressions with *kth-roots*.

65.2.2 BASIC LIBRARY

The basic library follows the design of the STL, the C++ Standard Template Library [Aus98]; generic algorithms are parameterized with iterator ranges that decouple them from data structures. In addition, CGAL invented the *circulator* concept to accommodate circular structures efficiently, such as the ring of edges around a vertex in planar subdivisions [FGK⁺00]. Essential for CGAL's flexibility is the separation of algorithms and data structures from the underlying geometric kernel with a *geometric traits class*.

³We could have written `Filtered_kernel().orientation_2_object()(p,q,r)` to have the predicate call in one line, but it is less readable to parse the C++ code this way.

GLOSSARY

Iterator: A concept for an abstraction of pointer into a linear sequence. Exists in different flavors: input, output, forward, bidirectional, and random-access iterator.

Circulator: A concept similar to iterator but for circular sequences.

Range: A pair of iterators (or circulators) describing a (sub-)sequence of items in a half-open interval notation, i.e., starting with the first item and ending before the second item.

Traits class: C++ programming technique to attach additional information to a type or function, e.g., dependent types, functions, and values.

Geometric traits: Traits classes used in CGAL to decouple the basic library from a geometric kernel. Algorithms and data structure define a geometric traits concept and the library provides various models that can be used. Often the geometric kernel itself is a valid model.

EXAMPLE OF UPPER CONVEX HULL ALGORITHM

We implement the upper convex hull algorithm following Andrew's variant of Graham's scan [Gra72, And79] with CGAL. First, we translate the implementation used in the LEDA example on page 1443 literally to STL and CGAL code for easy comparison. Therefore we use a sufficient default kernel and declare it globally. Both implementations look similar.

```
typedef CGAL::Exact_predicates_inexact_constructions_kernel Kernel;
typedef Kernel::Point_2 Point_2;
Kernel kernel; // our instantiated kernel object

std::list<Point_2> upper_hull( std::list<Point_2> L) {
    L.sort( kernel.less_xy_2_object());
    L.unique();
    if (L.size() <= 2)
        return L;
    Point_2 p_min = L.front(); // leftmost point
    Point_2 p_max = L.back();  // rightmost point
    std::list< Point_2> hull;
    hull.push_back(p_max);     // use rightmost point as sentinel
    hull.push_back(p_min);     // first hull point
    while (!L.empty() && !kernel.left_turn_2_object()(p_min,p_max,L.front()))
        L.pop_front();         // goto first point p above (p_min,p_max)
    if (L.empty()) {
        hull.reverse();         // fix orientation for this special case
        return hull;
    }
    Point_2 p = L.front();     // keep last point on current hull separately
    L.pop_front();
    for (std::list< Point_2>::iterator i = L.begin(); i != L.end(); ++i) {
        while (! kernel.left_turn_2_object()( hull.back(), *i, p)) {
```

```

        p = hull.back();    // remove non-extreme points from current hull
        hull.pop_back();
    }
    hull.push_back(p);      // add new extreme point to current hull
    p = *i;
}
hull.push_back(p);        // add last hull point
hull.pop_front();         // remove sentinel
return hull;
}

```

Now we rewrite the example to expose more of CGAL's flexibility and also of its own way of implementing generic code inside the library itself, which follows the conventional style of STL code with iterators and generic algorithms.

As a first obvious solution we can make the kernel exchangeable as a template parameter of the function. Before we do so, we factor out the core of the control flow—the two nested loops at the end—into its own generic function with an interface of bidirectional iterators and a single three-parameter predicate. We can eliminate the additional list data structure for the `hull` when we reuse the space that becomes available in the original sequence as our stack. So the result is returned in our original sequence starting with the iterator `first` and running to the past-the-end position that we return in the return value of the function. The interface abstraction with iterators hinders us in realizing the sentinel easily. But since the runtime difference was not measurable we go back to an explicit test for the boundary case, which accounts for the additional `break` statement, but also simplifies code later.

```

template <class Iterator, class Fct> // bidirectional iterator, function object
Iterator backtrack_remove_if_triple( Iterator first, Iterator beyond, Fct pred){
    if (first == beyond)
        return first;
    Iterator i = first, j = first;
    if (++j == beyond) // i,j mark two elements on the top of the stack
        return j;
    Iterator k = j;    // k marks the next candidate value in the sequence
    while (++k != beyond) {
        while (pred( *i, *j, *k)) {
            j = i;      // remove one element from stack, part 1
            if (i == first) // explicit test for stack underflow
                break;
            --i;        // remove one element from stack, part 2
        }
        i = j; ++j; *j = *k; // push next candidate value from k on stack
    }
    return ++j;
}

```

Having this generic function, we can implement a variant of the upper hull algorithm that returns all points on the upper convex hull (instead of only the extreme points) in two lines. All degeneracies are handled correctly in the generic functions. This implementation requires a range of random access iterators because of the sorting. It also uses now a template parameter for a geometric traits class and extracts the suitable predicate from this traits class for the call to the new generic function. A

kernel from CGAL is a valid model for this traits parameter. Here, CGAL's design makes things fit together smoothly.

```
template <class Iterator, class Traits> // random access iterator
Iterator upper_hull( Iterator first, Iterator beyond, Traits traits) {
    std::sort( first, beyond, traits.less_xy_2_object());
    return backtrack_remove_if_triple( first, beyond,
                                     traits.left_turn_2_object());
}
```

We apply the upper hull function to an array filled with three points. Because the resulting hull contains only two points, the `result` value is equal to `points + 2` and the array is modified to start with these two hull points.

```
Point_2 points[3] = { Point_2(0,0), Point_2(1,-1), Point_2(2,0) };
Point_2 *result = upper_hull( points, points + 3, kernel);
```

We go back to compute the extreme points and reuse the new generic function. The code simplifies because we do not use the sentinel technique anymore. However, we need a different orientation test than the `left_turn` predicate provided by CGAL. The other orientation predicates are omitted in CGAL since they can be realized easily with the `left_turn` predicate, permuted parameters, and negating the result. We can use higher order function objects from CGAL to achieve exactly that on a generic function object level; `swap_2` exchanges the order of the second and the third parameter of the `left_turn` predicate and `negate` is inverting the return value, and none of this is costing extra runtime.

We stay with the random-access iterator-based interface, but a list-based interface would be an obvious combination with the first implementation above.

```
template <class Iterator, class Traits> // random access iterator
Iterator upper_hull( Iterator first, Iterator beyond, Traits traits) {
    std::sort( first, beyond, traits.less_xy_2_object());
    beyond = std::unique( first, beyond, traits.equal_2_object());
    return backtrack_remove_if_triple( first, beyond, CGAL::negate(
                                     CGAL::swap_2( traits.left_turn_2_object())));
}
```

EXAMPLE OF USER KERNEL

In contrast to LEDA, data structures and algorithms in CGAL can be easily adapted to work on user data with a custom geometric traits class. Let us assume we already have a point class:

```
struct Point { // our point type
    double x, y;
    Point( double xx = 0.0, double yy = 0.0) : x(xx), y(yy) {}
    bool operator==( const Point& p) const { return x == p.x && y == p.y; }
    bool operator!=( const Point& p) const { return ! (*this == p); }
};
```

We want to use this point class with one of CGAL's convex hull algorithms. The reference manual tells us for the `CGAL::ch_graham_andrew` function that we need

a type `Point_2`, and function objects `Equal_2`, `Less_xy_2`, and `Left_turn_2`. A possible geometric traits class could look like this:

```
struct Geometric_traits { // traits class for our point type
    typedef double RT;      // ring number type, for random points generator
    typedef Point Point_2;  // our point type
    struct Equal_2 {        // equality comparison
        bool operator()( const Point& p, const Point& q) {
            return (p.x == q.x) && (p.y == q.y);
        }
    };
    struct Less_xy_2 {      // lexicographic order
        bool operator()( const Point& p, const Point& q) {
            return (p.x < q.x) || ((p.x == q.x) && (p.y < q.y));
        }
    };
    struct Left_turn_2 {    // orientation test
        bool operator()( const Point& p, const Point& q, const Point& r) {
            return (q.x-p.x) * (r.y-p.y) > (q.y-p.y) * (r.x-p.x); // inexact!
        }
    };
    // member functions to access function objects, here by default construction
    Equal_2    equal_2_object()    const { return Equal_2(); }
    Less_xy_2  less_xy_2_object()  const { return Less_xy_2(); }
    Left_turn_2 left_turn_2_object() const { return Left_turn_2(); }
};
```

In the last step we have to let CGAL know that our traits class belongs to our point class. We specialize CGAL's kernel traits for this:

```
namespace CGAL { // specialization that links our point type with our traits class
    template <> struct Kernel_traits< ::Point> {
        typedef ::Geometric_traits Kernel;
    };
}
```

Now, we can use the `CGAL::ch_graham_andrew` function on our points. The above implementation also suffices to employ the random point generators in CGAL. Here is a complete program computing the convex hull of 20 points from a random distribution in a disk.

```
#include <CGAL/ch_graham_andrew.h>
#include <CGAL/point_generators_2.h>
#include <CGAL/copy_n.h>
#include <vector>

int main() {
    std::vector<Point> points, hull;
    CGAL::Random_points_in_disc_2<Point> rnd_pts( 1.0);
    CGAL::copy_n( rnd_pts, 20, std::back_inserter( points));
    CGAL::ch_graham_andrew( points.begin(), points.end(),
                           std::back_inserter( hull), Geometric_traits());
    return 0;
}
```

The separation of the algorithms and data structures from the geometric kernel provides flexibility, the fingerprint of generic programming, resolved at compile time and therefore without sacrificing performance. We foster such flexibility in CGAL and design algorithms and data structures to be used in different contexts. One example is the geometric traits class `CGAL::Triangulation_euclidean_traits_xy_3` that allows to build a 2D triangulation of the projections on the xy -plane of 3D points, useful for terrain triangulations in GIS (cf. Chapter 58).

BASIC LIBRARY CONTENTS

The basic library contains data structures and algorithms. It is structured into packages that correspond to different chapters of the reference manual.

CONVEX HULL

The *2D convex hull* algorithms return the counterclockwise sequence of the extreme points. The *3D convex hull* algorithms return, in nondegenerate cases, the convex polytope of the extreme points. The *d-dimensional* convex hull algorithm returns a simplicial complex for the closure of the convex polytope. All implementations are iterator-based generic algorithms and data structures. See Table 65.2.2.

TABLE 65.2.2 Convex hull algorithms on a set of n points with h extreme points.

DIM	MODE	ALGORITHM
2	Static	Bykat, Eddy, and Jarvis march, all in $O(nh)$ time
	Static	Akl & Toussaint, and Graham-Andrew scan, both in $O(n \log n)$ time [Sch99]
	Polygon	Melkman for points of a simple polygon in $O(n)$ time
	Others	lower hull, upper hull, subsequences of the hull, extreme points, convexity test
3	Static	quickhull [BDH96]
	Incremental	randomized incremental construction [CMS93, BMS94b]
	Dynamic	by-product of the dynamic Delaunay tetrahedrization in 3D
	Test	convexity test as program checker [MNS ⁺ 99]
d	Incremental	randomized incremental constr. [CMS93, BMS94b], also as LEDA extension package

POLYGON AND NEF POLYGON

A *polygon* is a closed chain of edges. CGAL provides a container class for polygons, but all functions are generic with iterators and work on arbitrary sequences of points. The functions available are polygon area, point location, tests for simplicity and convexity of the polygon, and generation of random instances.

Polygons can also be *partitioned* into y -monotone polygons or convex polygons. The y -monotone partitioning is based on the sweep-line algorithm explained

in [dBvK⁺00]. For the convex partitioning an optimal algorithm w.r.t. number of pieces and a factor 4-approximation sweep-line algorithm are given [Gre83]. Another factor 4-approximation algorithm is based on the constrained Delaunay triangulation [HM83].

A *Nef polygon* is a point set $P \subseteq \mathbb{R}^2$ generated from a finite number of open halfspaces by set complement and set intersection operations. It is therefore closed under Boolean set operations and topological operations; intersection, union, complement, difference, closure, interior, boundary, regularization, etc. It also captures features of mixed dimension, e.g., antennas or isolated vertices, open and closed boundaries, and unbounded faces, lines, and rays. The theory of Nef polyhedra is explained in [Nef78, Bie95], and a full implementation report is available in [See01]. The potential unboundedness of Nef polygons is addressed with *infimal frames* and an extended kernel [MS01]. The representation is based on the *halfedge data structure* [Ket98] (see below), extended with face loops and isolated vertices.

PLANAR MAPS, SWEEP-LINE ALGORITHM, ARRANGEMENTS, AND POLYHEDRAL SURFACES

Planar maps are based on the halfedge data structure, an edge-based representation with two oppositely directed halfedges per edge [Ket98]. Planar maps extend the halfedge data structure with a geometric embedding in the plane and halfedge cycles for inner and outer loops around faces. Various basic manipulations of the map are available [FHH⁺00]. The point-location and vertical ray-shooting use an incremental randomized algorithm for a dynamic trapezoidal decomposition to achieve $O(\log n)$ expected location and update time [Mul90, Sei91].

Planar maps are generic with respect to the type of curve they allow for the embedding of the edges. Currently, segments, poly-lines, circular arcs, and general conic arcs are supported [Wei02]. It uses new techniques for handling degeneracies as the existing exact algebraic number types do not yet support all the operations required by intersecting conics, and it uses filtering techniques at the geometry level, and not only at the number type level.

Planar map curves must be non-intersecting and x -monotone. The *planar map with intersections* supports also intersecting curves. A sweep-line algorithm speeds up the construction compared to the incremental insertion. The *arrangements* extend the planar maps with intersections. They maintain the relationship between input curves and x -monotone subcurves in a flexible multi-layer curve hierarchy [HH00].

A *polyhedral surface* is a mesh data structure based on the halfedge data structure. It embeds the halfedge data structure in 3D space. The polyhedral surface provides various basic integrity-preserving operations, the “Euler operations” [Ket98].

TRIANGULATIONS, VORONOI DIAGRAMS, AND ALPHA SHAPES

The triangulations use a triangle-based data structure in 2D, and a tetrahedra-based data structure in 3D. Both are standard container classes with an iterator interface. The triangulations are built with a randomized incremental construction

and support efficient vertex removal [BDP⁺02, DT03]. The Voronoi diagram is only implicitly represented with its dual triangulation.

Point location is the walk method by default. The Delaunay hierarchy [Dev02] is available in 2D and 3D to speed up point location. It is recommended for triangulations of more than 10000 points [DPT02].

Regular triangulations are the dual of power diagrams, the Voronoi diagram of weighted points under the power-distance. Regular triangulations are available in 2D and 3D [ES96].

Apollonius graphs are the dual of the *Apollonius diagrams* that are also known as *additively weighted* Voronoi diagrams of weighted points. They are available in 2D with dynamic vertex insertion, deletion, and fast point location [KY02].

Alpha shapes are extensions of the triangulations. The simplicial subcomplex for the alpha shape of the Delaunay (or regular) triangulation can be efficiently selected for a given α parameter value. Alpha shapes are available in 2D and 3D, for unweighted and for weighted points under the power distance [EM94].

A constrained triangulation (cf. Chapter 25) accepts as input in addition to the points a set of constraining segments. These segments are required edges in the triangulation. Intersecting segments can be handled in various ways. A constrained triangulation and a constrained Delaunay triangulation are available in 2D only.

A d -dimensional Delaunay triangulation is available with the $(d+1)$ -dimensional convex hull algorithm and an adapter that implements the lifting map [BMS94b].

OPTIMIZATION

The geometric optimization algorithms in CGAL fall into three categories, *Bounding Volumes*, *Optimal Distances*, and *Advanced Techniques*; see Table 65.2.3.

TABLE 65.2.3 Geometric optimization.

DIM	ALGORITHM
2,3, d	Smallest enclosing disk/sphere of a point set [Wel91, GS98a, Gär99]
2,3, d	Smallest enclosing sphere of a set of spheres [FG03]
2	Smallest enclosing ellipse of a point set [Wel91, GS97, GS98b]
2	Smallest enclosing rectangle [Tou83], parallelogram [STV ⁺ 95], and strip [Tou83] of a point set
d	Smallest enclosing annulus [GS00]
2	Maximum (area and perimeter) inscribed k -gon of a convex polygon [AKM ⁺ 87]
2	Rectangular p -center, $2 \leq p \leq 4$ [Hof99, SW96]
d	Distance between the convex hulls of two given point sets [GS00]
3	Width of a point set
2	All furthest neighbors for the vertices of a convex polygon [AKM ⁺ 87]
d	Monotone [AKM ⁺ 87] and sorted [FJ84] matrix search

SEARCH STRUCTURES

CGAL provides generic *range trees* and *segment trees* [dBvK⁺00] that can be interchangeably nested to form higher-dimensional search trees. In addition, CGAL provides d -dimensional k -d-trees; however, they cannot be mixed with the other trees. All trees are static and provide the conventional window and enclosing queries.

More advanced queries are k -nearest and k -furthest neighbor searching, incremental nearest and incremental furthest neighbor searching [HS95]. All queries are available as exact and approximate searches. Query items can be points and other spatial objects. These queries are based on the d -dimensional k -d-trees.

Related to the segment tree is the interval skip list in CGAL, a data structure for finding all intervals that overlap a point, that is fully dynamic but works only in the one-dimensional case [Han91].

Furthermore, an interface class to the dynamic 2D Delaunay triangulation implements nearest neighbor, k -nearest neighbors, and range searching in the plane following the idea described in [MN00].

65.2.3 PROJECTS ENABLED BY CGAL

CGAL extension packages are external contributions on top of CGAL available from <http://www.cgal.org/CEP>. They allow more flexibility in licensing, documentation, or support questions. Currently CGAL offers one extension package for the Gale-transform of a set of points, the visibility complex data structure for planar scenes, and an adapter for the LEDA rational kernel. Others for parametric search, polygonal approximations, and shape matching are in progress.

CGAL was also successful in enabling new academic projects. The 3D Delaunay triangulation was used in surface reconstructions [DG01, AGJ00, GJ02] and in meshing [CSdVY02]. Planar maps and arrangements were used in exact Minkowski sums and motion planning [AFH02, HH02, Hal02]. They were also used to understand and experiment with an algorithmic idea on the union of geometric objects; for example, an arrangement was built from triangles with half-a-million vertices [EHS02]. The polyhedral surface was used in approximate swept volumes [Raa99, Hal02] and computing a canonical polygonal schema of an orientable triangulated surface [LPVV01]. The halfedge data structure was used in modeling pseudotriangulations [KKM⁺03].

Finally, the programming paradigm enabled a successful and practical implementation framework for parametric search [vOV02].

INDEX OF CITED AUTHORS

The name of each author cited in a chapter appears once with a reference to that chapter: either to its first appearance in the chapter's bibliography, or, if not cited there, to its first appearance in the text of the chapter.

INDEX OF DEFINED TERMS

- (0,1)-polytope 154, 363, 1030
- 1-castable 1249
- 1/ r -cutting 820, 899, 957
- (1,2)- B metric 186
- 2-castable 1249
- 2-coloring 298
- 2-face 440
- $2\frac{1}{2}D$ 657
- 2Tree partition, proper 1331
- 3-axis machine 1250
- 3-coloring 644
- 3D Printing 1243
- 3Tree2 partition, proper 1331
- 4-axis machine 1250
- 4-color theorem 457
- 5-axis machine 1250

- A-patch 1188, 1193
- A-spline 1195
- absolute bits 935
- abstract objective functions 463
- abstract polytope 447
 - chiral, 448
 - face of, 447
 - facet of, 447
 - regular, 447
 - locally spherical, 449
 - locally toroidal, 450
 - projective, 449
 - realization of, 448
 - (Schläfli) type of, 448
 - universal, 448
 - vertex of, 447
- Ackermann's function 82, 535, 1041, 1057
- active constraint 1015
- active loop 1216
- acyclic ordering 524, 565
- adjacent cells 331, 1039
- admissible scheme 944
- affine equivalence 356
- affine Gale diagram 143
- affine invariance 1188
- affine span 383
- affine spanning set 1336
- affine symmetry 658

- AG bound 1368
- AGD (software) 1425
- Akiyama-Alon theorem 232
- Aleksandrov-Fenchel inequality 707
- algebraic halfspace 1258
- algebraic number
 - interval representation, 753
 - order representation, 752
 - real, 749
 - sign representation, 753
- algebraic problem 935
- algebraic set 207
- algorithm
 - approximation, 940
 - infrastructure, 1265
 - output-sensitive, 940
 - precision-sensitive, 940
 - pseudo-approximation, 940
- aliasing 1106
- all-farthest neighbors 962
- all-nearest neighbors 959, 1156
- allowable sequence of permutations 101
 - simple, 101
- alpha complex 1398
- alpha hull 1147
- alpha shape 1398
- $\alpha(n)$ 535, 656, 844, 1041
- α -shape 679
- alternating sign map 137
- alternative law 1316
- amino acid 1396
- analysis
 - cluster, 1296
 - neighborhood, 1296
 - network, 1296
 - spatial, 1295
 - trend, 1296
- AND-OR tree 757
- angle
 - external, 377
 - internal, 377
- angular resolution *see* graph drawing
- animal 331
- animated map 1303
- anisotropic 521

- ANN *see* all-nearest neighbors
- antiprism 437
 - right, 437
- antisymmetric tensor 1316
- apeirogon 433
- aperiodic prototile set 66
- application procedural interface (API) 1265, 1266
- approximability number 296
- approximate bichromatic closest pair 883
- approximate bottleneck matching 884
- approximate chromatic closest pair 883
- approximate close pair 883
- approximate closest pair 883
- approximate degeneracy predicate 945
- approximate diameter 883
- approximate facility location 884
- approximate far pair 883
- approximate furthest neighbor 883
- approximate furthest pair 883
- approximate minimum spanning tree 884
- approximate near neighbor 878
- approximation 878
- approximation problem 701
- aquarium 623
- aquarium-keeper's problem 623
- Archimedean solid 442
- area
 - bisection, 589
 - of graph drawing, 1165
 - landmark, 1078, 1082
 - of plane set, 26
 - surface, 373
- arithmetic
 - exact, 1437
 - precision, 1417
- arrangement 529, 820, 957, 974, 1038
 - at-most- k -level of, 534, 536
 - cell of, 529
 - 0-border of, 534
 - 1-border of, 534
 - border of, 534
 - maximally covered, 549
 - subcell, 539
 - supercell, 539
 - combinatorial complexity of, 530
 - complete skeleton, 539
 - connected, 46
 - Coxeter, 445
 - on curved surface, 533
 - of curves, 531
 - cyclic, 111
 - decomposition of, 538
 - density of, 26
 - edge of, 530
 - envelope of, 533, 536, 538
 - lower, 533, 536, 546, 548
 - overlay of, 538
 - upper, 533
 - face of, 530
 - facet of, 530
 - of hyperplanes, 132, 420, 445, 529
 - of hyperspheres, 132
 - j -impassable, 46
 - k -cell of, 530
 - k -level of, 534, 538, 547
 - lattice, 26
 - of lines, 97, 530
 - many cells of, 547
 - multiple, 37
 - non-Pappus, 106
 - planar, 531
 - point-trapping, 46
 - of points, 131
 - of polytopes, 548
 - of pseudohyperplanes, 146
 - simple, 146
 - of pseudolines, 97, 133
 - of pseudoplanes, 146
 - of pseudospheres, 138, 139
 - of pseudotriangles, 108
 - red-blue, 957
 - simple, 530
 - simplicial, 108
 - single cell of, 534, 536, 547, 909
 - skeleton, 539
 - on sphere, 550
 - stretchable, 98, 133
 - of surfaces, 531, 532
 - of triangles, 548
 - union boundary, 534
 - vertex of, 530
 - zone of, 534, 536, 547
- art gallery 591
- art gallery theorem 643, 644
- aspect graph 657, 1149
- aspect ratio 588
- assembly 1071
 - operation, 1071
 - partitioning, 1071
 - planning, 1055

SECOND EDITION

Handbook of Discrete and Computational Geometry

A Volume in the Discrete Mathematics
and Its Applications Series

Series Edited by Kenneth H. Rosen, AT&T Laboratories

While high-quality books and journals in this field continue to proliferate, none has yet come close to matching the *Handbook of Discrete and Computational Geometry*, which in its first edition, quickly became the definitive reference work in its field. But with the rapid growth of the discipline and the many advances made over the past seven years, it's time to bring this standard-setting reference up to date.

Editors Jacob E. Goodman and Joseph O'Rourke reassembled their stellar panel of contributors, added many more, and together thoroughly revised their work to make the most important results and methods, both classic and cutting-edge, accessible in one convenient volume. Now more than 1500 pages, the *Handbook of Discrete and Computational Geometry, Second Edition* once again provides unparalleled, authoritative coverage of theory, methods, and applications.

HIGHLIGHTS OF THE SECOND EDITION:

- Thirteen new chapters: five on applications and others on collision detection, nearest neighbors in high-dimensional spaces, curve and surface reconstruction, embeddings of finite metric spaces, polygonal linkages, the discrepancy method, and geometric graph theory
- Thorough revisions of all remaining chapters
- Extended coverage of computational geometry software, now comprising two chapters: one on the LEDA and CGAL libraries, the other on additional software
- Two indices: An Index of Defined Terms and an Index of Cited Authors
- Greatly expanded bibliographies

Jacob E. Goodman is a Professor in the Department of Mathematics, City College, New York, New York, USA.

Joseph O'Rourke is a Professor in the Department of Computer Science, Smith College, Northampton, Massachusetts, USA.
